29.1 Introduction

Photodecarboxylation (PDC) is an important fundamental photoreaction that has significance in many areas of chemistry. PDC is responsible for the *in vivo* decomposition of many pharmaceuticals, including several nonsteroidal anti-inflammatory drugs (NSAIDs).¹⁻³ PDC reactions have found application in organic synthesis, particularly in the production of “disciplined radicals” by PDC of Barton esters⁴⁻⁶ and in the photodecarboxylative addition reactions of Griesbeck and Oelgemöller.⁷⁻¹⁰ The photodegradation of many organic compounds can be carried out through photocatalytic PDC reactions such as the photo-Kolbe reaction,^{11,12} and similar reactions can be used to initiate polymerization reactions.¹³

Several reviews are available that provide excellent coverage of various aspects of PDC chemistry.¹⁴⁻¹⁷ The focus of the present chapter is on the PDC of phenylacetic acids, since recent applications of this class of reactions have brought them into the spotlight.

29.2 PDC of Electron-Rich Arylacetic Acids

The photochemistry of phenylacetic acid (**1**) has been studied by Meiggs and Miller,¹⁸ who observed the production of bibenzyl (**3**) and polyacid following irradiation in methanol. Both products are consistent with initial homolysis to give the benzyl radical (**2**) (Equation 29.1). The authors observed a transient absorption ($\lambda_{\text{max}} = 302$ and 314 nm) that they attribute to **2**. The observation of this transient and later deuterium incorporation studies both support a homolytic mechanism for the reaction of **1**.¹⁹

SCHEME 29.1

The quantum yield for production of CO_2 on irradiation of **1** is only 0.037, indicating that the homolytic reaction is relatively inefficient. The phenylacetate ion (I^-) undergoes PDC in water with similarly low efficiency, although via a different mechanism: photoejection of an electron gives the phenylacetyl radical, which then loses CO_2 to give the benzyl radical (**2**).²⁰ In methanol (but not in water), toluene was formed as the major product, and is consistent with formation of the benzyl anion, indicating that a solvent-dependent heterolytic pathway might potentially be competitive.

Addition of alkyl groups to phenylacetic acid does not significantly modulate its photochemical behavior. For example, ibuprofen (**4**), a widely used NSAID, is an alkylated derivative of **1**. Irradiation of **4** in methanol has been observed to give six products, five of which are expected photoproducts resulting from homolytic decarboxylation to give the benzyl radical (Scheme 29.1).²¹ The origin of the sixth product (**5**) accounting for nearly half of the product mixture is not known, but is not an obvious product arising from either the benzyl radical or anion. Although a PDC quantum yield was not reported, the long irradiation times required to achieve ~50% decomposition (7 h) suggest an inefficient reaction.

Reaction pathways analogous to those for **1** and **4** were observed for 1-naphthylacetic acids. Radical derived products were observed on irradiation of 1-naphthylacetic acid in ethanolic or in aqueous solution,^{22,23} and signals corresponding to the 1-naphthylmethyl radical (λ 330 nm) and solvated electron (λ = 700 nm) were observed by laser flash photolysis (LFP).²³ These results point to a mechanism in which the primary photochemical step is photoejection of an electron to the solvent, followed by decarboxylation to give the naphthylmethyl radical.

Electron-rich NSAIDs naproxen and carprofen are aryl acetic acids, and exhibit photochemistry similar to **1**.^{24–27} Both initially photoionize, producing solvated electrons, and subsequently decarboxylate to give radical intermediates. PDC proceeds with very low efficiency ($\Phi \sim 0.01$), both when they are in their acid and carboxylate forms. Radical PDC pathways, either involving direct homolysis or involving initial photoionization, have come to typify the photochemistry of electron-rich arylacetic acids.

29.3 PDC of Electron-Poor Arylacetic Acids

29.3.1 Trifluoromethylphenylacetic and Mandelic Acids

Burns and Lukeman have recently investigated the photochemistry of a variety of phenylacetic and mandelic acids substituted with trifluoromethyl substituents, and found that they undergo PDC efficiently in aqueous solution (pH 7 or higher), to give substituted toluene products consistent with initial formation of carbanion intermediates.²⁸ A total of eight examples (**6–13**), comprising *ortho*, *meta*, *para*, and di-substituted derivatives, all underwent the reaction efficiently, with relative efficiencies apparently

governed by the “*meta* effect” ($\Phi_m > \Phi_o > \Phi_p$). The derivatives were much less reactive at lower pH values, indicating that the reaction proceeds from the carboxylate rather than the acid form. Sensitization and quenching studies support reactivity occurring from the singlet state.

The efficient PDC of **6–13** to produce products consistent with ionic intermediates is very different behavior from that of electron-rich arylacetic acids. The carbanion intermediates produced following PDC of these derivatives can result either from direct heterolysis from the excited state, or homolysis followed by a rapid electron transfer.

29.3.2 Nitrophenylacetic Acids

The photochemistry of the carboxylates of nitrophenylacetic acids **14–17** in aqueous solution was investigated by Margerum and Petrusis, and all derivatives were found to undergo PDC.^{29,30} Very high quantum yields ($\Phi \sim 0.6$) were observed for the *meta* and *para* derivatives **14** and **15**, although the efficiencies of the *ortho* isomers **16** and **17** were much more modest ($\Phi \sim 0.04$). The only products observed following irradiation of **15–17** were the corresponding nitrotoluenes, which are consistent with the formation of carbanion intermediates. Irradiation of *para*-nitrophenylacetate (**14**) gave rise to carbanion **18**, which persisted with a lifetime of close to 1 min, and was easily detectable by conventional UV-Vis spectroscopy ($\lambda_{\text{max}} = 355$ nm). This strongly resonance-stabilized carbanion decayed to give two products: reaction with water gave *p*-nitrotoluene as a minor product (3%) while the major product was bibenzyl **19**, a product known to result from carbanion **18** (Equation 29.2). Craig and Atherton later studied the chemistry of carbanion **18** in greater detail using LFP, and provided rate constants for formation of the two reaction products.³¹

Wan and coworkers later showed that the ability of the nitro group to facilitate heterolytic PDC is actually enhanced on moving from the nitrophenyl to the nitrobiphenyl chromophore, despite the greater distance between the activating nitro group and the reaction center.³² Nitrobiphenylacetic acid **20** undergoes PDC with unity quantum yield to give the corresponding nitrobiphenyltoluene via carbanion **21** (Equation 29.3).

The α -carboxy-2-nitrobenzyl (CNB) photoremovable protecting group (PPG) is a water-soluble derivative of the popular *ortho*-nitrobenzyl PPG, and has been used to enact the photorelease of bioactive molecules in aqueous solution.^{33,34} Prior to a recent report by Corrie and coworkers,³⁵ it had always been assumed that the photochemistry of CNB is the same as for related *o*-nitrobenzyl systems and that the benzylic carboxylate is retained throughout the reaction. However, given the structural similarity between CNB and *o*-nitrophenylacetate **16**, it would have been reasonable to expect PDC to be a competing side reaction. Indeed, Corrie et al. determined that PDC does play a role in the photochemistry of the CNB group when they were able to directly observe the generation of CO₂ on photolysis of CNB-caged glycine (via carbamate linkage) and phosphate.³⁵ In subsequent work, Hagen et al. have detected products arising from PDC of CNB caged peptides using HPLC, but found that the extent to which PDC reduces the photorelease efficiency is strongly dependent on the nature of the peptide and the buffer system used.³⁶

29.3.3 Keto-Substituted Phenylacetic Acids

The photochemistry of ketoaromatics has been intensely studied for more than 100 years, effectively beginning when Ciamician observed the photoreduction of benzophenone in isopropanol when he exposed such solutions to sunlight on the rooftop of the Bologna laboratories.³⁷ The photochemistry of ketoaromatics is typified by radical formation via homolytic processes as hydrogen abstraction and Norrish type I and II reactions. As we shall see, the photochemistry of keto-substituted phenylacetic acids is distinctly different; radical chemistry is almost entirely avoided and heterolytic PDC to give ionic intermediates predominates.

Wan and coworkers investigated the photochemistry of 3- and 4-acetylphenylacetic acids **22** and **23** in aqueous solution, and found both to undergo efficient PDC at pH 7 ($\Phi = 0.6$ and 0.22 for **22** and **23**, respectively).³⁸ The transients detected by LFP and the products observed were consistent with a mechanism involving heterolytic PDC to give carbanion intermediates. Both derivatives react from the triplet state of the carboxylate form, although reaction was still observed for **22** at pH values lower than 3, suggesting an additional acid-catalyzed pathway.

The photochemistry of the *ortho* derivative **24** in benzene was examined by Sobczak and Wagner, who also found that decarboxylation took place efficiently in this solvent to give a single isolable product—2-methylacetophenone.³⁹ In this same solvent, no reactivity is observed from **22** and **23**, indicating a unique reaction mechanism only available to the *ortho* isomer. Indeed, later work by Ding et al. indicates that the likely mechanism in the PDC of **24** involves an initial intramolecular proton transfer from the carboxylic acid to the carbonyl oxygen—a reaction that is geometrically forbidden in the *meta* and *para* cases.⁴⁰ This proton transfer would generate a protonated carbonyl group, a suggestion that is in line with the acid-catalyzed route proposed by Wan for **22**.³⁸

Less work has been carried out with the corresponding formylphenylacetic acids, however, the results from a recent report by Kresge and co-workers suggest that similar chemistry takes place, at least for the *para* derivative.⁴¹

29.3.3.1 Ketoprofen and Related Derivatives

Ketoprofen (**25**) is an NSAID whose photochemistry has received much more attention than the other NSAIDs, partially because the ionic chemistry it displays is very unusual for a benzophenone derivative. Costanza first reported that ketoprofen undergoes PDC in neutral aqueous solution with a quantum yield of 0.75.⁴² When irradiated in de-aerated solution, the only product was 3-ethylbenzophenone (**26**), as would be expected from a heterolytic mechanism involving a carbanion intermediate (Equation 29.4). In aerated solution, **26** was still the major product, however three additional oxidation products were obtained, suggesting that the reactive intermediate responsible for the reaction is sufficiently long lived to react appreciably with dissolved oxygen. Bosca et al. proposed a mesolytic mechanism whereby the carboxylate of ketoprofen undergoes photoejection of an electron and PDC to generate a benzylic radical and a solvated electron.⁴³ The oxidation products are proposed to result from capture of the radical by oxygen, while **26** would arise from carbanion **27** formed by recombination of the benzylic radical and the solvated electron. Martinez and Scaiano were able to detect both solvated electrons and carbanion **27** on LFP of ketoprofen in neutral aqueous solution.⁴⁴ Laser power dependence studies showed that the solvated electron was formed as a result of a biphotonic process, and would therefore not contribute to the observed photochemistry under steady-state photolysis conditions that employ much less intense light sources. Also, the generation of the carbanion is prompt, having formed within the time window of the laser pulse. They propose an alternative mechanism in which **27** is formed directly from the ketoprofen carboxylate, either from a singlet or very short-lived triplet state. Additional mechanistic details have been provided by the work of Monti et al.,^{45,46} and while their work is mostly consistent with the overall mechanism presented by Martinez and Scaiano (PDC within 10 ns, followed by slower protonation); consensus has yet to be reached regarding the multiplicity of the reaction. Using picosecond LFP, Monti et al. have observed a subnanosecond transient with spectral features reminiscent of the ketoprofen triplet state and whose decay rate matches the rate of appearance of the carbanion signal.⁴⁵ Cosa and Scaiano have instead offered convincing evidence of a singlet pathway⁴⁷; they observed both the triplet state of ketoprofen and carbanion **27** simultaneously on LFP of **25** in water–acetonitrile mixtures, thus ruling out a product–precursor relationship between the two, at least in acetonitrile–water mixtures. Computational studies carried out by Eriksson and coworkers suggest that it is feasible for the ketoprofen carboxylate to undergo PDC from either the singlet or triplet manifold.⁴⁸ Suzuki et al. proposed

that the intermediate formed via the prompt decarboxylation of ketoprofen is in fact a triplet carbanion (with biradical character), which undergoes protonation at the oxygen to form a neutral biradical, which then converts to **26** on the microsecond timescale.⁴⁹ Phillips and co-workers investigated the photochemistry of ketoprofen using time-resolved resonance Raman spectroscopy and similarly conclude that the transient formed following the prompt PDC is a triplet carbanion, based on its sensitivity to oxygen.⁵⁰ However, the ionic reactions that ketoprofen-derived carbanions undergo (S_N2 , E1cb, *vide infra*) are inconsistent with triplet biradical character.

Scaiano and co-workers have extensively investigated the chemistry of carbanions obtained on PDC of ketoprofen analogues, beginning with derivatives **28–30** that have varying degrees of alkylation of the benzylic carbon.⁵¹ Each of **28–30** was found to undergo PDC with high quantum yield, similar to that of **25**. The degree of substitution was found to have a dramatic effect on the rate at which the carbanions generated by the PDC reaction were protonated by water: the primary benzylic carbanion obtained on PDC of **28** was protonated with a rate constant of $2.7 \times 10^7 \text{ s}^{-1}$ whereas the tertiary benzylic carbanion obtained on PDC of **29** reacted a full order of magnitude more slowly. This result runs contrary to expectations based on carbanion stability, since alkyl groups are electron donating and should increase the charge localized on the benzylic site, thus making them more reactive. The reactivity reversal has been rationalized as being the result of entropic rather than enthalpic factors, that the steric hindrance imposed by the additional alkyl groups is responsible for the slowing of the rate of protonation.

Scaiano et al. also investigated ketoprofen derivatives substituted with benzylic haloalkyl groups (**31–42**) with chain lengths of 4 or 5 carbons.^{52,53} The idea behind this series was that the carbanions produced on PDC of these derivatives would have additional reaction pathways available to them other than protonation by solvent. The expected reactions from these carbanions were intramolecular S_N2 substitutions to produce cyclic alkanes, and E2 eliminations to produce alkenes. When irradiated in an aqueous solvent, protonation was the dominant reaction for all derivatives, and S_N2 or E2 processes were not able to effectively compete. However, when the solvent was changed to dry DMSO, the major products obtained in all cases were the cyclized products expected from the S_N2 reaction, with no elimination products detected. LFP of **31–42** in dry DMSO enabled characterization of the intermediate carbanions and determination of the S_N2 rate constants in this solvent. The dependency of the rate constants on the leaving group followed expected trends, with $k_{\text{Cl}} < k_{\text{Br}} < k_{\text{I}}$. Cyclization to give five-membered rings was found to be around two orders of magnitude faster than the analogous reaction to produce six-membered rings.

**31** R = H, $n = 2$, X = Cl**32** R = H, $n = 2$, X = Br**33** R = H, $n = 2$, X = I**34** R = CH₃, $n = 2$, X = Cl**35** R = CH₃, $n = 2$, X = Br**36** R = CH₃, $n = 2$, X = I**37** R = H, $n = 3$, X = Cl**38** R = H, $n = 3$, X = Br**39** R = H, $n = 3$, X = I**40** R = CH₃, $n = 3$, X = Cl**41** R = CH₃, $n = 3$, X = Br**42** R = CH₃, $n = 3$, X = I

Interest in the mechanistic details of the PDC of ketoprofen has spurred a number of groups to examine the photochemistry of derivatives closely related to ketoprofen, but with modified chromophores. Wan and Xu studied 3- and 4-benzoylphenylacetic acids (**28** and **43**) and found both to undergo reactions similar to ketoprofen itself—heterolytic PDC to give benzoyltoluenes consistent with initial formation of carbanion intermediates.^{54,55} Transients were detected on LFP of **28** and **43** that were conclusively assigned to the carbanion intermediates. Wan and coworkers also prepared and studied the photochemistry of **44** and **45**, which are derivatives of ketoprofen in which an additional phenyl ring was placed between the activating carbonyl group and the acetic acid functionality.⁵⁴ Both of these derivatives also underwent efficient PDC to only the corresponding benzoylphenyltoluenes ($\Phi = 0.73$ and 0.30 for **44** and **45**, respectively). A heterolytic mechanism involving carbanion intermediates was proposed for both derivatives, and absorptions attributable to the expected carbanion intermediates were detected by nanosecond LFP. However, several interesting mechanistic details were uncovered during the study of **44** and **45**. Firstly, both derivatives show enhanced PDC at low pH values, suggesting that there may exist an acid-catalyzed mechanism of PDC for these derivatives. Secondly, **44** and **45** show large solvent deuterium isotope effects (4.3 and 2.3, respectively), indicating that a proton transfer from the solvent (or at least formation of significantly strong hydrogen bonds) to the substrate occurs during the primary photochemical step. For *para* derivative **45**, such an interaction can be easily envisioned since PDC could occur simultaneously with proton (deuteron) transfer from the solvent to the carbonyl oxygen to directly generate the neutral enol (Equation 29.5), bypassing the carbanion/enolate altogether.

Blake et al. investigated the photochemistry of the conjugate bases of 2-, 3-, and 4-xanthoneacetic acids **46**–**48** in aqueous solution (pH 7.4), and found very efficient PDC for **46** and **48** ($\Phi \sim 0.65$), whereas **47** was photoinert.⁵⁶ The stark contrast in the PDC efficiency of the positional isomers was attributed to the “*meta* effect,” since the two reactive isomers have the electron-withdrawing keto group positioned *meta* to the reaction center. The methyl xanthone products observed on PDC of **46** and **48** are consistent with a carbanion intermediate and heterolytic PDC, although no transients attributable to these carbanions

were detected by LFP.^{56,57} Quenching and fluorescence results provided strong evidence that the reaction proceeds exclusively from the S1 state, behavior that is unusual for aromatic ketones.

A new class of PPGs (**49**) has been developed by Lukeman and Scaiano that rely on PDC as the primary photochemical step.⁵⁸ These PPGs consist of ketoprofen as the core structure, with a leaving group (X) attached to β to the benzylic carbon. PDC of the conjugate base of the “ketoprofenate” PPG **49** (which is the major prototropic form at physiological pH) gives a benzylic carbanion (**50**) that subsequently ejects the leaving group as an anion via an E1cb-type mechanism (Equation 29.6). Several leaving groups were successfully released in this way, including halides, carboxylates, and methoxide. For most leaving groups, protonation of the intermediate cation was unable to compete with the elimination, and the alkene product (**51**) was the only one observed. Using the known protonation rate constants of 3-benzoylbenzyl carbanions in water, a minimum elimination rate constant of 10^8 s^{-1} was estimated for the elimination of good leaving groups. In the case of methoxide release, protonation was able to effectively compete with elimination, and the elimination product **51** was found to comprise only 20% of the product mixture. The intermediate carbanion was detected using LFP for this example, and a rate constant for elimination of methoxide was determined to be $5.1 \times 10^6 \text{ s}^{-1}$, which is more than six orders of magnitude faster than for release of the same leaving group from the *o*-nitrobenzyl PPG in the same solvent.⁵⁹ The ketoprofenate PPG shows several advantages over the *o*-nitrobenzyl group including very fast release kinetics (subnanosecond for most leaving groups), high quantum yield ($\Phi > 0.7$), good water solubility, and the production of relatively noninterfering products.

Subsequent to the initial report of the photochemistry of the ketoprofenate PPG, Blake et al. reported the development of a second-generation carbanion-mediated PPG based on the known PDC reaction of xanthone acetic acid.⁵⁷ These “xanthonate” PPGs (**52**) are believed to operate via a mechanism entirely analogous to that of **49**, and release of carboxylic acids and amines (via the carbamate) has been demonstrated. The xanthonate PPGs appear to retain all of the advantages of the ketoprofenate PPGs, but have a much higher molar absorptivity in the UVA region. In addition, the vinylxanthone photoproduct that is formed on photolysis of **52** shows strong fluorescence emission, which can be used as a “reporter” allowing quantification of the decaying reaction.

SCHEME 29.2

A related PPG for carboxylic acids that involves PDC in the photorelease mechanism has been developed by Soldevilla and Greisbeck.⁶⁰ PPG 53 contains the phthalimide chromophore, which is a good electron acceptor for photoinduced electron transfer (PET) reactions. The proposed mechanism is shown in Scheme 29.2: irradiation of 53 prompts an intramolecular PET from the carboxylate to the phthalimide to generate biradical 54, which can then undergo PDC (Scheme 29.2) to give carbanion 55. E1cB elimination of acetate from 55 leads to release of the caged substrate and production of alkene 56. Based on analogy to the known photochemistry of the phthalimide chromophore and on sensitization studies, the authors support a triplet-mediated mechanism. The eventual photorelease yields are strongly linked to the PPG stereochemistry; the *threo* and *erythro* diastereomers of 53 show markedly different product distributions. The *threo* form shows essentially only elimination products (56) on irradiation, whereas the *erythro* form shows up to 30% of 57, which would arise as the result of simple protonation, and is indicative of a slower elimination reaction.

29.4 Conclusions and Outlook

Great strides have been made over the past two decades in our understanding of the mechanisms of PDC reactions. In general, arylacetic acids that possess electron-withdrawing groups, such as the trifluoromethyl, nitro, and keto groups, undergo PDC with high efficiency to give carbanion intermediates and the associated ion-derived products. Arylacetic acids lacking such groups will generally undergo PDC inefficiently to give radical-derived products. Because heterolytic PDC reactions often proceed cleanly and efficiently, efforts have been made to make use of the carbanion intermediates generated. They have been successfully employed in S_N2 substitution (alkylation) reactions, although their use as nucleophiles in synthetic applications is so far limited in scope. Perhaps more promising, the PDC reactions of arylacetic acids that produce carbanions have been exploited in the design of a new class of PPGs with superior attributes. There is little doubt that PDC reactions will continue to be a source of interest for both those interested in the development of new applications (such as PPGs) and those interested in improving our understanding of the underlying mechanisms.

30.1 Introduction

The great synthetic potential of peroxides accounts for the wide interest of scientific community to the photooxygenation reaction that represents one of the most versatile and simple procedures to prepare a variety of peroxides. Generally the reaction is carried out in the presence of a sensitizer whose role is important to determine the type of mechanism. The use of a sensitizer such as a dye whose energy of excited triplet state can be transferred to the ground state oxygen produces singlet oxygen (Type II photooxygenation) [1]. This species adds to unsaturated substrates by [4+2] or [2+2] or ene-mode leading to endoperoxides or dioxetanes or allylic hydroperoxides, respectively (Scheme 30.1) [2–4].

Singlet oxygen is a highly reactive electrophilic species, but it is possible to control the order and timing of such reactions. Chemoselectivity is dictated by structural features. Thus, the [4+2]-cycloaddition is favorite with *s-cis*-dienes but competes with [2+2]-cycloaddition particularly in the presence of heteroatom substituents, which have a pronounced activation effect on dioxetane formation, or with the ene-reaction in the presence of allylic hydrogens. The electrophilic character of singlet oxygen (it prefers to react with electron-rich bonds) [5], steric interactions (in spite of the small dimensions, singlet oxygen attacks the less hindered side) [6], or favorable structural features (the correct alignment of the allylic hydrogen to the olefinic plane promotes ene-addition) [4] are other determinant factors. Singlet oxygen can also react with sulfur, selenium, phosphorous, and nitrogen compounds or undergo physical quenching [7,8].

The high potential of singlet oxygen together with the mild reaction conditions accounts for the high number of publications on this topic, in some cases exclusively dedicated [9,10]. No book nor publication on peroxides ignores singlet oxygen oxygenation [11,12].

SCHEME 30.1 Reaction modes of singlet oxygen.

In this Chapter, we focus on the [4+2] and [2+2] photooxygenations that involve singlet oxygen. The chapter is concentrated to evidence the high potential of these reactions and recent interesting applications in the field of stereoselective reactions.

30.2 Experimental Procedure for Type II Photooxygenation

The classical conditions to carry out oxygenation with singlet oxygen require halogenated or deuterated solvents, low temperatures, continuous flow of oxygen, halogenated lamps and dyes as methylene blue (MB), rose bengal (RB), or tetraphenylporphyrin (TPP) [13], and recently fullerene derivatives [14]. The use of halogen lamps prevents the possibility of the peroxide decomposition, which may occur with UV lamps, and with the latter the use of filters is necessary. Due to the high number of the dye sensitizers available, the reaction can be carried out in a variety of organic solvents, from apolar to polar, from water to ionic liquids [15]. Photooxidation has also been performed using supercritical carbon dioxide (scCO_2) as medium and a perfluorinated analogue of TPP, 5,10,15,20-tetrakis(pentafluorophenyl)porphyrin (TPFPF), as sensitizer [16]. This procedure requires an appropriate apparatus but offers a number of advantages since scCO_2 is fully oxidized and hence nonflammable and nontoxic, completely miscible with gaseous O_2 and has lower viscosity and higher diffusivity than more conventional solvents. The use of fluorinated surfactants and co-solvents enlarges the applicability of the system to polar sensitizer and substrates [17].

Homogeneous conditions generally used in these oxygenations have some disadvantages with respect to the removal of the solvent or the separation of the sensitizer from the reaction mixture. Promising results have been obtained by carrying out the oxygenation under solvent-free conditions [18] or using heterogeneous media as zeolites [19], micelles and vesicles [20], by immobilization of sensitizers (commercially available polystyrene-bound RB, polyethylene glycol-supported tetraarylporphyrin [18], silica gel-linked [60]fullerene [21] or nafion-supported catalyst [22], or by using heterogeneous sensitizers as photoexcited porous silicon (PSi) nanostructures [23]. During recent years, investigation has also been directed to perform singlet oxygenation in miniaturized processes by means of nano- [24] and micro-reactors [25,26].

30.3 [4+2]-Cycloaddition

[4+2]-Cycloaddition of singlet oxygen to unsaturated systems is generally described as concerted, even if nonsynchronous [27], $[4\pi+2\pi]$ -cycloaddition [28]. Conjugated systems from acyclic to cyclic, from aromatic to heteroaromatic compounds are the appropriate substrates for this reaction.

SCHEME 30.2 Singlet oxygen cycloaddition to acyclic dienes 1–3.

30.3.1 Substrates

30.3.1.1 Acyclic and Carbocyclic Conjugated Systems

30.3.1.1.1 Acyclic Dienes

Oxygenation of conjugated dienes occurs preferentially via a 1,4-cycloaddition to form an endoperoxide, but it is complicated by the possibility that all the three pathways of singlet oxygen can occur [3,4]. Apolar solvents may favor this mode [29], but the chemoselectivity in acyclic dienes mainly depends on the amount of *s-cis*-conformer in the equilibrium necessary for a concerted [4+2]-addition. Even the presence of a little of the *s-cis*-conformer can give rise to an appreciable amount of endoperoxide due to the very low activation energies of this reaction mode. The decreasing yield of 1,4-adducts from **1** to **2** [30] can be easily explained on the basis of steric factors that play a role in the *s-cis*/*s-trans* conformational isomerism (Scheme 30.2). A *cis*-1-substituent increases the strain energy of the *cis*-conformation required for the 1,4-cycloaddition so that this reaction mode becomes difficult and other oxygenations, [2+2] or ene-addition, take place. On the contrary, a bulky substituent at 2-position as in **3** makes the *trans*-conformation less stable and, hence, favors the 1,4-addition [30]. Attempts have been made to rationalize the stereocontrolling factors in the oxygenation of acyclic dienes with scarce results due to the flexibility of these substrates and hence to the role of conformational features [6].

30.3.1.1.2 Vinyl Compounds

Substrates having one endocyclic C–C double bond (even in carbo- or heteroaromatic rings) and one conjugated exocyclic C–C double bond undergo [4+2]-cycloaddition, even in the presence of allylic hydrogens [31,32] or alkoxy groups [33].

In the oxygenation of vinylcycloalkenes **4**, the ratio [4+2] vs. ene-products changes with ring size, due to the influence of this factor on the alignment of allylic hydrogens [31] (Scheme 30.3).

The photooxygenation of a vinylbenzene derivative, such as **5**, leads to dihydrobenzo-1,2-dioxin in the primary step, which is followed by rapid oxygenation of the cyclohexadiene chromophore to give diendoperoxides as **6** and **7** (Scheme 30.4) [32].

The oxygenation of vinylnaphthalenes *trans*- and *cis*-**8** occurs with retention of stereochemistry [33]. The lower yield of the endoperoxide *cis*-**9** than that of *trans*-**9** would be due to the steric interaction between the two methoxy groups, which makes the [4+2]-cycloaddition more difficult and, therefore, makes the [2+2] reaction on the electron-rich double bond competitive (Scheme 30.5).

30.3.1.1.3 Cyclic Dienes and Polyenes

Endoperoxidation is the preferred process with cyclic dienes, and simple five-, six-, seven-, and eight-membered ring aliphatic dienes lead, by photooxygenation, to the corresponding endoperoxides that, except for that of cyclopentadiene, are quite stable (Scheme 30.6).

The oxygenation of cyclopentadiene **10** has been experimented in a falling-film microstructured reactor (Scheme 30.7) [25]. The unstable endoperoxide **11** is formed in the reactor, kept at 10°C, and reduced

SCHEME 30.6 Oxygenation of cyclic dienes.

SCHEME 30.7 Photooxygenation of cyclopentadiene (**10**) in falling-film microreactor.

immediately after leaving it by passing the effluent into a solution of thiourea in methanol at 10°C. The diol **12** has been obtained in 20% yield for the non-optimized process [25]. The procedure evidences the feasibility of this reaction type on a safe preparative scale. Indeed, the system ensures that the quantity of the potentially explosive endoperoxide intermediate is always kept at a safe level and the volume of aerated solvent in the system at any time is in the region of microliters.

For 1,3-cyclopentadiene derivatives, the 1,4-cycloadduct is still the only product independently from the alkylation or arylation at positions 1–4 [6]. For higher homologues, the chemoselectivity can change depending on the substitution. Thus, oxygenation of cyclohexadiene **13** affords a mixture of *syn/anti*-endoperoxides **14** and ene-products in 65% and 35%, respectively while 1,4-disubstituted α -terpinene **15** gives endoperoxide ascaridol **16** almost quantitatively [38] (Scheme 30.8).

α -Terpinene is widely used as $^1\text{O}_2$ trap in model oxygenation reactions due to its easy reactivity with singlet oxygen. Hence, oxygenation of this compound to ascaridol has been recently investigated using scCO_2 as solvent and TPFPP as sensitizer [16,17]. Experiments have also been performed in a continuous reactor [39]. Under these conditions, the reaction is rapid (of the orders of few minutes) and quantitative. The reactor operates with unchanged efficiency over 8 h, and the result represents a 3000-fold scale-up of the batch reaction. Oxygenation has also been performed in a microreactor using [60]fullerene as sensitizer [26]. This device has been designed to host, within the microchannels network, the photosensitizer [60]fullerene that has been immobilized on polystyrene beads or silica gel microparticles. Nearly quantitative conversion has been achieved in about 50 s, but a partial photodegradation of the ascaridole (30%–50% yield) has been observed [26].

The stereoselectivity of the cycloaddition can be influenced by steric factors and depends on the substitution and the ring type. The presence of the encumbered $\text{OSi}(\text{Me})_2\text{Bu}^t$ substituent induces the selective formation of the *anti*-isomer **17**, and this peroxide has been usefully employed for the synthesis of natural chiral compounds (Scheme 30.9) [40]. The photooxygenation of cycloheptadiene **18** leads to the diastereomeric mixture of peroxides *syn/anti*-**19** in *ca* 5:1 molar ratio (Scheme 30.9) since conformational requirements to better allocate the silyl group direct singlet oxygen to the less hindered β -face [41]. The major isomer has been used as precursor of deoxy-hexoses and -heptoses.

1,3,5-cycloheptatrienes undergo valence tautomerization and may exist as the tropilidenes **20** or the norcaradiene valence isomers **21** (Scheme 30.10). Consequently, the photooxygenation can lead to the

SCHEME 30.8 [4 + 2]-Cycloaddition vs. ene-reaction of cyclic dienes **13** and **15**.

SCHEME 30.9 Stereoselectivity of the photooxygenation of cyclic dienes.

bicyclic endoperoxides **22** and/or tricyclic derivatives **23** and this depends on the steric and electronic nature of the substituents. The tropilidene endoperoxide **22** is the main or the only one formed when $\text{R}^1 = \text{H}$ [42] or with electron-rich substituent as OMe, respectively (Scheme 30.10) [43]. The norcaradiene endoperoxide **23** is favored with bulky groups as alkyl or aromatic groups [44] and, especially, with π -electron acceptor substituents as CO_2Me or CHO [43].

Fused bis-cycloheptatriene **24** gives the stable norcaradiene peroxide **25** and by further addition of singlet oxygen the *syn*-bis(norcaradiene) bis(endoperoxide) **26** (Scheme 30.11) [45].

Oxygenation of asymmetric cycloheptatrienes affords complex mixtures of endoperoxides depending on the location and type of the substituent. Thus, compounds **27** and **29** give the peroxides **28** [46] and **30** [47] while benzotropone **31** affords the peroxide **32** (Scheme 30.12) [48]. Peroxide **30** shows an unusual behavior since it produces singlet oxygen and the parent tropone **29** upon thermolysis and, hence, represents one of the rare non-benzenoid systems generating singlet oxygen [47]. The development of general and flexible synthetic routes to tropone (cyclohepta-2,4,6-trien-1-one) and tropolone (2-hydroxycyclohepta-2,4,6-trien-1-one) derivatives is of continuous

interest since they represent the structural key elements in a wide range of natural products, many of which display interesting biological activity [46–48].

As found for the cycloheptatriene system, cycloocta-1,3,5-triene affords a mixture of both the relatively stable bicyclic and tricyclic endoperoxides **33** and **34** (Scheme 30.13) [49].

Cyclooctatetraene **35a** reacts with singlet oxygen to give the endoperoxide 7,8-dioxabicyclo[4.2.2]deca-2,4,9-triene **36a** in 26% yield (Scheme 30.14) [50]. Substituted derivatives **35b,c** give the endoperoxides with the substituents located at the vinylic position **36b,c** and at the bridgehead position **37b** (Scheme 30.14) [50].

30.3.1.1.4 Aromatic Compounds

The capability of aromatic compounds to react with singlet oxygen enhances when the number of condensed rings is increased [51]. Benzene derivatives react only if electron-donating substituents are present [52] or when the benzene moiety is incorporated into strained metacyclophanes [53,54]. The reaction of compound **38** proceeds in high yields in various solvents, even in the absence of sensitizer, affording the endoperoxide **39** (Scheme 30.15) [53].

Analogously, singlet oxygen adds to electron-rich naphthalenes. Derivatives with electron-donating substituents at 1- and 4-position lead to the 1,4-endoperoxides. The regioselectivity can be modified by both electronic and steric effects. 5,8-Endoperoxides have been observed when at least one additional

SCHEME 30.15 Photooxygenation of metacyclophane **38**.SCHEME 30.16 Photooxygenation of 1,4-disubstituted naphthalenes **40**.

methyl group is placed on the 6,7 [55] or 8 position [6], or when bulky groups are present in 1,4-positions. Naphthalene **40a** reacts with singlet oxygen in water and/or methanol, giving both 1,4- and 5,8-endoperoxide **41a** and **42a**, even if the latter as minor product (Scheme 30.16) [56]. When an oxygen linker separates the alkyl chain from the aromatic core as in compound **40b**, the aldehyde ester **44b** is found probably via the typical C–C/O–O fragmentation of a preliminarily formed dioxetane, such as **43b** (Scheme 30.16) [57].

The extent and purpose of π -facial selectivity can be controlled in the reaction of chiral naphthalenes **45** by electronic factors [6]. In particular, *syn*-selectivity is highly favored by attractive interactions between a hydroxy group, even in the homobenzylic position, and the incoming $^1\text{O}_2$, while crowded substituents or electrostatic repulsions as those caused by a methoxycarbonyl group or a halogen favor the *anti*-attack (Scheme 30.17).

Oxidation of anthracene or higher acenes occurs even in the absence of a dye, since the same substrates act as sensitizers in singlet oxygenation [51]. These compounds react mainly at the meso-positions of the aromatic nucleus but electron-donating groups have a strong directing effect when placed at the 1- and 4-positions [28,51]. Due to the high reactivity toward singlet oxygen, suitably substituted anthracene derivatives are used as $^1\text{O}_2$ traps, even in biological systems [58]. Currently, acene derivatives are receiving high attention since they are useful in organic electronics for preparing organic field-effect transistor films [59]. Synthetic studies are therefore conducted on various pentacene derivatives to acquire more information on this compound type. Pentacene derivatives **47** and **49** have been prepared

and investigated for their electronic properties as well as for their photoaddition reactions with oxygen. In both cases, the corresponding peroxides **48** [60] and **50** [61] are formed by simple exposure to sunlight (Scheme 30.18).

The thermal stability of the endoperoxides of aromatic compounds enhances going from the only spectroscopically detectable endoperoxides of benzene derivatives to those from acenes, which are stable enough to be stored for several days [51]. A peculiar property of these endoperoxides is that they can revert thermally to the aromatic molecule and oxygen. Naphthalene or anthracene peroxides generally produce singlet oxygen, so that they are currently used to generate singlet oxygen by means of an alternative route to photosensitization [13]. This behavior of naphthalene endoperoxides is of particular interest, especially for mechanistic studies in biological systems. Water-soluble derivatives known as NDP [62] and DHPN [63,64] are widely used in the biological media to generate singlet oxygen free from other reactive oxygen species at the physiological temperature (Scheme 30.19).

Interestingly, for 1-naphthol derivatives **51**, the [4+2]-cycloaddition of singlet oxygen is followed by a breakdown of the endoperoxide intermediate leading to 1,4-naphthoquinones **52** (Scheme 30.20).

SCHEME 30.19 Reversible oxygenation of water-soluble naphthalene derivatives.

SCHEME 30.20 Photooxygenation of 1,4-naphthols 51.

The reaction has been investigated under non-concentrated and concentrated sunlight [65–67]. In particular, oxygenation of **51** (R¹ = OH) gives **52** (R¹ = OH) known as juglone, a versatile building block for the synthesis of bioactive quinoid compounds. The solar-chemical synthesis with medium concentrated sunlight operates efficiently and affords juglone in moderate to good yields up to 79% on multiple gram-scales [67].

In addition to the substituent effects, the extent of reversion of acene peroxides to the parent compounds and singlet oxygen depends on the number of condensed rings and decreases from anthracene to higher acenes. Thus, compound **54** reverts slowly to **53** and oxygen by heating above 100°C (Scheme 30.21) [68]. The thermal stability of these and similar compounds together with the diverse colored forms of the endoperoxides and parent compounds are useful properties in the field of organic photochromism [69]. The retrocycloaddition in fact can be induced photochemically. Representative is heterocoerdianthrone endoperoxide **56** (HECDPO) (Scheme 30.21). It is formed from an air-saturated solution of heterocoerdianthrone **55** (HECD) in methylene chloride that has been irradiated by sunlight with a 420–480 nm band-pass filter and stored in the dark [70]. The oxidation of heterocoerdianthrone is reversible, and the system can be used as a reversible actinometer with oxygen addition in the visible and reversion in the UV range (248–334 nm region) [70]. Between 253 and 302 nm, the reaction efficiency does not depend on irradiation wavelength.

30.3.1.2 Heterocyclic Compounds

Pentatomic aromatic heterocycles react with singlet oxygen, generally via [4+2]-cycloaddition leading to unstable endoperoxides [71]. As expected on the basis of higher aromaticity than pyrroles or furans, thiophenes undergo hardly addition of singlet oxygen [72]. Isoxazoles, 1,2,5-oxadiazoles and 1,3,4-oxadiazoles are apparently inert under dye-sensitized photooxygenation [73] as well as nitrogen-containing six-membered heterocycles [71]. Endoperoxides of heterocycles are generally highly thermally unstable and can afford characteristic rearranged products.

SCHEME 30.21 Reversible oxygenation of acenes **53** and **55**.

In the series of furans, the thermal stability of the related endoperoxides, as well as the type of rearranged products, is rigorously related to the nature of the α,α -substituents, and follows the order $\text{Me (0}^\circ\text{C)} > \text{Ph} > \text{H} > \text{OMe (-80}^\circ\text{C)}$ when these substituents are in α -positions [71,74]. Epoxides, diepoxides, enol esters, enediones, ketoesters, epoxyfuranones, furanones are only some of the products obtainable from the photooxygenation of furans depending on substituents, solvents, and concentration [71,74]. Investigation has evidenced that straight correlations exist between the electronic effects of the functional groups and the type of the observed rearrangement products so that the fate of the endoperoxide is predictable. More complex is the photooxygenation of pyrroles, imidazoles, and other heterocycles since they exhibit low chemoselectivity, giving generally mixtures of products deriving from [4+2]- and [2+2]-cycloaddition or hydroperoxides [19,71,75]. Anyhow, these heterocyclic systems continue to be extensively studied because they are involved in photobiosynthesis and other biological processes (see, e.g., the special issue of Photochemistry and Photobiology-2006 [10]).

Oxazoles are highly reactive toward singlet oxygen [19,71,76]. In particular, endoperoxides of aryl- or alkyl-substituted oxazoles are highly unstable, converting almost quantitatively to triamides **58** [76] (Scheme 30.22). Since the imide group is an activated leaving group, this reaction represents a means of generating a masked carboxyl function. Indeed, the oxygenation of aryl and/or alkyl oxazoles **57** has been employed in diverse synthetic applications [76]. Remarkably, 5-alkoxyoxazoles **59** afford 3*H*-1,2,4-dioxazoles **60** either in homogeneous medium [77] or under solvent-free conditions by using sensitizer/polymer system (PP-S-DVB) [78] (Scheme 30.22).

Condensed derivatives as benzofurans or indoles undergo mainly [2+2]-cycloaddition, the latter also give hydroperoxides [71]. The large resonance energies of the benzene ring are dominant to such an extent that [4+2]-cycloadditions are not possible. Recently, it has been reported that 4,7-dimethylbenzofurazan (**61**) adds singlet oxygen to give the corresponding 4,7-endoperoxide **62** [79]. The latter decomposes back to the parent compound and singlet oxygen at room temperature (Scheme 30.23).

SCHEME 30.22 Photooxygenation of oxazoles **57** and **59**.SCHEME 30.23 Reversible oxygenation of benzofurazan **61**.

30.3.2 Synthetic Applications

Photooxygenation of [4+2] type is a powerful synthetic tool to introduce, simultaneously, oxygenated *syn*-1,4-functionalizations in 1,3-diene systems. The endoperoxide can undergo a variety of transformations, which can either or not involve the cleavage of the O–O bond and, often, can be performed *in situ* and at low temperature overcoming the thermal instability problem of the peroxide intermediate. Selective transformations include reductions to unsaturated (with thiourea, sodium tetrahydroborate) or saturated (with PtO_2 , Ni, Pd/C) diols or to dioxanes (with diimide), rearrangements to hydroxyl carbonyl compounds (with base as NEt_3 or metal catalysis) or to epoxy carbonyl compounds (by metal catalysis) or to bis-epoxides (by metal catalysis, by thermolysis), acid-mediated heterolysis [3,19,80–82]. Here just a brief description of some recent applications to evidence the synthetic potential of this reaction starting mainly from dioxines, endoperoxides of tropone derivatives, aromatic compounds, and furans is presented.

30.3.2.1 Endoperoxides of Acyclic and Carbocyclic Conjugated Systems

The possibility to control stereoselectively, the endoperoxide formation, and the reduction of O–O bond with thiourea has been successfully employed in the stereospecific synthesis of diverse polyhydroxylated compounds, as the bis-homoinositol **63** [83] (Scheme 30.24), or aminocyclitols [84]. Highly oxygenated cyclohexane derivatives (cyclitols) occur widely in nature and usually possess interesting biological activities [85].

SCHEME 30.24 Synthesis of a precursor of bis-homoinositol **63**.SCHEME 30.25 Synthesis of 1,2,4-trioxanes **65** and **67** via acid-catalyzed reaction of cyclic peroxides **64** and **66** with carbonyl compounds.

Acid-catalyzed reaction of bridged 1,2-dioxines, e.g., **64**, with carbonyl compounds leads to 5,6-*cis* fused 1,2,4-trioxanes **65** in high yields (Scheme 30.25) [86]. The acid usually employed is trimethylsilyl trifluoromethanesulfonate (TMSOTf). This reaction also occurs with 1,4-dimethylnaphthalene endoperoxide **66** [86], even intramolecularly [87]. Synthetic cyclic peroxides as trioxanes are receiving high attention since many derivatives show significant promise as antimalarial drugs because of their artemisinin-like activity [88].

An interesting application of the acid-catalyzed ring opening of endoperoxides is depicted in Scheme 30.26. In the presence of TMSOTf, the peroxides **68** react with allyltrimethylsilane to give the *cis*-configured endoperoxides **69** via the attack of the allylsilane on the carbocation derived from heterolytic cleavage of the endoperoxide bridge [89]. The reaction proceeds with a high degree of diastereoselectivity due to the bulky $-CH_2SiMe_3$ substituent that adopts an equatorial position in a product-like transition state.

SCHEME 30.26 Synthesis of peroxides **69** via acid-catalyzed reaction of bicyclic peroxides **68** with allylsilane.

Peroxides undergo a base-catalyzed rearrangement to *cis*- γ -hydroxyenones, known as the Kornblum-DeLamare rearrangement [3,80–82]. This treatment has been performed using a cinchona-alkaloid catalyst (deMeQDAc) on diverse peroxides of 1,3-dienes leading to enantioenriched γ -hydroxyenones [90]. Thus, hydroxyenone **71** has been prepared from the diene **70** by a two-step sequence involving TPP-sensitized photooxygenation and chiral base-catalyzed desymmetrization of the resulting endoperoxide (Scheme 30.27).

Application of base treatment to the endoperoxide **28** represents a novel method for stipitatic acid isomer **72** (Scheme 30.28) [46]. Interestingly, treatment with CoTPP gives the other isomer **74**, probably via the ring opening of the initially formed bis-epoxide **73** [46].

In 1,2-dioxines **75**, the transformation to enones **76** may be difficult to control due to the inherent instability of these compounds. Enones can convert to 1,4-diketones **77**, under excessively basic conditions [91] or undergo dehydration to generate furans **78** in the presence of acid (Scheme 30.29) [92].

Some nucleophiles have been shown to be weakly basic to rearrange the 1,2-dioxine and then undergo proton exchange with the hydroxyl enone allowing for one-pot ring-opening/nucleophilic addition. Malonate is sufficiently mild to promote rearrangements of substituted naphtho- and phenanthro-1,2-dioxines **79** and **81** to the transient *cis*- γ -hydroxyenone species with no further rearrangement (Scheme 30.30) [93]. Hence, malonate as nucleophile readily adds to the double bond of the *cis*- γ -hydroxyenones in a highly diastereoselective fashion, which yield highly substituted *cis*-fused bis-lactones **80** and **82** through an intramolecular domino cyclization.

SCHEME 30.27 Enantioselective synthesis of γ -hydroxy enone **71**.

SCHEME 30.28 Synthesis of stipitatic acid isomers **72** and **74**.SCHEME 30.29 Transformations of γ -hydroxy enones **76** under stressed basic or acid conditions.SCHEME 30.30 Bis-lactones **80** and **82** by reaction of 1,2-dioxines **79** and **81** with diethyl malonate.

SCHEME 30.31 Synthesis of cyclopropane derivatives **84** and **85** by reaction of 1,2-dioxines **83** with phosphonates.

Removal of the acidic proton adjacent to the O–O linkage by a stabilized phosphorous ylide acting as base is the key step for the synthesis of cyclopropane derivatives from dioxines [94]. The *cis*- γ -hydroxyenone undergoes Michael addition and concomitant P–O bond formation with the phosphorus ylide giving an oxaphospholane intermediate (**A**) ultimately leading to a cyclopropane (Scheme 30.31). This reaction has been applied to dioxines **83** using stabilized phosphonate nucleophiles and has afforded β -cyclopropyl amino acids **84** and **85** in good yields [95].

Transition metals as Fe(II), Ru(II), Co(II) catalyze rearrangement to *cis*- γ -hydroxyenones by homolytic cleavage of the peroxide bond [81]. In addition to the dehydration to furans and/or rearrangement to 1,4-diketones, metal catalysis can induce the formation of 1,4-diols and bis-epoxides, often yielding mixtures of products [81]. Optimized conditions using FeSO₄ have been pointed out and have led to the synthesis of 2,3-di- and 2,3,4-trisubstituted furans **88** and **89** starting from 1,2-dioxines **87**. The latter have been generated by Diels–Alder reaction of the enyne-RCM (ring-closing metathesis) adducts with singlet oxygen (Scheme 30.32) [96].

Intramolecular insertion of a carbenoid into a peroxide linkage of dioxines **90** generates bicyclic compounds **91** via a rhodium (II) catalyzed cyclization (Scheme 30.33) [97]. Insertion into the olefin moiety gives tricyclic peroxides **92**.

An intermolecular cyclopropanation with diazomethane has been performed on endoperoxides **93** using palladium acetate as catalyst (Scheme 30.34) [98]. The unsaturated endoperoxides in the [2.2.1] series are attacked by the carbene from the *exo* face while the analogs with larger bridges are preferentially attacked from the face *syn* to the peroxo bridge, affording **94** and **95**, respectively. Only in the case of the benzannelated [2.2.2] system **96** does the attack occur exclusively from the face proximal to the benzene ring leading to **97** (Scheme 30.34).

Diimide is able to reduce the double C=C bond preserving the peroxide linkage and this reaction constitutes the most important breakthrough in the synthesis and characterization of stable saturated endoperoxides [99]. Many peroxides previously postulated as intermediates in the singlet oxygenation of cyclic dienes have thus been rendered stable enough for further exploration of chemical, physical, and spectroscopic properties [82]. Transformations of endoperoxides that preserve the peroxide linkage are limited since the presence of the olefin inherently makes any proton adjacent the peroxide linkage acidic, resulting in compounds highly sensitive to acidic and basic media and metal-based reagents may induce fragmentation of the peroxide bond. In addition, in a bicyclic framework, the weak peroxide bond ($-36 \text{ kcal mol}^{-1}$) is compounded by the additional strain brought on by the double bond in the bicyclic framework. The peroxide linkage of 1,2-dioxines exhibits stability to epoxidation with

30.3.2.2 Furan Endoperoxides

Although endoperoxides are formed from heterocyclic dienes containing nitrogen or sulfur, this section will deal only with those of furans since (1) furans are the most studied and used among the heterocyclic compounds due to the widespread occurrence of this functionality both in biologically important substrates and pharmaceuticals [104], (2) the high reactivity toward singlet oxygen overcomes even that of

SCHEME 30.34 Palladium-catalyzed cyclopropanation of endoperoxides **93** and **96**.

tri- and tetrasubstituted olefins in side chains [105] and, hence, (3) diverse derivatives are used as probes for the presence of this species even in aqueous media [106], (4) this system has a prominent role as key architectural feature in organic synthesis for natural products [107,108].

In particular, we focus on two general applications of the photooxygenation of furans for the preparation of 4-hydroxybutenolides and enediones, compounds of great synthetic interest. A large number of these derivatives have been incorporated into the framework of more complex molecules and have been obtained by the action of singlet-oxygen-mediated reaction sequences [104,107,108].

Butenolides are obtained by oxygenation of α - and α,α' -unsubstituted furans through a Kornblum-DeLamare rearrangement of the related endoperoxides, which is favored by a basic solvent as acetone [109] or water or ionic liquids [15], or MeOH. Using this solvent, butenolides have been directly formed in the self-sensitized photooxygenation of 3,4-dialkoxyfurans [110]. In particular, irradiation of derivative **98** possessing photodegradable groups affords ascorbic acid **99** in a one-pot reaction in 74% (Scheme 30.35).

The regiospecific generation of the carbonyl function may be achieved using a hindered base (which promotes hydrogen abstraction from the sterically most accessible bridgehead in the furan endoperoxide) [111] or, better, starting from 2-trimethylsilylfurans [112]. The Katsamura protocol has been employed as key step in a wide number of complex syntheses [19,104,107,108]. A fascinating application is in the construction of the tricyclic bis(spiroketal) core of prunolides, a family of cytotoxic natural products (Scheme 30.36) [113]. Photosensitized oxidation of both the (*Z*) and (*E*)-bis(2-trimethylsilylfuran) **100** followed by *in situ* dehydration of the intermediate bis(γ -hydroxy butenolide) **101** and spirocyclization provides the same 2:1 mixture of the *trans*- and *cis*-**102**.

SCHEME 30.35 Synthesis of L-ascorbic acid **99**.

SCHEME 30.36 Synthesis of the bis-spiroketal **102** via butenolides **101**.SCHEME 30.37 Synthesis of norzoanthamine precursor **104**.

Oxidation of furan **103** followed by treatment with tetrabutylammonium fluoride (TBAF) and iodo-methane affords the methyl ester **104** that is a crucial product in the 41-steps total synthesis of the alkaloid norzoanthamine (Scheme 30.37) [114].

Cis-1,4-enediones are prepared by low temperature treatment of furan endoperoxides with reductants such as triphenylphosphine or dialkyl sulfides [71]. They generally form almost quantitatively and hence are used without isolation as, e.g., in the synthesis of the spirocyclic C-nucleoside **107** (Scheme 30.38) [115]. Compound **107** has been obtained by NEt_3 addition to the crude intermediate enedione **106** in 50% yield (from furan **105**).

The use of an acid catalyst has allowed to obtain 3-keto-tetrahydrofurans, such as **109**, from 2-(β -hydroxyalkyl) furans such as **108** in one-pot synthetic operation (Scheme 30.39) [116].

Oxidation of the enantiomerically pure furan **110** followed by *in situ* treatment with Me_2S gives pyranone **111** that is the key product for the ring A in the total synthesis of (+)-ambruticin S (Scheme 30.40) [117].

To overcome the thermal instability of furan endoperoxides, and hence working at low temperatures, a convenient alternative to the use of endoperoxides is to carry out the reduction on the methanol-trapping products which are more stable at room temperature and hence, more manageable than the related endoperoxides. These derivatives (e.g., compound **113** in Scheme 30.41) are simply

SCHEME 30.38 Synthesis of spirocyclic nucleoside 107.

SCHEME 30.39 Synthesis of 3-keto-tetrahydrofuran 109.

prepared by oxygenating furans in methanol and are reduced by alkyl sulfide generally *in situ*. This approach starting from furan **112** and the base-catalyzed cyclization of enediones using Hünig's base have been used to construct the 4-hydroxycyclopentenone core in a series of litseaverticillols [105]. The authors exploit the chemo- and regioselectivity of the reaction of singlet oxygen with the [4+2]-cycloaddition occurring at a much faster rate than the subsequent ene-mode to obtain the first (derivatives **A** and **C**, via *a* in Scheme 30.41) and second generation (derivatives **D**, **E**, **G** from **A** via *b* in Scheme 30.41) of these compounds.

The *cis*-relationship of the two carbonyl groups in enedione **115** has allowed to carry out a cyclization to a pyridazine C-nucleoside **116** in a one-pot three-steps synthesis starting from furan **114** (Scheme 30.42) [118].

30.4 [2+2]-Cycloaddition

Two research groups synthesized independently for the first time 1,2-dioxetanes by photooxygenation of electron-rich alkenes, namely the *trans*- and *cis*-3,4-diethoxyderivatives [119] and tetramethoxy-1,2-dioxetane [120]. Since then the photooxygenation of electron rich alkenes such as vinyl ethers, ketene acetals, enamines, vinyl sulfides as well as of olefins without allylic hydrogens or with inaccessible allylic hydrogens (on bridgeheads) is a general route for 1,2-dioxetanes [121,122]. [2+2]-Cycloaddition is generally the route in the photooxygenation of condensed aromatic compounds as indenenes, benzofurans, indoles, sometime it occurs in pyrroles [71] and in partially saturated heterocycles [8]. In many cases dioxetanes are thermally unstable and their formation has been postulated on the basis of the characteristic cleavage products, frequently accompanied with emission of light. Synthesis and isolation are the major difficulties encountered with these peroxides, and photochemical methods represent a valid alternative to thermal approaches [121,122].

The most accredited mechanism for dioxetane mode involves polar species as open zwitterions [123]. Experimental evidences have been provided by solvent effects [124] and trapping reactions with alcohols and aldehydes [123].

30.4.1 Chemoselectivity and Diastereoselectivity

Chemoselectivity in favor of dioxetane-mode is observed by increasing solvent polarity [124] or in the presence of heteroatom substituents. The mesomeric effect of heteroatoms is evident in the oxygenation of 5,6-dihydro-1,4-oxathiin **117a** [125] and 1,4-dithiin **117b** [126] (Scheme 30.43). Despite the presence of allylic hydrogens and sulfide moiety, the sole reaction products are dicarbonyl compounds **119** deriving from the corresponding dioxetanes **118** through the classical fragmentation of this peroxide class [125,126].

SCHEME 30.43 Photooxygenation of 1,4-oxathiin **117a** and 1,4-dithiin **117b**.

Me	Me	<i>i</i> -Pr	98:2	100:0
Me	Me	<i>t</i> -Bu	100:0	100:0

SCHEME 30.44 [2 + 2]-Cycloaddition vs. ene-reaction of olefins **120** at different temperatures.

Dioxetane mode is also favored at low temperature as demonstrated in the oxygenation of olefins **120** (Scheme 30.44) [127]. The formation of dioxetanes **121** increases on lowering the temperature from 25 to -78°C. As shown in Scheme 30.44, the ratio 1,2-addition/ene-reaction is also increased by increasing the bulkiness of the alkoxy group due to unfavorable steric factors that make the appropriate alignment of allylic hydrogens difficult to give the ene-reaction [127].

Optically active oxazolidinones have been successfully used as sterically controlling chiral auxiliaries [128,129]. Thus, the photooxygenation of oxazolidinone-substituted enecarbamates **122** leads to diastereomerically pure dioxetanes **123** (Scheme 30.45). The selectivity is independent from the size of the alkyl group at the C4 of the oxazolidinone but does depend on whether this stereogenic center is *R* or *S* configured [128]. For example, oxazolidinone with an *R* configuration at the C4 favors the 1'S/2'S dioxetane **123**. Alternatively the oxazolidinone with an *S* configuration at the C4 favors the 1'R/2'R dioxetane [128]. The chirality at the phenethyl group (C3') does not influence the π -selectivity. Temperature, solvent and alkene geometry are instead important factors [129]. As shown in Scheme 30.45, the diastereofacial control followed by appropriate reagents can be used to obtain synthetically useful, enantio-merically pure hydroxylated products [128].

Diastereoselectivity can also be controlled by electronic effects as hydrogen bonding [130]. The hydroxyl-directed stereocontrol has been observed in the photooxygenation of adamantylidene-substituted chiral allylic alcohol **124** that gives *threo*-dioxetane **125** with high stereoselectivity (Scheme 30.46) [130]. The use of CD₃OD/CCl₄ as solvent causes a drop in diastereoselectivity from >95:5 in CDCl₃ to 89:11. This is due to the loss of the above mentioned hydrogen bonding between the substrate and ¹O₂. Instead,

SCHEME 30.45 Diastereoselective dioxetane formation in the photooxygenation of enecarbamates **122**.

Solvent	<i>threo/eritro</i>	Yield (%)

SCHEME 30.46 Diastereoselective dioxetane formation in the photooxygenation of chiral allylic alcohol **124**.

intermolecular hydrogen bonding occurs with the solvent methanol. The polar solvent increases the dioxetane yield from 47% (in CDCl₃) to 95%.

30.4.2 Chemiluminescent Properties

Bis(adamantylidene)dioxetane **127a** (Scheme 30.47) is the most thermally stable among hitherto known dioxetanes [131] and a single adamantylidene group has been proven to exert a strong stabilizing effect [132]. Really, steric hindrance between geminal substituents of a dioxetane (3,3-steric interaction) appears to especially stabilize the peroxidic ring [127]. Dioxetanes with annelated six-membered rings are less stable than their five- or seven-membered analogues [133]. The steric interaction of a bulky *tert*-butyl group at the 5-position with two methyls at the 4-position can improve the thermal persistency of the peroxide ring in five- [134] and six-annulated dioxetanes [133]. Conversely, the presence of an easily oxidized substituent, which has a low oxidation potential [135,126], or of a heteroatom as sulfur [72] at the double bond considerably decreases the thermal stability of the peroxidic intermediate. Indeed, sulfur-substituted dioxetanes are much more thermally unstable than the O-analogues and have been detected by spectroscopic means at very low temperature, if at all [125,126,136]. Some representative stable dioxetanes prepared by photooxygenation of alkenes are drawn in Scheme 30.47.

There is a high interest to know the structural features that endow the thermal stability of dioxetanes since this property makes the molecule easy to handle and, if accompanied with high chemiluminescence [142], usable as enzyme labels in bioanalytical clinical applications [143,144].

SCHEME 30.47 Photooxygenation of olefins **126**.

Dioxetanes have the unique property to decompose thermally to electronically excited carbonyl products with consequent emission of blue light (λ_{max} 400–430 nm) (e.g., **127a** in Scheme 30.48) [145]. Thus, functionalized adamantylideneadamantane-1,2-dioxetanes have been described as labels for thermochemiluminescent immunoassays [146].

Particularly in the last years, more effective are CIEEL-active dioxetanes that decompose in a manner quite distinct from rather simple dioxetanes [142]. A CIEEL-dioxetane generally contains an adamantyl group to provide stability and a fluorogenic electron-donor substituent, mostly a protected phenolic substituent. On demand, the stable dioxetane can be transformed into an unstable dioxetane that bears a phenolate ion and decomposes spontaneously to emit light by CIEEL mechanism (CIEEL = chemically initiated electron exchange luminescence). This has been explained through an intramolecular electron

SCHEME 30.48 Thermal decomposition of dioxetane **127a**.

SCHEME 30.49 CIEEL decomposition of dioxetane **127**.

transfer that occurs from the aryloxy to the O–O bond and generates an intermediate, which produces the excited singlet product. Scheme 30.49 reports some examples of CIEEL-dioxetanes for which the phenolic hydroxy group is protected as *t*-butyldimethylsilyl ether and phosphate [147,148]. These dioxetanes are thermally stable and can be triggered as desired by deprotection, chemically or enzymatically.

Compound **127h** (R¹ = Na₂O₃P) is the commercially available AMPPD (or PPD[®]) and is used for biochemical and clinical applications [146]. The advantages of the use of luminescent labels if compared with that of radioactive isotopes are that they are safer, faster, and more sensitive (two or three orders of magnitude more sensitive than scintillation counting).

30.4.3 Synthetic Applications

The [2+2]-cycloaddition of singlet oxygen to alkenes is generally followed by thermal decomposition of the dioxetane intermediate to carbonyl fragments so that it can represent an alternative to ozonolysis, although limited to electron-rich olefins due to the competition of the other reaction modes (ene and [4+2]-addition). This behavior has been exploited for the synthesis of 11-oxaestrogens starting from some estrogens with vinylanisole structure, such as **128** (Scheme 30.50) [149]. Oxygenation of this compound leads to **129** via vinyl moiety oxidative cleavage.

The oxygenation of 5-dialkylamino-4-pyrrolin-3-ones **130** gives highly functionalized ureas **132** by cleavage of the initially formed [2+2] cycloadducts **131** (Scheme 30.51) [150].

The photooxidative double bond cleavage can be usefully adopted for the construction of large heterocyclic rings containing carbonyl groups. Thus, oxygenation of the enamine **133** is a convenient route to compound **134** in the synthesis of protopine-type alkaloids (Scheme 30.52) [151].

The oxidative ring-opening to keto-amide **136**, followed by *in situ* treatment with aqueous NaHCO₃, is the key step to convert the indole **135** to quinoline **137** in the synthesis of the quinine alkaloid camptothecin (Scheme 30.53) [152].

SCHEME 30.50 Synthesis of 11-oxaestrogen **129**.

SCHEME 30.51 Synthesis of functionalized ureas **132**.SCHEME 30.52 Synthesis of protopine-type compounds **134**.SCHEME 30.53 Synthesis of camptothecin precursor **137**.

SCHEME 30.54 Synthesis of the allylic alcohol **140**.

With careful control of the temperature or with stable dioxetanes, reduction to 1,2-diols can be obtained by treatment with reductants as lithium aluminum hydride [3,121,122]. Epoxides are instead formed by treatment with phosphines or sulfides [3,121,122], often followed by rearrangement or ring contraction. Thus, a peculiar open product, the allylic alcohol **140**, has been obtained by treatment of dioxetane **139** with P(OMe)₃ or Me₂S (Scheme 30.54) [153].

Labile undetected epoxides formed by an intramolecular nucleophilic attack of sulfur to the O–O bond have been proposed to explain the formation of sulfoxides, e.g., **144** (Scheme 30.55), instead of the expected dicarbonyl compounds in the oxygenation of some oxathiins and dithiins substituted with electron-withdrawing groups at the double bond [125,126]. It has been suggested that in the dioxetane, e.g., **142**, the increased electron demand by the O–O bond favors the intramolecular nucleophilic attack of the ring sulfur, leading to the final product **144** via the sulfoxide epoxide **143** (Scheme 30.55) [126].

One of the most interesting and useful applications of dioxetanes is in the synthesis of 1,2,4-trioxanes. This is due to the capacity of some alkoxy-substituted dioxetanes to undergo heterolytic C–O bond cleavage to zwitterionic intermediates, which can be trapped inter- or intramolecularly by carbonyl compounds [123,154]. This behavior has been exploited for the total synthesis of the antimalarial (+) artemisinin [155] and related analogs [156]. In particular, the Posner reaction is based on the generation of 1,2-dioxetanes, e.g., **146**, through low-temperature photooxygenation of electron-rich vinyl ethers, e.g., **145**, and *in situ* acid-induced intramolecular coupling with carbonyl groups to give peroxides **147** (Scheme 30.56) [154]. The reaction allows the introduction of a variety of substituents at positions 3,4,5',7,9, and 10 of the tricyclic molecular core.

SCHEME 30.55 Synthesis of sulfoxide **144**.

SCHEME 30.56 Synthesis of 1,2,4-trioxanes 147.

30.5 Conclusion

As shown in this chapter, photooxygenation of unsaturated compounds continues to receive high attention from scientists. After the 1970s–1980s, dedicated to mechanistic investigation on singlet oxygenation and to exploring the scope of the reaction, in recent years efforts have been directed to the stereochemical aspects and to the exploitation of stereoselective (in many cases, also stereospecific) applications in order to improve the use of this procedure for the synthesis of natural bioactive compounds and/or their analogues [157]. Moreover, post photo-oxidation modification reactions containing cyclic peroxide functionalities while maintaining the peroxide linkage intact are becoming relatively common.

In the last decade, a newly relevant challenge is in adapting photooxygenation processes for large-scale production. Hence, an emerging area of interest is in research of new technologies to be applied to these reactions, and has been stimulated by developments in microreactor design [158] and use of more specific light sources, as light-emitting diodes (LEDs) [26,159]. Due to the short holdup in the microstructures, the hazard of highly exothermic and explosive reactions is considerably reduced. Solar photooxygenations with medium concentrated sunlight are also investigated [160]. This increasing interest is due to the growing demand for environmentally friendly technologies, and photochemical approaches are regarded as clean routes. Dye-sensitized photooxygenation, in addition, uses oxygen as oxidant with a complete atom economy, leading to products that generally present both atoms of oxygen, and hence represents one of the most efficient and cleanest oxidation processes.

31.1 Introduction

The chemistry of singlet molecular oxygen ($^1\text{O}_2$)¹ has attracted continuous and remarkable attention for its synthetic,² mechanistic, environmental,³ as well as therapeutic applications.⁴ In 1931, Kautsky first demonstrated the importance of a “reactive oxygen molecule” in dye-sensitized photooxidation reactions.⁵ However, Kautsky’s pioneering work and careful reasoning were largely ignored for many years. Later on, Foote and Wexler^{6a} provided new experimental evidence for the involvement of $^1\text{O}_2$ as the reactive intermediate in photochemical processes in solution.⁶ This breakthrough brought $^1\text{O}_2$ into the mainstream of chemical research. The reaction of $^1\text{O}_2$ with C=C bonds can be classified into three fundamental categories: (1) conjugated dienes react preferably by [4 + 2] cycloaddition to yield endoperoxides;⁷ (2) electron-rich alkenes, without allylic hydrogen atoms of proper orientation, react by [2 + 2] cycloaddition to form 1,2-dioxetanes^{7c,8} and (3) inactivated alkenes bearing allylic hydrogen atoms react via the so-called ene or Schenck⁹ reaction yielding allylic hydroperoxides. The latter reaction type has arguably drawn the most extensive experimental as well as theoretical attention.¹⁰ Notably, this reaction has been applied toward the synthesis of several natural products¹¹ as well as 1,2,4-trioxanes.¹² Moreover, the allylic hydroperoxides that have been obtained from this reaction can be further transformed to useful target molecules such as allylic or epoxy alcohols and enones.

31.2 Mechanistic Studies

The mechanistic aspects of the title reaction were for many years the subject of considerable discussion and arguments; the main question was whether the reaction is concerted¹³ (via a cyclic six-membered transition state **1**, Scheme 31.1) or involves intermediates. The reported stepwise pathway has invoked an open biradical/dipolar **2**,¹⁴ a dioxetane **3**,¹⁵ a perepoxide **4**,¹⁶ or an exciplex **5**¹⁷ intermediate. The lack

SCHEME 31.1 Proposed mechanisms for the $^1\text{O}_2$ -mediated ene reaction.

of Markovnikov-type directing effects,^{1a,6a} specific trapping experiments,¹⁸ the results of intra/intermolecular kinetic isotope effects (KIEs) (Section 31.2.2), as well as the observed selectivities (Section 31.3) provide strong evidence for the intermediacy of a perepoxide in the $^1\text{O}_2$ -mediated allylic oxidation. Ultimately, recent theoretical and experimental results (which will be described in Sections 31.2.1 and 31.2.3, respectively) provide important implications for the precise mechanism of the title reaction.

31.2.1 Theoretical and Computational Methods

Theoretical and computational methods have been widely used in order to either elucidate reaction mechanisms or provide useful mechanistic details. However, in the case of $^1\text{O}_2$ -mediated reactions, these mechanistic tools have encountered complicated as well as challenging problems.¹⁹

Early and recent theoretical calculations concerning the mechanism of $^1\text{O}_2$ ene reaction are notably contradictory. In the mid-1970s, according to semiempirical MINDO/3 calculations, the addition of $^1\text{O}_2$ to propene appears to be non-concerted involving the formation of *cis*- and *trans*-methylperoxirane as intermediates.²⁰ In 1980, Harding and Goddard predicted (using a combination of *ab initio* calculation and thermochemical methods) that the title reaction proceeds via a favorable biradical intermediate; the perepoxide is 40 kJ/mol higher in energy.²¹ One year later, Yamaguchi et al. reported that perepoxides are too high in energy to qualify as viable intermediates (as are zwitterions) in $^1\text{O}_2$ -mediated allylic oxidations of weakly polar alkenes.²² In the early 1990s, calculations have shown that both concerted and stepwise pathways (involving strained perepoxide-type intermediates), exist on PM3 semiempirical potential-energy surfaces for the addition of $^1\text{O}_2$.²³ In the mid-1990s, *ab initio* molecular orbital studies supported a concerted mechanism (involving a non-radical transition state with a perepoxide-like conformation) for the ene reactions of allylic olefins and enol ethers bearing allylic hydrogen atoms.²⁴ In 2001, the $^1\text{O}_2$ addition to 1,3-cyclohexadiene was calculated to occur in a concerted fashion without any intermediates along the reaction coordinate.²⁵

Among the more notable contributions toward understanding the mechanism of the title reaction is the collaborative effort by the Singleton, Houk, and Foote groups.²⁶ In particular, they proposed (mainly based on high level *ab initio* calculations) that the $^1\text{O}_2$ ene reaction with simple alkenes proceeds via two transition states without an intervening intermediate. In this “two-step no intermediate” mechanism, the symmetrical addition of $^1\text{O}_2$ is rate limiting on a potential-energy surface that bifurcates at a valley-ridge inflection (VRI) point²⁷ into two isomeric products. It is worth mentioning that the second transition structure (with the elusive perepoxide-like structure) lays near the VRI point. Later on, Maranzana et al. investigated the “gas-phase” mechanism of the $^1\text{O}_2$ ene reaction with propene^{28a} and (*E*)-2-methyl-but-2-enal.^{28b} The main result of these studies is that a stepwise pathway, passing through a polar biradical intermediate, is sharply favored. In 2008, B3LYP/6-31G* and CASMP2 calculations

have been employed in order to study the title reaction with *trans*-cyclooctene or tetramethylethylene.²⁹ In the case of *trans*-cyclooctene (which imposes a substantial strain in the transition state for hydrogen abstraction), these methods predict that the reaction involves a perepoxide intermediate. On the other hand, for tetramethylethylene (in accordance with previously reported calculations)²⁶ the $^1\text{O}_2$ ene reaction takes place through a *two-step no-intermediate* mechanism. Importantly, Sheppard and Acevedo (using novel three-dimensional potentials of mean force calculations coupled to QM/MM simulations) reported that the $^1\text{O}_2$ addition to tetramethylethylene proceeds through a stepwise mechanism with a perepoxide intermediate.³⁰ Furthermore, this computational study provides, for the first time, insight into the effect of solvent on the $^1\text{O}_2$ -mediated allylic oxidation.

31.2.2 Kinetic Isotope Effects

Over the last 40 years, several KIE measurements for the $^1\text{O}_2$ -mediated allylic oxidation have been reported. In the early 1970s, no significant intermolecular KIE was found for *cis*- or *trans*-1,2-dimethylstilbene.³¹ Later on, low intermolecular KIE was also measured in the case of tetramethylethylene (**6**- d_0 versus **6**- d_{12} and **6**- d_0 versus *gem*-**6**- d_6 , Scheme 31.2).^{16b,32} The first detailed as well as revealing mechanistic study, by means of intramolecular KIEs on the title reaction, was reported by Stephenson et al.^{16b,33} In particular, three types of isotope competition, namely, *cis*, *trans*, and *geminal*, were identified; these types of isotope competition were measured by using *cis*-**6**- d_6 , *trans*-**6**- d_6 , and *gem*-**6**- d_6 deuterated tetramethylethylenes (TMEs) as the substrates, respectively (Scheme 31.2). It is important to underline the fact that the product isotope effect was found to exhibit a stereochemical dependence; an isotope effect was only observed when the competing isotopes were *cis* to one another (as in *trans*-**6**- d_6 and *gem*-**6**- d_6). At this point, it can be concluded that the small intermolecular, in combination with the substantial intramolecular KIEs in TMEs, provide strong evidence for an intermediate in the $^1\text{O}_2$ ene reaction with structural requirements to the perepoxide.

Similar results were observed in the case of *cis*-disubstituted³⁴ and trisubstituted³⁵ alkenes. On the other hand, for the highly unreactive *trans*-butene- d_3 , an intramolecular KIE of $k_{\text{H}}/k_{\text{D}} = 1.25$ was observed;^{34b} this KIE was much larger than that measured with *cis*-**6**- d_6 ($k_{\text{H}}/k_{\text{D}} = 1.04$ – 1.09 , Scheme 31.2). The $^1\text{O}_2$ -addition to *trans*-butene- d_3 was suggested to proceed through the reversible formation of a perepoxide intermediate.^{34b} In the late 1990s, the $^1\text{O}_2$ ene reaction of 2,5-dimethyl-2,4-hexadiene- d_6 was examined.³⁶ Particularly, a substantial primary isotope effect of $k_{\text{H}}/k_{\text{D}} = 1.58$ was measured. In a similar manner with the case of *trans*-butene- d_3 , this isotope effect was rationalized in terms of partial reversion of the perepoxide intermediate to the starting materials.

SCHEME 31.2 Inter/intramolecular KIEs on the $^1\text{O}_2$ ene reaction of TMEs.

31.2.3 Recent Experimental Developments: The Use of Hypersensitive Probes

Despite the great amount of studies reported over the last decades (Sections 31.2.1 and 31.2.2), there is no consensus about the precise mechanism of the $^1\text{O}_2$ -mediated allylic oxidation. The aim of a recent experimental study was to investigate the possible involvement of an open biradical/dipolar intermediate in the title reaction.³⁷ For this purpose, informative alkenes that bear mono- and disubstituted cyclopropyl groups as mechanistic probes were assayed.

It is instructive to note that several very fast radical rearrangements based on cyclopropylcarbinyl radical ring openings have been applied in various mechanistic studies. In the early 1990s, Newcomb et al. reported that 2,2-diphenylcyclopropylcarbinyl radical (**7**, Scheme 31.3) rearranges exceedingly fast (to the homoallyl radical **8**) with an experimental rate constant of $5 \times 10^{11} \text{ s}^{-1}$ at room temperature.³⁸ Later on, the same research group designed a second-generation hypersensitive probe **9**, which is presented in Scheme 31.3.³⁹ This probe is capable of distinguishing between radical and carbocation intermediates. It is obvious that a phenyl group will stabilize an incipient radical center more strongly than does an alkoxy group, whereas the reverse is true for an incipient carbocation.

The photooxidations of alkenes *E*-**12**, *Z*-**12** and *E/Z*-**15** (Scheme 31.4) were run in several aprotic as well as protic solvents. In all cases, the only detected, isolated, and fully characterized products (after their reduction with PPh_3) were allylic alcohols **13**, **14**, **16**, and **17**. Notably, these alcohols bear an intact cyclopropyl ring. Even when the reaction solvent was MeOH, no rearranged products were detected. Importantly, the reaction mechanism seems to be independent of solvent polarity. At this point, it is worth mentioning that if a biradical intermediate (having a lifetime greater than 10^{-11} – 10^{-12} s)^{38,40}

SCHEME 31.3 Radical/cationic rearrangements based on cyclopropylcarbinyl radical/cation ring openings.

SCHEME 31.4 $^1\text{O}_2$ addition to alkenes *E*-**12**, *Z*-**12** and *E/Z*-**15**.

had been formed during the $^1\text{O}_2$ ene reaction, the rearranged oxygenated products should have been detected. Taking into account the findings reported in Section 31.2, it is difficult to propose a biradical or dipolar mechanism for the title reaction. On the other hand, these findings in combination with the results reported in the Sections 31.2.1 and 31.2.2 support the formation of a perepoxide as the reaction intermediate.

31.3 Studies on Selectivity

31.3.1 Regioselectivity

The study on site selectivity of $^1\text{O}_2$ -mediated allylic oxidation has proven to be a powerful mechanistic tool in order to determine the trajectory of the enophile attack. Two excellent reviews have extensively covered this issue.⁴¹ Several noteworthy empirical rules (such as the “*cis* effect,” the *anti* “*cis* effect,” the large group nonbonding effect and the “*gem* effect”) have been proposed in order to allow the *a priori* determination of the regioselectivity in the $^1\text{O}_2$ addition to a variety of alkenes. Moreover, some interesting solvent and electronic effects on the regioselectivity have provided valuable information regarding the reaction mechanism.

31.3.1.1 “*cis* Effect”

In the $^1\text{O}_2$ addition to acyclic or cyclic trisubstituted alkenes⁴² as well as enol ethers,⁴³ the more substituted side of the double bond has been found to be the more reactive (Scheme 31.5). Several models have been proposed in order to explain the so-called “*cis* effect” selectivity. The majority of these models is consistent with the existence of an interaction between the incoming $^1\text{O}_2$ and two allylic hydrogen atoms, which highly stabilizes the transition state TS_1 , versus TS_2 , of perepoxide formation (Scheme 31.5). Particularly, in the late 1970s, Frimer and Bartlett et al. suggested that the formation of the C–O bond requires a closer approach to the alkene carbons compared to the C–H bond cleavage; a transition state, which is less hindered, is energetically preferred.⁴⁴ In 1980, Stephenson reported that an interaction between the LUMO orbital of the oxygen and the HOMO orbital of the alkene stabilizes the transition state for the formation of perepoxide intermediate.⁴⁵ In the same year, Schulte-Elte and Rautenstrauch proposed that for a cycloalkene there is a correlation between the orientation of the allylic hydrogen atoms in the ground state and their reactivity; the allylic hydrogen atoms at the axial

SCHEME 31.5 “*cis* Effect” selectivity. In the representative substrates, numerical values indicate percentage of double bond formation in the ene adducts.

position are more reactive.^{42c} In 1981, Houk et al. (using STO-EG semiempirical calculations) postulated that the lower the rotational barrier of a specific alkyl group at the double bond, the higher the reactivity of this group toward hydrogen abstraction by $^1\text{O}_2$.⁴⁶ However, this postulate was later on challenged by experimental results which showed that rotational barriers do not always predict the reactivity of the allylic hydrogens during the ene abstraction step.⁴⁷ Finally, Hurst et al. (based on measurements of the activation parameters ΔH^\ddagger and ΔS^\ddagger in the $^1\text{O}_2$ ene reaction with a variety of alkenes) reported that there is a type a hydrogen bonding interaction in the rate-limiting step of the formation of the perepoxide intermediate.⁴⁸

31.3.1.2 *anti* “*cis* Effect”

In trisubstituted alkenes with highly crowded *cis* alkyl groups, the “*cis* effect” selectivity could not apply. In contrast, it has been found that in these cases there is a strong preference for hydrogen abstraction on the less substituted side of the double bond (Scheme 31.6).⁴⁹ Accordingly, this selectivity has been defined as the *anti* “*cis* effect.” Examination of the possible transition states that lead to the ene products has provided reasonable mechanistic explanation for the observed selectivity. For instance, in TS_3 (that leads to the minor ene product), the nonbonding interactions between the incoming oxygen and the large *t*-Bu group are stronger than those in TS_4 where these interactions are diminished (Scheme 31.6).

31.3.1.3 Large Group Nonbonding Effect

The $^1\text{O}_2$ addition to *cis/trans* alkenes^{41a,50} as well as *geminal* dimethyl/diethyl trisubstituted alkenes^{41a,51} shows a general preference for hydrogen abstraction from the side of the large alkyl group of the double bond (Scheme 31.7). This selectivity has been rationalized by examining the possible transition states that lead to the formation of the ene adducts. In the case of a *cis* alkene, TS_6 is expected to have lower energy than TS_5 (Scheme 31.7); in TS_6 , the repulsive 1,3-nonbonding interactions between the oxygen atom and the large group are smaller than those in TS_5 . For a *geminal* dimethyl/diethyl trisubstituted alkene, TS_7 is also expected to be higher in energy than TS_8 (Scheme 31.7); in the latter transition state, the nonbonding interactions involving the large group and the oxygen atom are smaller than those of TS_7 .

SCHEME 31.6 *anti* “*cis* Effect” selectivity. In the representative substrates, numerical values indicate percentage of double bond formation in the ene adducts.

SCHEME 31.7 Large group nonbonding effect selectivity. In the representative substrates, numerical values indicate percentage of double bond formation in the ene adducts.

31.3.1.4 Geminal Selectivity

In similar independent studies, Clennan and Orfanopoulos and their coworkers have reported that the $^1\text{O}_2$ ene reaction of alkenes (which bear a large substituent either at the allylic,⁵² or at the vinylic^{52c} position) and substituted cycloalkenes⁵³ occurs regioselectively by hydrogen abstraction in the alkyl group *geminal* to the large double-bond substituent. This selectivity has been defined as the “*gem effect*.” Some general examples are depicted in Scheme 31.8. The observed *geminal* selectivities have been mainly rationalized by the energy difference of isomeric transition states in the product

SCHEME 31.8 Geminal selectivity on the $^1\text{O}_2$ ene reaction of alkenes bearing a large substituent either at the allylic or at the vinylic position.

SCHEME 31.9 *Geminal* selectivity on the $^1\text{O}_2$ ene reaction of alkenes bearing an electron withdrawing group at the α position. In the representative substrates, numerical values indicate percentage of double bond formation in the ene adducts.

determining step. These energy differences arise from the repulsive nonbonding interactions of the incoming oxygen with the large substituent. In particular, TS_9 has lower energy than TS_{10} and TS_{12} , due to the relief of 1,3-repulsions; TS_9 leads to the formation of the major ene adduct (Scheme 31.8). On the other hand, TS_{10} and TS_{12} are unfavorable due to the presence of 1,3-nonbonding interactions between the oxygen atom and the L group; these transition states lead to the formation of minor ene products. It is worth mentioning that, in the case of TS_{11} , two *geminal* substituents (L and Me) adopt a *cis* conformation in the newly forming double bond. This pathway is highly unfavorable and thus no product is detected.

The *geminal* site selectivity is also observed for alkenes which bear an electron withdrawing group (such as an aldehyde,⁵⁴ a ketone,⁵⁵ a carboxylic acid,⁵⁶ an ester,⁵⁷ an amide,⁵⁸ a cyano,^{54a} an iminyl,⁵⁹ a sulfinyl,⁶⁰ a silyl,⁶¹ or a stannyl⁶² group) at the α position. Some representative examples are outlined in Scheme 31.9. For the aforementioned alkenes, there are two competing factors that affect the site selectivity in the $^1\text{O}_2$ -mediated allylic oxidation: (1) the driving force to form the new double bond in conjugation with the functionality in the ene product and (2) the 1,3-nonbonding interactions between the oxygen atom and the electron withdrawing group, which favor again the conjugated product.

31.3.1.5 Solvent and Electronic Effects

Previously reported studies have shown that the site selectivity as well as the rate of the $^1\text{O}_2$ ene reaction of alkenes is almost independent on the solvent polarity.⁶³ However, later work has shown that a change on the solvent polarity causes a small but significant variation in the distribution of the ene adducts (using either non-functionalized⁶⁴ or functionalized⁶⁵ alkenes as starting materials).

At this point, it is worth mentioning that in the addition of $^1\text{O}_2$ to α,β -unsaturated ester **18** (Scheme 31.10),^{65a} the efficiency of a hydrogen abstraction from the methyl group, which is *geminal* to the ester group (forming **19**), decreases substantially as the solvent polarity increases. In particular, the

SCHEME 31.10 Solvent effect on the site selectivity in the $^1\text{O}_2$ ene reaction of α,β -unsaturated ester **18**.

ratio of ene products **19/20** decreases by a factor of 5 in going from carbon tetrachloride to the more polar solvent dimethyl sulfoxide. This solvent effect has been rationalized by examining the possible transition states that lead to the formation of perepoxide intermediate (Scheme 31.10). In TS_{14} , the pendant oxygen atom is oriented *syn* with respect to the ester group and the net dipole moment is expected to be larger than in TS_{13} ; in the latter transition state, the pendant oxygen atom is placed *anti* to the ester group. Ultimately, TS_{14} (which is more polar than TS_{13}) is better stabilized by polar solvents than TS_{13} .

In the late 1990s, the regioselectivity in the photooxidation of β,β -dimethylstyrene [**21** ($\text{R} = \text{H}$), Scheme 31.11] with $^1\text{O}_2$ was examined.⁶⁶ Specifically, the major ene product was derived from the preferential hydrogen abstraction from the methyl *syn* to the phenyl group. In addition, it was found that the magnitude of this selectivity depends on the solvent polarity. For instance, the ratio of *syn/anti* ene products (**22/23**, $\text{R} = \text{H}$) increases by a factor of 3.4 on going from carbon tetrachloride to methanol. In accordance with previously reported studies, this selectivity has been rationalized by examining the possible transition states that lead to the formation of perepoxide intermediate. In particular, $^1\text{O}_2$ prefers to form the transition state on the more crowded side (TS_{15} , Scheme 31.11); there are positive interactions between the incoming electrophile and the phenyl ring. In TS_{15} , the benzylic carbon of the double bond has significant cationic character and it is stabilized by the phenyl group through resonance. The partially negative charge, which is developing into the pendant oxygen atom during

SCHEME 31.11 Solvent and electronic effects on the site selectivity in the $^1\text{O}_2$ ene reaction of alkenes **21**.

the formation of the perepoxide, is stabilized by the partially positive charge on the phenyl ring. Therefore, the overall effect stabilizes better the *syn* transition state TS₁₅ than the *anti* TS₁₆ where this effect is absent.

In the light of the above-mentioned *syn* selectivity, electronic and solvent effects of the addition of ¹O₂ to labeled isobutenylarenes have been also studied.⁶⁷ Concerning the electronic effect, it was found that the site selectivity depends on the electronic nature of the aryl substituents.^{67a} Electron withdrawing substituents, such as -CF₃ or -F, increase the reactivity of the allylic hydrogen atoms in the *syn* methyl group. In contrast, electron donating substituents, such as -OMe, significantly increase the reactivity of the allylic hydrogen atoms in the *anti* methyl group. Similarly, the transition states presented in Scheme 31.11 were again used in order to rationalize these results. For instance, electron-withdrawing substituents decrease the electron density of the phenyl group, thus the stabilizing interaction of the partially negative charged oxygen to the arene is more efficient. A similar argument may be applied in the case of electron-donating substituents. Concerning the solvent effect, it has been found that there is a similar trend for the site selectivity as that observed in the case of β,β-dimethylstyrene.^{67b}

31.3.2 Diastereoselectivity

In the late 1990s, Prein and Adam categorized the factors that govern the π-facial selectivity of the ¹O₂-mediated allylic oxidation.⁶⁸ These factors are (1) steric, when nonbonding repulsion between substrate and ¹O₂ makes the one π face of the double bond less accessible than the other; (2) stereoelectronic, when one face of the double bond displays a higher π electron density due to some features of the substrate's geometry (e.g., orbital distortion); (3) electronic, related to hydrogen bonding and electrostatic attractions/repulsions between a substituent of the substrate and the enophile; and (4) conformational, which deals with the proper alignment of substrate's allylic hydrogen atoms. Concerning this concept, some case studies in the diastereoselectivity of the ¹O₂ addition to either acyclic or cyclic alkenes will be presented.

31.3.2.1 Acyclic Alkenes

31.3.2.1.1 Alkenes Bearing Chiral Auxiliaries

There is no doubt that ¹O₂ (a linear two-atomic molecule) cannot itself transmit steric effects. Thus, diastereoselection in ¹O₂-mediated reactions may only arise through substrate control. Examination of the ¹O₂ addition to alkenes bearing chiral auxiliaries might open up promising prospects in the preparation of optically active building blocks for asymmetric synthesis. The majority of attempts reported so far has concentrated on the incorporation of an α,β-unsaturated carboxylic acid unit into a chiral environment, though with only low or moderate diastereoselectivity.^{58,68,69} Three of the most satisfying examples concerning the diastereoselectivity of the ¹O₂ addition to optically active tiglic acid derivatives **24** and **26** are outlined in Scheme 31.12.⁷⁰ In the early 2000s, Adam et al. reported a high chiral-auxiliary-controlled diastereoselectivity in the ¹O₂ addition to oxazolidine-substituted alkenes **28** (Scheme 31.12).⁷¹ It is worth mentioning that the observed diastereoselectivity was attributed to electronic attraction through hydrogen bonding between the negatively charged pendant oxygen and the NH group of the urea functionality. This hydrogen bonding directivity will be presented in detail in the following section.

31.3.2.1.2 Alkenes Bearing Adjacent Stereogenic Centers

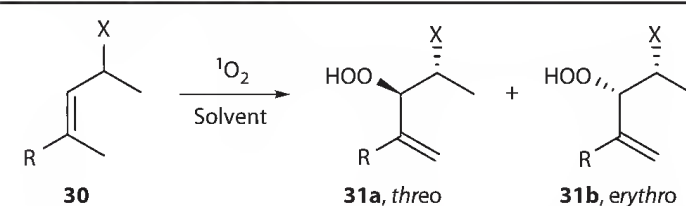

Over the last 40 years, a variety of allylic substituents has been tested for their directing properties in the ¹O₂-addition to chiral acyclic alkenes.⁶⁸ The substituents can be classified into two classes with respect to their tendency to direct the ¹O₂ attack either with *erythro* or *threo* diastereoselectivity.

It is generally conceded that chiral alkenes bearing on the asymmetric-adjacent carbon atom other than the hydroxyl or amino functionality afford preferentially *erythro* allylic hydroperoxides.^{72,73}

SCHEME 31.12 Diastereoselection in the chiral-auxiliary-controlled ¹O₂ ene reaction.

Some typical examples are listed in Table 31.1 (entries 1–9). This high diastereoselectivity is explained in terms of the reversible formation of perepoxide-like diastereomeric exciplexes E₁ and E₂ (Scheme 31.13). Notably, the preferable conformational arrangement in these exciplexes is fixed by 1,3-allylic strain.⁷⁴ For chiral alkenes without functional groups containing heteroatom at the stereogenic center (X = *t*-Bu or Ph), the observed *erythro* selectivity is attributed to the operating steric repulsion between the X substituent and the incoming oxygen in the *threo*-configured exciplex E₂. In the case of chiral alkenes, which bear an electron-accepting substituent on the stereogenic center (X = NHBoc, NBoc₂, Cl, Br, SO₂Ph, COOH or COOEt), the electrostatic repulsion between the X substituent and the incoming oxygen in the *threo*-configured exciplex E₂ appears to be primarily responsible for the high preference of the *erythro* ene product.

On the other hand, Adam et al. have examined the diastereoselectivity of the ¹O₂-mediated allylic oxidation with chiral allylic alcohols⁷⁵ or amines^{72b,76} and found a high *threo* selectivity in nonpolar solvents (Table 31.1, entries 10 and 12). When the reaction solvent is methanol-*d*₄, a substantial drop in *threo* selectivity is observed in both cases (Table 31.1, entries 11 and 13). Moreover, an important increase of *erythro* selectivity has been achieved either by protection of the allylic hydroxyl or by acylation of the amino group (for the latter, see the entries 3 and 4 in Table 31.1). The requirement of a substituent in the *cis* position relative to the hydroxyalkyl group in order to induce 1,3-allylic strain was also demonstrated; this strain proved to be essential for the observation of a high *threo* selectivity.⁷⁵ The proposed mechanistic rationalization, for the aforementioned results, is based on the development of a hydrogen bond (in the *threo*-configured exciplex E₂, Scheme 31.13) between the partially negatively charged ¹O₂ and the hydroxyl or amino group.^{72b,75,76} This type of stabilizing electronic interaction is ineffective in the *erythro*-configured exciplex E₁ (Scheme 31.13) due to the presence of unfavorable 1,3-allylic strain.

**SCHEME 31.13** Newman projections views of possible exciplexes for the $^1\text{O}_2$ ene reaction of alkenes bearing adjacent stereogenic centers.

Additional studies revealed that 1,2-allylic strain (caused by a *geminal* substituent near the stereogenic center) does not play a crucial role in the hydroxyl group directed $^1\text{O}_2$ ene reaction.⁷⁷ It was also reported that electron-poor allylic alcohols react with $^1\text{O}_2$ in a *threo*-selective manner, regardless of whether the hydroxyl functionality is free or masked by alkyl or silyl groups.⁷⁸ This diastereoselectivity was attributed to stereoelectronic effects. Soon after, it was shown that a hydroxyl group at a stereogenic center in homoallylic position is incapable of controlling the stereochemical outcome in photo-oxidations.⁷⁹ In the same year, Dussault and Schultz examined the $^1\text{O}_2$ additions to chiral 2-alkenols and found that the diastereoselectivity of hydroxyl-directed oxidations decreased by the presence of an ester (adjacent to the stereogenic center) or an hydroxyl/alkyloxy group (in the 2 position relative to the stereogenic center). This decrease has been rationalized considering the development of a competitive intramolecular hydrogen bond and steric effects.⁸⁰

SCHEME 31.15 Diastereoselection in the $^1\text{O}_2$ ene reaction of cyclohexadienes **38**.

diastereoselectivity of substituted 7-isopropylidenenorbornene was found to be sensitive to the electronic interactions between the incoming enophile and electron-donating/withdrawing substituents on these substrates.⁸⁷ Notably, Linker and Fröhlich observed high diastereoselectivities in the photooxidation of cyclohexadienes **38** to afford hydroperoxides **39a,b** (Scheme 31.15).⁸⁸ These selectivities have been rationalized in terms of a combination of electronic and steric interactions. Similar interactions also determine the diastereoselectivity of the photooxidations of α -cyclogeranyl derivatives.⁸⁹

31.3.3 Stereoselectivity

The first detailed stereochemical investigation of the $^1\text{O}_2$ -mediated allylic oxidation was reported in 1980.⁹⁰ Recently, the stereochemistry of this reaction was reinvestigated by a more informative substrate. In this study, the addition of $^1\text{O}_2$ to (*S,S*)-*cis*-1,4-diphenyl-2-butene-1,4-*d*₂ (**40**, Scheme 31.16) has been examined.⁹¹ It is worth mentioning that this alkene has three distinctive characteristics: (1) chirality at the two reactive allylic carbons, (2) different substituents at both allylic carbons, and (3) a C_2 symmetry axis resulting such that the two faces of the double bond are equivalent.

The sensitized oxidations of **40** were run in CHCl_3 , $(\text{CH}_3)_2\text{CO}$, CH_3CN , and MeOH . In all cases, the allylic hydroperoxides **41a** and **41b** (Scheme 31.16) were obtained in high yield. The mechanistic possibilities, considering the approach of $^1\text{O}_2$ from only one of the two equivalent faces of the double bond, are presented in Scheme 31.16. In particular, approach of $^1\text{O}_2$ from the top face will abstract hydrogen and will form a new *S* stereogenic center (at the allylic hydroperoxide **41a**). On the other hand, abstraction of deuterium will form a new *R* stereogenic center (at the allylic hydroperoxide **41b**). The ratio of

SCHEME 31.16 Stereoselection in the $^1\text{O}_2$ ene reaction of chiral alkene **40**. (Reprinted with permission Alberti, M.N., Vassilikogiannakis, G., and Orfanopoulos, M., Stereochemistry of the singlet oxygenation of simple alkenes: A stereospecific transformation, *Org. Lett.*, 10, 3997–4000, 2008. Copyright 2010 American Chemical Society.)

products **41a:41b** (which is proportional to the primary isotope effect) was determined by the ^1H NMR integration of their vinylic signals. A primary isotope effect $k_{\text{H}}/k_{\text{D}} = 1.20 \pm 0.05$ was found when CHCl_3 , $(\text{CH}_3)_2\text{CO}$, CH_3CN , and MeOH were used as the reaction solvents. The diastereomeric ratio S/R of **41** was measured by the ^1H NMR integration of the diastereotopic benzylic protons of **41a** and **41b**. In CHCl_3 , the chirality of the new stereogenic centers S/R was found to be 1.23 ± 0.05 . Identical diastereomeric ratios were measured when $(\text{CH}_3)_2\text{CO}$, CH_3CN , and MeOH were used as the reaction solvents. Herein, it is important to emphasize the correspondence of the isotopic $k_{\text{H}}/k_{\text{D}}$ ratio of 1.20 with the diastereomeric S/R ratio of 1.23.

The aforementioned findings are best rationalized by involving the formation of a perepoxide (PE, Scheme 31.16) as an intermediate. H atom abstraction from PE and subsequent C–O bond formation leads to the formation of the new S stereogenic center with deuterium remaining in the product double bond. In a similar manner, D atom abstraction from PE leads to the formation of the new R stereogenic center with hydrogen remaining in the product double bond. These results confirm that the $^1\text{O}_2$ -mediated allylic oxidation of simple olefins is a highly stereospecific suprafacial process, independent of solvent polarity. Last but not least, the observation of an isotope effect, which matched exactly the diastereomeric ratio, makes it difficult to argue that the title reaction proceeds through an open biradical or dipolar intermediate.

31.4 Photooxidation in Confined Media

A great deal of attention has been devoted in recent years to influence the selectivity in photochemical reactions. The use of molecular microreactors seems to be a promising method to pursue this issue.⁹² Molecular microreactors refer to heterogeneous, organized, and constrained systems that provide cavities and/or surfaces to accommodate the substrate molecules and allow photochemical reactions to occur. Generally speaking, the interactions of the substrate with these media may direct the photochemical reaction to the desired product(s). Considering the $^1\text{O}_2$ -mediated allylic oxidation, the dye-supported Y-type zeolites have been extensively used as media, mainly by the research teams of Ramamurthy,⁹³ Clennan,⁹⁴ and Stratakis.⁹⁵ It is instructive to note that the study of the title reaction using alternative molecular microreactors, such as pentasil zeolites,⁹⁶ Nafion- Na^+ membranes,⁹⁷ surfactant vesicles,⁹⁸ polystyrene beads,⁹⁹ mesoporous silica SBA-15,¹⁰⁰ octa acid capsules,¹⁰¹ and IRA-resin,¹⁰² has also received considerable attention in recent years.

32.1 Introduction

Molecular oxygen (O_2) was independently discovered by Joseph Priestly and Carl Wilhelm Scheele in the late eighteenth century [1]. It can react at sulfur and with nearly every other element under a variety of conditions to produce oxides [2]. The first photooxygenations (photochemically initiated incorporation of oxygen into molecules) were reported as early as 1867 [3], well before the electronic character of oxygen was understood. It was not until 1924 that G. N. Lewis attributed the paramagnetism of oxygen to a structure with unpaired electrons [4,5]. This discovery was rapidly followed in 1928 by R. S. Mulliken's suggestion that the electronic configuration of oxygen, $[(\sigma_{1s})^2(\sigma_{1s}^*)^2(\sigma_{2s})^2(\sigma_{2s}^*)^2(\sigma_{2p})^2(\pi_{2p})^4(\pi_{2p}^*)^2]$, leads to three states in order of increasing energy, $^3\Sigma_g^-$, $^1\Delta_g$, and $^1\Sigma_g^+$ since the π_{2p}^* orbital is only half filled [6,7]. Finally, it was not until the early 1930s that Kautsky and coworkers [8,9] reported that the metastable $^1\Delta_g$ state of oxygen was involved in many of these photooxygenations. It is now well appreciated that photooxygenations can involve both the ground-state triplet, $^3\Sigma_g^-$, and the metastable $^1\Delta_g$ oxygen. On the other hand, the higher energy $^1\Sigma_g^+$ state at 37 kcal/mol above the $^3\Sigma_g^-$ ground state is vibrationally and quantitatively deactivated to the lower energy $^1\Delta_g$ state (22.5 kcal/mol) and does not have a sufficient lifetime to chemically react with organic substrates [10].

Photooxygenations of sulfur compounds have been most often conducted using photosensitization. This technique employs sensitizers such as Rose Bengal, methylene blue, tetraphenylporphine, protoporphyrin IX dimethyl ester, 2,4,6-triphenylpyrylium tetrafluoroborate, and N-methylquinolinium tetrafluoroborate (Figure 32.1) that absorb in the visible where competitive absorption by substrate does not occur [11]. These sensitizers can induce photooxygenation of sulfur compounds by either Type I or Type II processes [12]. These two reaction types differ in the order in which the substrate and oxygen appear on the reaction surface and in the identity of the reactive intermediate produced by interaction with the sensitizer. In the Type I reaction, the substrate is activated by either electron transfer or hydrogen transfer to the sensitizer and then subsequently

FIGURE 32.1 Photooxygenation sensitizers.

reacts with oxygen. In the Type II reaction, oxygen is initially activated by energy transfer from the sensitizer to form singlet oxygen, which then reacts with the substrate.

32.2 Type II Sulfur Photooxygenations

32.2.1 Sulfides

Type II photooxygenations of dialkyl sulfides were first reported by Schenck and Krausch in 1962 as a new synthetic method for the formation of sulfoxides [13]. The reaction has subsequently proven to be generally applicable to a wide range of sulfides including dialkyl- [14,15], aryl alkyl- [16], and cyclic sulfides [17,18] as shown in Figure 32.2. For example, photooxygenation of 2-methylthiirane, **4**, in methylene chloride which produces no major product at room temperature nevertheless reacts to give the *cis*- and *trans*-sulfoxides at -20°C along with a small amount of polymeric material [17]. These products, however, polymerized upon warming the reaction mixture to room temperature. This report is consistent with earlier work of Ando and coworkers [19,20], who reported polymerizations of these sensitive small-ring sulfoxides. These workers also reported that addition of dimethyl sulfoxide allowed isolation of the sulfoxide at room temperature and resulted in concomitant formation of dimethyl sulfone. A temperature effect was also observed during photooxygenation of pentamethylsulfide, **3** [18]. In this case, the sulfoxide is the exclusive product of the reaction at room temperature but approximately 30% of the sulfone was also observed at -80°C .

Small amounts of by-products are also formed in the reactions of **1**–**4** and in the reactions of many sulfides with singlet oxygen. For example, photooxygenation of di-*n*-butyl sulfide, **1**, to 98% conversion with 2.6×10^{-4} M Rose Bengal produces approximately 7% of dibutyl disulfide in addition to the sulfoxide (87%) and sulfone (6%) [14]. Photooxygenation of thioanisole, **2**, in methanol produces the sulfoxide as the major product (85%) along with minor amounts of the sulfone (5%), diphenyl disulfide (1%), methyl benzenesulfonate (4%), and benzene sulfinate (3%) [16]. In some unusual cases, cleavage products become major components of the reaction mixtures. (Figure 32.3) For example, the combined yield of the anticipated sulfoxide and sulfone in the photooxygenations of 9-ethylthiofluorenone, **5** [21], and

FIGURE 32.2 Sulfide photooxygenation products.

dibenzyl sulfide, **6** [22], are less than 50% and the reaction mixtures are dominated by carbon–sulfur bond cleavage products. (Figure 32.3) There are also sulfides that do not react or react extremely slowly with singlet oxygen. These appear to fall into three categories; (1) sulfides that are sterically shielded; (2) sulfides that are electronically deactivated; and (3) sulfides that have appended reactive functional groups that preferentially react with singlet oxygen. Diphenyl sulfide and di-*tert*-butyl sulfide both deactivate singlet oxygen at rates more than 400–500 times slower than diethyl sulfide, and the sulfoxides are only formed upon extended irradiations [23]. This can be attributed to a steric effect in di-*tert*-butyl sulfide, however, Albini and coworkers [23] have pointed out that the low reactivity of diphenyl—in comparison to diethyl sulfide—must be due in part to electronic effects. The HOMO on diethyl sulfide is localized for the most part on sulfur while in the C_2 symmetric diphenyl sulfide [24], it is significantly delocalized onto the phenyl rings reducing reactivity at sulfur [25]. The HOMO on thiophenes in general are more delocalized and in thiophene itself is completely localized on the π -system [25] and as a consequence, *cis*- or *trans*-3-styrylthiophenes, **7**, do not react with singlet oxygen even after 10 h of irradiation [26]. On the other hand, reactions of singlet oxygen with more highly substituted thiophenes, such as 2,5-dimethylthiophene [27], do occur but prefer $[4 + 2]$ cycloadditions to form thiozonides rather than reaction at sulfur. The less substituted *trans*-2-styrylthiophene, **8**, also reacts, but in this case primarily by the thiophene ring functioning as part of a diene acceptor in a $[4 + 2]$ cycloaddition rather than to form the thiozonide [28]. The electronic deactivation of vinyl sulfides also preclude sulfoxide formation and $[2 + 2]$ cycloadditions are often observed (e.g., **9**) [29–32]. Thioanisole, **2**, reacts readily with singlet oxygen but the more reactive tetrasubstituted double bond in **10** competitively inhibits this reaction and allylic hydroperoxides are the observed products [33,34].

32.2.2 Mechanism of Sulfoxide Formation

The current understanding of the mechanism of sulfoxide formation is depicted in Figure 32.4 [35–39]. Two important features of this mechanism are (1) the presence of two intermediates on the reaction surface on the way to the sulfoxide product, the persulfoxide, **PS**, and the S-hydroperoxy sulfonium ylide, **SY**; and (2) the decomposition of the **PS** via a physical quenching step, k_q [40]. Evidence for the existence of the intermediates was obtained by detailed kinetic studies of reaction mixtures containing diphenyl sulfoxide, Ph_2SO , and diphenyl sulfide, Ph_2S [41]. Neither Ph_2SO nor Ph_2S reacts appreciably with singlet oxygen; however, under these co-photooxygenation conditions, they are readily converted to diphenyl

FIGURE 32.4 Mechanism of sulfoxide formation.

($k_q = 0$), the chemical rate constant for sulfoxide formation, k_r , should be equal to $2k_T$ since disappearance of one singlet oxygen produces two sulfoxide molecules. Experimentally, it has been shown for many sulfides that physical quenching, k_q , dominates the interactions with singlet oxygen. For example, in the reaction of diethyl sulfide, 95% of the singlet oxygen is deactivated to form triplet oxygen and only 5% is incorporated into product. Addition of Ph_2S to sulfide, photooxygenation reactions does not improve the efficiencies of the reactions since k_{PhS} does not compete with k_q . On the other hand, addition of Ph_2SO does improve the efficiency by converting PS to the sulfoxide, k_{SO} , before it has a chance to decompose by the physical quenching channel, k_q .

The chemistry and properties of the persulfide intermediate, PS, are well established. However, whether or not it has been isolated is a matter of debate. Its direct observation has been claimed in an infrared spectroscopy experiment by irradiation at 13 K into an oxygen sulfide charge-transfer band [43]. The presence of the two required nonequivalent oxygen atoms was confirmed by observing a splitting in the assigned S–O stretch when ^{16}O – ^{18}O was used in the experiment. Jensen, however, has questioned this assignment pointing out the poor agreement with the MP2/6-31G* derived vibrational frequencies [44]. Other sulfur bis-oxides would also be expected to have nonequivalent oxygens, and one such species, the thiadioxirane, (TD in Figure 32.5), has calculated vibrational frequencies much closer to the experimentally observed values.

FIGURE 32.5 The thiadioxirane, TD, and two perspectives of the MP2/6-31G* minimized dimethyl persulfide.

A minimum energy structure corresponding to the **PS** has been located with several different computational models [45–47]. Two different views of the MP2/6-31G* minimized dimethyl persulfoxide are shown in Figure 32.5. The **PS** has C_s symmetry with a nearly tetrahedral-like geometry with a $>C-S-C$ angle of 99.71° , and $>C-S-O$ angles of 100.39° . The $O-O$ bond length is 1.43\AA and $S-O$ bond length is 1.65\AA but shortens to 1.59\AA at the MP2/6-311+G(2df) level of theory. The most striking structural feature is the fact that the $O-O$ bond bisects the $C-S-C$ angle despite the close approach (2.10\AA) to a hydrogen atom on each methyl group. The transition state for formation of the persulfoxide involving donation of the sulfur lone pair into the empty π_g orbital on singlet oxygen has also been located with both the MP2/6-31G(d) and MP2/6-311+G(2df) computational models. This transition state bears a remarkable similarity to the persulfoxide, suggesting a small barrier for dissociation [46].

The Mulliken charges on the **PS** indicate a sulfonium-like sulfur and build up of negative charge on both oxygens. The nucleophilic character of the pendant oxygen is supported experimentally by a Hammett reaction constant of 0.252 in the trapping of dimethyl persulfoxide with substituted diaryl sulfoxides [48]. Sulfoxides are not the only molecules that can accept an oxygen from a persulfoxide. Electrophilic trapping agents such as phosphites [49], sulfenate esters [50], sulfinate esters [51], and sulfinamides [51] can also remove an oxygen from the **PS**. An interesting example of the nucleophilic reaction of a **PS** was observed during the photooxygenation of [1-(ethylthio)-1-methylethoxy]trimethylsilane, **11** [52] (Figure 32.6). In this reaction, the pendant oxygen in the **PS** attacks at the silicon to give a six-membered ring intermediate that decomposes by a methyl migration to give a silicate product, **12**. The formation of the six-membered ring intermediate was detected by observing increasing amounts of the sulfoxide, **13**, with increasing concentrations of **11**. The silicate **12**, on the other hand, does not react with sulfide, **11**.

In Figure 32.4, the **PS** is also shown (k_x) abstracting a α -hydrogen to produce the S-hydroperoxy sulfonium ylide, **SY**. Several groups [53–58] have suggested this ylide as an intermediate and it has been located as a viable species using a variety of different computational models [49,59–61]. Dimethyl S-hydroperoxysulfonium ylide exists in several conformations but the most stable is the rotomer in which the peroxy hydrogen is located 3.15\AA above the CH_2 group [46]. This is the ideal geometry for the subsequent reaction that involves attack of the starting material on the peroxy linkage, delivery of the hydroperoxy hydrogen back to the α -carbon, and formation of two sulfoxide products. At the MP2/6-311+G(2df) level of theory, dimethyl S-hydroperoxysulfonium ylide has a short 1.62\AA CH_2-S bond indicative of substantial double bond character and a long 1.85\AA $S-O$ bond similar to that found in sulfuranes. G2-extrapolated CCSD(T)/6-311+G(2df) energies place the **SY** 6 kcal/mol lower in energy than the **PS**.

A transition state has been located for interconversion of dimethyl persulfoxide to dimethylhydroperoxysulfonium ylide with the CCSD(T)/6-31G(d) computational model. It is 6 kcal/mol above the **PS** and is characterized by $S-O$ and $C-H$ bond lengths of 2.02\AA and 1.44\AA , respectively. A thiadioxirane, **TD**, (Figure 32.5) has also been located computationally [46]. However, the barrier for its formation from

FIGURE 32.6 Trapping of a persulfoxide by silicate formation.

the **PS** is considerably larger than the barrier for formation of **SY** and it is not likely to be an important intermediate on the reaction path to the sulfoxide.

Experimental evidence for the interconversion of the **PS** and **SY** is also compelling. For example, photooxygenations of 1,3-dithianes **14** and **15**, occur with substantial isotope effects at C₂ to give a sulfoxide as the exclusive product [62]. (Figure 32.7) In addition, the isolation of an unusual dimer during photooxygenation of 1,3-dithiane **16** is most easily rationalized by invoking an intramolecular electron transfer in the hydroperoxysulfonium ion intermediate to give a captodatively stabilized radical, **17**. Formation of 1,2-dithiolane, **18**, and a 1,2-dithiolane-oxide, **19**, provide supporting evidence for this mechanism. A smaller, yet substantial isotope effect, in the photooxygenation of 2,2,6,6-tetra-deuterio-1,4-dithiane, **20**, provides evidence for the generality of **SY** formation even in simple sulfides with less acidic α -hydrogens [63]. (Figure 32.7) An independent confirmation of **SY** formation was also provided by photooxygenation of β -chloroethyl ethyl sulfide, **21**, that formed an elimination product by β -elimination in a hydroperoxysulfonium ion intermediate [64].

Persulfoxide will also undergo several other reactions not depicted in Figure 32.4. For example, persulfoxides are susceptible to attack by nucleophiles at the sulfonium ion center. Dialkyl sulfides are in general too sterically bulky to function as nucleophiles in this reaction. An exception to this generalization, however, occurs in the photooxygenation of thietane, **22** [65]. (Figure 32.8) Thietane **22** and a

FIGURE 32.7 Evidence for S-Hydroperoxysulfonium ylide formation.

FIGURE 32.8 Mechanism of photooxygenation of thietane.

typical sulfide such as diethyl sulfide quench the emission of singlet oxygen at approximately the same rate, $(3.13 \pm 0.22) \times 10^7 \text{ M}^{-1}\text{s}^{-1}$ and $(3.04 \pm 0.52) \times 10^7 \text{ M}^{-1}\text{s}^{-1}$, respectively, suggesting that in both cases the initial interaction with singlet oxygen leads to a **PS**. However, under conditions where all the singlet oxygen is captured, the extent of product formation is dependent upon the thietane concentration but independent of diethyl sulfide concentration. This observation can easily be accommodated by suggesting that thietane attacks the **PS** to form a sulfurane intermediate, **23**, and competes with chemically unproductive physical quenching, k_q . The straight line observed when plotting the inverse of the chemical rate constant of product formation, $1/k_p$, versus the inverse of the sulfide concentration, $1/[22]$, is consistent with this mechanism. The intercept/slope ratio in this plot, k_x/k_q , reveals that addition of **22** to the **PS** is six times faster than decomposition of the persulfoxide via the physical quenching route, k_q . The unusual behavior of **22** in comparison to other sulfides is a result of the smaller C–S–C angle of 78° , compared to the MP2/6-31G(d) C–S–C angle in dimethyl sulfide of 98.6° , which allows for unencumbered approach to the sulfonium-like sulfur in the **PS**. The identity of an electrophilic intermediate trapped in this reaction has not been conclusively identified (*vide infra*); however, a hydroperoxy sulfonium ylide, **SY**, or thiadioxirane, **TD** are likely candidates.

Oxygen nucleophiles can also attack at the sulfonium center in the **PS**. For example, the attack of a hydroxyl group at the sulfonium sulfur of a **PS** is responsible for the formations of unusual oxidative elimination products during the photooxygenations of a series of γ -hydroxyalkyl aryl sulfides, **24** [66,67]. (Figure 32.9) The addition of the hydroxyl group to the sulfonium sulfur generates diastereomeric sulfuranes that decompose by intramolecular hydrogen abstraction to form a novel hydrated sulfone that loses water to form the unusual elimination products. (Figure 32.9) When ^{17}O labeled starting material, **24**– ^{17}O , was used, the label quantitatively migrated to the sulfur consistent with this mechanism. In addition, the ^{17}O was only found in the alkenes and not in the sulfoxide or sulfone **25** formed by the normal sulfide photooxygenation mechanism shown in Figure 32.4.

Persulfoxides can also function as hydrogen bond acceptors [68]. Additions of as little as 1.5% methanol to benzene has the effect of increasing the rate of photooxygenation of diethyl sulfide by a factor of 10 [69]. This is consistent with hydrogen bonding competitively inhibiting the decomposition of diethyl persulfoxide via the physical quenching reaction channel, k_q . (Figure 32.4) In their 1983 seminal paper discussing the mechanism of sulfide photooxygenation, Foote and coworkers reported that only a single intermediate was necessary to fit the kinetic data in methanol [40]. In that paper they speculated that

FIGURE 32.9 Addition of an oxygen nucleophile to a persulfoxide.

this result was either consistent with hydrogen bonding to the pendant oxygen of the PS or nucleophilic addition to form a sulfurane intermediate. In support of the hydrogen bonding hypothesis, Albini and coworkers have subsequently shown that the rate constants for photooxygenation of diethyl sulfide are linearly correlated to the acid strengths of additives in the reaction [68]. Sulfurane formation, however, certainly occurs as demonstrated by the intramolecular addition shown in Figure 32.9. However, sulfurane formation cannot be responsible for the increased efficiency in the reaction and it is not the kinetically important intermediate formed in protic nucleophilic solvents. This can be deduced by examining the kinetic results depicted in Figure 32.10 from the study of a series of sulfides connected to a hydroxy group with variable length alkyl tethers [70]. The ratio of the physical quenching and chemical reaction rate constants, k_q/k_r , is the smallest for the sulfide that can form a five-membered ring sulfurane (circled value in Figure 32.10). This is consistent with a considerable amount of evidence that five-membered ring bidentate ligands can provide more stabilization to hypervalent species, including sulfuranes, than can ligands that form other ring sizes [71]. However, despite the favorable intramolecular entropic effect and the enthalpic effect of forming a five-membered ring, physical quenching still dominates the reactivity by more than a factor of 30, suggesting that another factor (hydrogen bonding) is responsible for the complete inhibition of physical quenching in protic solvents.

32.2.3 Mechanism of Sulfone Formation

In a large number of sulfide photooxygenations, the sulfoxide product is accompanied by formation of a small amount of sulfone. It is unlikely that the sulfones are formed directly by reactions of sulfoxides with singlet oxygen. Sawaki and Ogata [48] have reported that diphenyl sulfoxide reacts approximately 50 times slower than dimethyl sulfide with singlet oxygen. Trapping the PS intermediate by adventitious sulfoxide (k_{SO} in Figure 32.4), however, is a viable pathway to form sulfones. (Figure 32.4)

Careful examination of the photooxygenation of di-*n*-butyl sulfide in benzene to very low conversions followed by extrapolation back to time zero reveals a sulfone/sulfoxide ratio of approximately $\frac{1}{2}$ [72]. This suggests that trapping, k_{SO} in Figure 32.4, cannot be the only mechanism for sulfone formation. Oxygen-18 tracer studies indicate that both oxygens in the “early formed” sulfone product come from the same oxygen molecule. This data suggest that a thiadioxirane, TD, (Figure 32.5) is a potential precursor. However, a detailed theoretical study of the thiadioxirane was unable to locate a path to sulfone [73]. Instead a mechanism involving the hydroperoxy sulfonium ylide, SY, is currently thought to

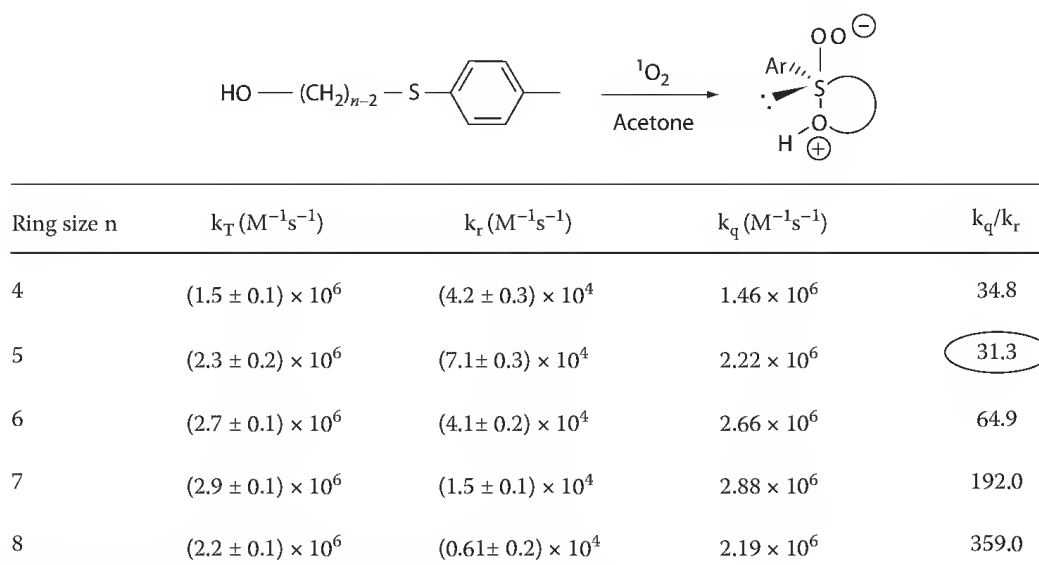

FIGURE 32.10 Kinetic behavior of hydroxy tethered sulfides.

FIGURE 32.11 A mechanism for sulfone formation.

be responsible for sulfone formation in the early part of photooxygenation reactions [61] (Figure 32.11). This mechanism is supported by observation of hydrogen–deuterium exchange during sulfone formation and a kinetic isotope effect, k_H/k_D , of 2–4 in a variety of different solvents [61]. Theoretical calculations (RHF-PM3) also suggest that this pathway is energetically accessible.

32.2.4 Mechanism of Cleavage Product Formation

The cleavage of carbon–sulfur bonds during photooxygenations of organic sulfides was first reported by Corey and Ouannes in 1976 [54]. Two different mechanisms to account for the cleavage reactions have been proposed, as shown in Figure 32.12. In both mechanisms, an α -hydroperoxy sulfide, **HY**, is a key intermediate. In one mechanism, the reaction occurs via the persulfoxide, **PS** (pathway **a** in Figure 32.12) [74], and in the second mechanism the persulfoxide is bypassed completely (pathway **b** in Figure 32.12) [22] and the α -hydroperoxy sulfide is instead formed via a radical pair, **A**. The α -hydroperoxy sulfide, **HY**, can then either decompose by bimolecular reduction with the sulfide (pathway **d** in Figure 32.12) or in a unimolecular process (pathway **c** in Figure 32.12). The electronic character of the sulfide dictates the choice of the intramolecular pathway **c** or intermolecular pathway **d** [74]. For example, the electron-withdrawing group in $\text{EtSCH}_2\text{CO}_2\text{Et}$ destabilizes the three-member oxothiiranium ion and directs the reaction along the intermolecular pathway, **d**. On the other hand, the electron-donating $-\text{SEt}$ group in EtSCH_2SEt promotes the intramolecular process and thiosulfinate product, EtS(O)SEt rather than EtSSeEt is formed exclusively.

FIGURE 32.12 Mechanism of carbon–sulfur bond cleavage.

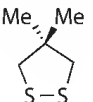

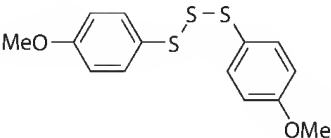

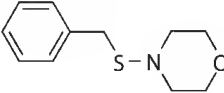

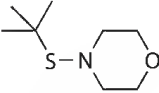

32.2.5 Disulfides, Sulfenate Esters, and Sulfenamides

Photooxygenations of sulfenic acid derivatives have not received the same level of investigative interest as dialkyl sulfides. In general, the reactivity with singlet oxygen decreases in the order sulfides > disulfides > trisulfides. (Table 32.1) Furthermore, as the electronegativity of the atom attached to sulfur increases, the rate constants for removal of singlet oxygen from solution decrease. (i.e., dialkyl sulfides > sulfenamides > sulfenate esters) Steric effects play a dominant role in determination of the rate constants for reaction of singlet oxygen with dialkyl sulfides and sulfenamides. On the other hand, steric bulk of the substituents do not control the reactivity of disulfides, and di-*tert*-butyl disulfide actually deactivates singlet oxygen more than four times more efficiently than diethyl disulfide.

Disulfides **26** and **27** (Figure 32.13) react with singlet oxygen to give both thiosulfonates, RS(O)SR, and thiosulfonates, RS(O)₂R [75–78]. Disulfide **26** has the small methyl group appended and disulfide **27** has a constrained –CH₂SSCH₂– dihedral angle allowing unfettered close approach of singlet oxygen to the disulfide linkage to form a persulfoxide, PS, intermediate. Formation of the PS in the reaction with **27** also replaces a destabilizing electron lone-pair–lone-pair interaction with a less destabilizing bonding-pair–lone-pair electronic interaction. However, many disulfides only physically deactivate singlet oxygen without giving any product [79]. A plot of log *k_T* versus IP_{eV} for these disulfides is linear (Figure 32.14) consistent with a charge-transfer mechanism for deactivation of singlet oxygen. The deviation of both disulfides **26** and **27** from the linear regression line reflects both deactivation of singlet oxygen by chemical reaction and by decomposition of the persulfoxide to disulfide and triplet oxygen.

The remarkable solvent effect observed during photooxygenation of **27** is a general phenomenon for disulfides and is potentially synthetically useful [80]. The mechanism of this process is not completely understood. However, an oxygen isotopic tracer study has revealed that the two oxygens in the sulfonate product are from the same oxygen molecule [81]. This result differentiates disulfides from every other sulfenic acid derivative and implicates a unique photooxygenation mechanism. It is tempting to suggest that the reaction proceeds by insertion of singlet oxygen into the sulfur–sulfur bond, perhaps via the persulfinate intermediate, to give a dithioperoxide, RSOOSR, that would be expected to decompose to a sulfenate acid radical, RSO•, that would be expected to dimerize to give the thiosulfonate product.

FIGURE 32.13 Sulfenic acid derivative photooxygenation products.

Akasaka and Ando have reported that triazolinediones insert into the sulfur–sulfur bond of disulfides to give the nitrogen analogue of the dithioperoxide [82].

Ethyl phenylsulfonate ester, **28**, reacts with singlet oxygen to give both the sulfinate and sulfonate ester product [50]. At low conversions, the sulfinate ester was the exclusive product consistent with it, acting as the precursor of the sulfonate ester. A careful kinetic study of this reaction reveals that it is 100% efficient and that only one intermediate is kinetically required on the reaction surface. The lack of physical quenching is in stark contrast to the reactions of sulfides in which deactivation of singlet oxygen to form triplet oxygen is often the dominant process. Sulfenamides, **29** and **30**, are in many ways intermediate in reactivity between dialkyl sulfides and sulfonate esters [83,84]. Like sulfides, they react via two intermediates, but **29**, like sulfonate esters, does not physically deactivate singlet oxygen

FIGURE 32.14 Log (k_T) versus photoelectron spectroscopy ionization potentials of disulfides. **a**-di-(1-adamantyl) disulfide; **b**-di-*tert*-butyl disulfide; **c**-1,2-dithiacyclohexane; **d**-di-*iso*-propyl disulfide; **e**-diethyl disulfide; **f**-27; **g**-26.

and it chemically reacts with high efficiency. However, *tert*-Butyl 4-morpholinyl sulfide does physically quench singlet oxygen in 45%–55% of its encounters.

The reactions of singlet oxygen with N-monosubstituted sulfenamides, such as **31**, are far more complicated than reactions of N,N'-disubstituted sulfenamides and give poor mass balances [59]. Co-photooxygenations of **31** with norbornene led to the formation of norbornene oxide. Epoxidation was not observed if norbornene was added after completion of the photooxygenation except in the presence of N-*tert*-butylphenyl sulfenamide (PhSNH-*t*-butyl) [59]. This suggests the intriguing possibility that an iminopersulfonic acid (IPS in Figure 32.13) is formed in the reaction. Indeed, computational studies with the MP2/6-31G* model were successful in locating an iminopersulfonic acid and established that its minimum energy conformation has an internal hydrogen bond reminiscent of the structures of peracids.

32.2.6 Organometallic Sulfides

Metal-bound thiolate photooxygenations have only been investigated for approximately 15 years. They are of interest to bioinorganic chemists because of numerous reports of oxidative damage to sulfur-rich metalloenzymes. Convincing evidence that this damage occurs in several metalloenzymes by oxidation at sulfur in S-bound cysteine has been reported [85]. Studies of the reactions of singlet oxygen with transition metal thiolates are complicated by reactivity with triplet oxygen that can result in formation of polymetallic complexes [86]. Nevertheless, reactions of singlet oxygen with several organometallic thiolates with sterically shielded sulfurs and/or rigid ligands that stabilize the systems from unwanted side reactions have been examined [86–92] (Figure 32.15). Both persulfoxide and thiadioxirane intermediates have been suggested in these reactions [86]. However, trapping of the persulfoxide with phosphite in the photooxygenation of the Co(III) thiolato complex shown in Figure 32.15 was unsuccessful [93]. It is clear that much work needs to be done to establish the mechanisms of these interesting reactions.

32.2.7 Sulfide Photooxygenations in Heterogeneous Media

Sulfide photooxygenations have been conducted in both micelles [94] and on clay surfaces [95]. However, the most detailed work has been in sensitizer doped zeolite-Y [96]. Zeolites are crystalline porous inorganic solids with long-range order that are better known as molecular sieves. Zeolite-Y is a aluminosilicate characterized by a network of silicon and aluminum tetrahedra with a typical unit cell composition of $M_{56}(AlO_2)_{56}(SiO_2)_{136} \cdot 253(H_2O)$. Zeolite-Y (Figure 32.16) has local T_d symmetry with four

FIGURE 32.15 Photooxygenations of organometallic thiolates.

FIGURE 32.16 Conventional stick drawing of zeolite-Y with oxygen bridges represented by lines between the vertices.

FIGURE 32.17 A comparison of solution and intrazeolite photooxygenations of sulfides.

tetrahedrally disposed 7.4 Å diameter windows surrounding a larger 13 Å supercage. The metal ions, M, are needed to provide electrical neutrality and balance the charge on the framework aluminum atoms and their identity determines the void volume of a supercage that is available for substrate intercalation. These cations can also be exchanged in order to modify the electrostatic potential experienced by substrates within the supercage.

The intrazeolite photooxygenations shown in Figure 32.17 were conducted by irradiations of hexane slurries of zeolite-Y doped with both methylene blue (Figure 32.1) and the sulfide substrates [97,98]. The loading level of methylene blue was on average one molecule per every 100 supercages and the loading level of the sulfide was much higher at approximately 1 molecule per supercage. These reactions occur in the interior of the zeolite and involve singlet oxygen since product formation was quenched by addition of 2,3-dimethyl-2-butene, which can migrate into the zeolite, but not by addition of β -carotene, which is size excluded.

Intrazeolite sulfide photooxygenations are very efficient and 100% conversions to products, even with substrates that are unreactive in solution (e.g., 35), are often observed within 60 min or less. In addition,

the carbon–sulfur bond cleavage reactions, which can dominate many sulfide photooxygenations, are nearly completely suppressed (e.g., **32**, **33**, and **34** in Figure 32.17) in the zeolite. In order to rationalize the remarkable influence of the zeolite environment, a metal complexed persulfoxide has been invoked as the key intermediate. The importance of the metal is especially evident in the reaction of diphenyl sulfide, **35**, (Figure 32.17), which does not react in solution but reacts nearly quantitatively in methylene blue doped sodium Y. The precipitous drop in % conversion of **35** (Figure 32.17) as the sodium is replaced with cations that generate decreasing electrostatic fields is also consistent with stabilization of the persulfoxide by metal complexation. Finally, a dramatic increase in the rate of sulfide photooxygenation in substrates containing a tethered olefinic linkage in the zeolite in comparison to solution is best explained by suppression of physical quenching (k_q in Figure 32.4) by this complexation [99].

32.3 Type I Sulfur Photooxygenations

The vast majority of Type I sulfide photooxygenations occur by sensitized formation of sulfur radical cations. A noteworthy exception to this was recently reported by Shiraishi et al. [100], who reported the photooxygenations of a series of dialkyl sulfides within amphiphilic dendrimers consisting of a benzophenone core, a nonpolar interior, and a polar dendron exterior surface. They suggested that the triplet-excited benzophenone core undergoes energy transfer to give triplet sulfide that reacts with ground state triplet oxygen. These reactions gave exclusively sulfoxide products with no trace of either sulfones or carbon–sulfur cleavage products. The product uniformity along with the lack of substantial quenching by DABCO was used as evidence for the triplet energy-transfer reaction mechanism. No detail on the identity of intermediates or mechanism of oxygen transfer was given.

In 1977, Foote and coworkers [101] reported that 9,10-dicyanoanthracene, **DCA**, (Figure 32.18) sensitized photooxygenation of diphenyl sulfide, **35**, gave diphenyl sulfoxide while diethyl sulfide reacted under the same conditions to give both the sulfoxide and sulfone. Neither reaction was quenched by the potent singlet oxygen quencher, β -carotene. These workers suggested that **DCA** was acting as an electron shuttle removing an electron from the sulfide and donating it to oxygen. The efficiency of the reaction is governed by the competition between return electron transfer (RET in Figure 32.18) and trapping of the **DCA** radical anion with oxygen to give superoxide. The sulfoxides and sulfones were subsequently formed in a reaction between the superoxide and sulfide radical cation. (Figure 32.18)

Foote and coworkers never suggested a structure for the initial adduct formed in the reactions between superoxide and the sulfides; however, several authors have assumed that it is a persulfoxide [102,103]. However, this view changed in 2003 when Baciocchi and coworkers [104] reported that diphenyl sulfoxide does not trap an intermediate in electron-transfer-initiated photooxygenations. (Figure 32.19) On the other hand, they reported that the intermediate formed in the reaction between thianthrene, **TA**, radical cation, and KO_2 is capable of oxidizing diphenyl sulfide [105]. These results led to the suggestion that a thiadioxirane rather than a persulfoxide is the key intermediate in sulfide radical cation-mediated photooxygenations [106] (Figure 32.19).

The key feature of the **DCA** (Figure 32.18) and **NMQ**⁺ (Figure 32.19) catalyzed Type I photooxygenations is the ability of the reduced sensitizers (**DCA**^{•−} and **NMQ**^{•−}) to transfer an electron to triplet oxygen

FIGURE 32.18 Mechanism of 9,10-dicyanoanthracene photooxygenations of sulfides.

FIGURE 32.19 Sulfide photooxygenations involving thiadioxirane intermediates.

FIGURE 32.20 A chain mechanism for a type I sulfide photooxygenation.

to generate superoxide $\text{O}_2^{\bullet-}$. On the other hand, 2,4,6-triarylpyrylium tetrafluoroborates (Figure 32.1) catalyze sulfide Type I photooxygenations despite the fact that the pyrylium radicals are thermodynamically incapable of reducing oxygen. In order to rationalize these non-superoxide photooxygenations, Che [107] and Memarian [108] have both suggested mechanisms initiated by direct reaction of the sulfide radical cation with oxygen to give a persulfide radical cation, $\text{PS}^{\bullet+}$. (Figure 32.20) However, this reaction is not observed on the pulse radiolysis time scale [109,110] and a detailed computational study by Huang and Rauk [111] was unable to locate a bound structure corresponding to $\text{PS}^{\bullet+}$. Instead, they located a loose ion-dipole complex between oxygen and dimethyl sulfide radical cation bound by 3.2 kcal/mol, with a sulfur–oxygen distance only slightly shorter than the sum of the van der Waals radii.

In 2006, Albini and coworkers pointed out that unproductive electron transfers between superoxide and sulfur radical cations are substantially more exothermic than reactions to form thiadioxiranes [112]. Consequently, they rejected the Baciocchi thiadioxirane mechanism [104] and instead suggested the chain reaction depicted in Figure 32.20. They circumvent the problem with the instability of $\text{PS}^{\bullet+}$ by suggesting its rapid trapping by the sulfide substrate to give an unusual dithioperoxide radical cation, $\text{Ph}_2\text{S}^{\bullet+}\text{-OOS}(\text{Ph})_2$. However, in 2008, Clennan and Liao [113] reported that the mechanism shown in Figure 32.20 is not general and that the function of electron-transfer sensitizers can be more complex than simply fulfilling a role as an electron shuttle.

33.1 Introduction

Synthesis of porphycene, first reported in 1986,¹ opened up a new area of interdisciplinary research, devoted to constitutional isomers of porphyrin. Four pyrrole rings and four methine units can be reshuffled in many different ways. Seven “nitrogen in” structural isomers of porphyrin that preserve an N₄ coordination site are possible.² Of those, four have been obtained until now—all, except porphycene, in the form of alkylated derivatives.^{3–7} In addition, another isomer, labeled “inverted”⁸ or “confused”⁹ porphyrin, has also been synthesized. The structures and names of these compounds are presented in [Figure 33.1](#).

Owing to their crucial role in such processes as photosynthesis, electron and oxygen transport, and detoxification, porphyrins have justly been dubbed “pigments of life.”¹⁰ Their biological importance stems from spectral, photophysical, and redox properties, combined with complexing abilities. An obvious question, therefore, regards these properties in the structural isomers. It turns out that while the basic patterns are often quite similar, quantitative characteristics can make the isomers even more attractive than the parent compound. This is especially true for porphycenes, which remain by far the most investigated class of porphyrin isomers, with ca. 300 different derivatives described in the literature. Various potential applications of porphycenes have been suggested. These include information storage,¹¹ catalysis,¹² and use of porphycenes as molecular conductors¹³ and transistors.¹⁴ Liquid crystalline materials based on porphycenes have been reported.¹⁵ It was also possible to modify proteins by replacing the native heme by an artificial one, based on iron¹⁶ or cobalt¹⁷ porphycenes.

FIGURE 33.1 Porphyrin (1) and its constitutional isomers: porphycene (2), hemiporphycene (3), corrphycene (4), isoporphycene (5), inverted (“confused”) porphyrin (9). Molecules 6–8 have not yet been synthesized.

A particularly important field where porphycenes are likely to replace porphyrins is photodynamic therapy, destruction of malignant tissue by reactive oxygen species, produced after light absorption by a photosensitizer.¹⁸ Some porphycenes have been found to be much more effective as phototherapeutic agents than Photofrin®, a drug based on a mixture of porphyrin derivatives.¹⁹

With regard to fundamental research, porphycenes became role models for investigating intramolecular cooperative hydrogen transfer.^{20–39} The two inner hydrogen atoms can migrate between four nitrogen atoms which form the inner cavity. The same process has been studied earlier for porphyrins, but the mechanisms are very different for the two isomers. The intramolecular $\text{NH}\cdots\text{N}$ hydrogen bonds in porphycenes are very strong compared to those in porphyrin. Actually, DFT calculations predict that free base porphycene is lower in energy by about $1.5 \text{ kcal mol}^{-1}$ than porphyrin.⁴⁰ This is due to the nearly rectangular shape of the cavity in porphycene, enabling short and linear hydrogen bonds. On the other hand, the same property leads to weaker metal-complexing propensity of porphycenes as compared with porphyrins, which have larger and square cavity.

The intramolecular exchange of two hydrogens in porphyrins and porphycenes leads to a chemically equivalent structure (Figure 33.2). The symmetrical double minimum character can be perturbed by appropriate substitution. This provides excellent models for studying tunneling, as it is very sensitive to the shape and symmetry of the potential energy governing the proton/hydrogen transfer. Moreover, studies of porphycenes in the regime of isolated molecule (supersonic jets, helium nanodroplets) provide evidence of coherent double proton tunneling as well as of the multidimensional character of the hydrogen transfer path; the latter is manifested by the coupling between vibrations, involving protons

FIGURE 33.2 Possible tautomeric forms of porphycene and their relative energies predicted by calculations. The symmetric double minimum potential character indicated schematically at the bottom.

and heavy atoms. In turn, the fact that two hydrogen bonds are present makes it possible to study cooperativity effects, both in the hydrogen bonds and in tautomerization. Finally, for studies in condensed phase, it is important that the hydrogen transfer occur in the cavity located inside a molecule and well shielded from the environment, which minimizes the influence of the latter.

In this work, we start by presenting the basic features of electronic absorption of porphycenes and the origin of differences with respect to porphyrins. We, then, review the photophysical properties of variously substituted porphycenes (see [Figure 33.3](#) for numbering) and discuss a recently proposed model, which explains large differences in emissive properties in different alkyl derivatives.⁴¹ This model involves intramolecular hydrogen exchange, the primary subject of this paper, discussed further in detail for both the excited and the ground electronic states of porphycenes.

FIGURE 33.3 Atom numbering and symbols indicating the positions of substitution for porphycene.

33.2 Electronic Spectra

The electronic absorption spectra of porphyrins are quite complex and substituent dependent. Different patterns are observed in the region of the low-energy transitions, comprising the so-called Q bands. They correspond to a single, doubly degenerate electronic transition in high-symmetry (D_{4h}) porphyrins. When the symmetry is lowered, the degeneracy is lifted, and two electronic transitions, Q_x and Q_y , are observed. The x and y indices indicate the transition moment directions. In free-base porphyrin, which has D_{2h} symmetry, x corresponds to the direction along the $NH\cdots HN$ bonds and y to the in-plane direction perpendicular to it. The intensity of Q bands is usually much lower than that of the Soret bands, observed in the blue part of the visible range (Figure 33.4). Moreover, the 0–0 transition of the lowest energy band is often quite weak, and followed by rich vibronic structure.

The absorption spectra of porphycenes are significantly different from those of the porphyrins (Figure 33.4). Even though the basic pattern, Q transitions followed by stronger Soret bands, is preserved, their intensities are now quite similar. In parent porphycene, the ratio of the absorption coefficient of the maximum of the first Q band to that of the Soret band maximum is about 0.37. This is due to much stronger absorption of porphycenes in the low-energy range, about an order of magnitude larger in porphycenes than in porphyrins. Contrary to the behavior of porphyrins, the absorption intensity of porphycenes is not strongly affected by solvent or substitution. Moreover, the 0–0 transitions are quite strong, and their intensity not much sensitive to substitution or environment.

These differences in absorption patterns can be readily explained using a four orbital model, developed for porphyrins by Gouterman⁴² and extended by Michl,⁴³ as a “perimeter model” in order to interpret the absorption and magnetic circular dichroism (MCD) spectra of $4N+2$ π electrons aromatic compounds. The properties of four lowest $\pi\pi^*$ electronic states may be described by taking into account four singly excited configurations involving single electron promotions from the two highest occupied π orbitals (HOMO) into the two lowest unoccupied ones (LUMO). Configuration interaction leads to four electronic transitions of which the intensities depend on the relative energy splittings in the pairs of LUMO and HOMO. In Michl’s terminology, the situation where the splittings are equal or similar ($\Delta HOMO \approx \Delta LUMO$) corresponds to the so-called “soft chromophores,” whereas molecules characterized by $\Delta HOMO > \Delta LUMO$ or $\Delta HOMO < \Delta LUMO$ are labeled “hard chromophores” (positively hard or negatively hard, respectively).

FIGURE 33.4 Electronic absorption spectra of porphyrin in toluene (a) and porphycene in *n*-hexane (b) at 293 K. The positions of Q and Soret bands are indicated.

FIGURE 33.5 Derivation of porphyrin and porphycene from a $4N+2$ electron $C_{20}H_{20}^{++}$ ideal perimeter and the resulting orbital splitting patterns.

The splitting pattern is quite easy to predict: it can be done by inspecting the nodal properties of the orbitals of the parent $4N+2$ π electrons $[n]$ -membered perimeter. For porphyrin and its isomers, this perimeter corresponds to $C_{20}H_{20}^{++}$, containing 18 electrons. Formation of a molecule from an ideal perimeter is treated by introducing two NH and two N^- bridges (Figure 33.5). This lifts the degeneracy of HOMO and LUMO pairs. Due to different topology of the two isomers, $\Delta HOMO \approx \Delta LUMO$ for porphyrin, whereas for porphycene, $\Delta HOMO \ll \Delta LUMO$. The former is thus a soft chromophore, while the latter is a negatively hard chromophore. It has been demonstrated that the intensity of Q transitions relative to the Soret ones should grow with the increasing difference in the HOMO and LUMO splittings. Different absorption patterns of porphyrins and porphycenes can then be understood.

Differences between soft and hard chromophores are even more spectacular when probed by MCD spectroscopy. For the two lowest electronic transitions, the sign of Faraday B terms, which characterize the MCD spectra, is determined by the sign of $\Delta HOMO - \Delta LUMO$. For soft chromophores, such as porphyrins, it is, therefore, very sensitive even to minor structural perturbations, for example, substitution or change in the tautomeric equilibrium involving the inner protons. For hard chromophores, however, this is not the case. Since in porphycenes $\Delta HOMO \ll \Delta LUMO$, a $-,+$ sequence of B terms is predicted. This sequence is not expected to change for differently substituted porphycenes. Indeed, the same pattern of MCD spectra has been observed for all porphycenes studied so far, including free bases, dianions, dications, and metal complexes. As an example, Figure 33.6 shows the absorption and MCD spectra of porphycene and three differently substituted derivatives.

According to the perimeter model, porphycene is the strongest hard chromophore of all the porphyrin isomers. Corrophycene should be a soft chromophore, whereas hemiporphycene, a hard one. The absorption and MCD characteristics of the latter are expected to resemble those of porphycene, whereas

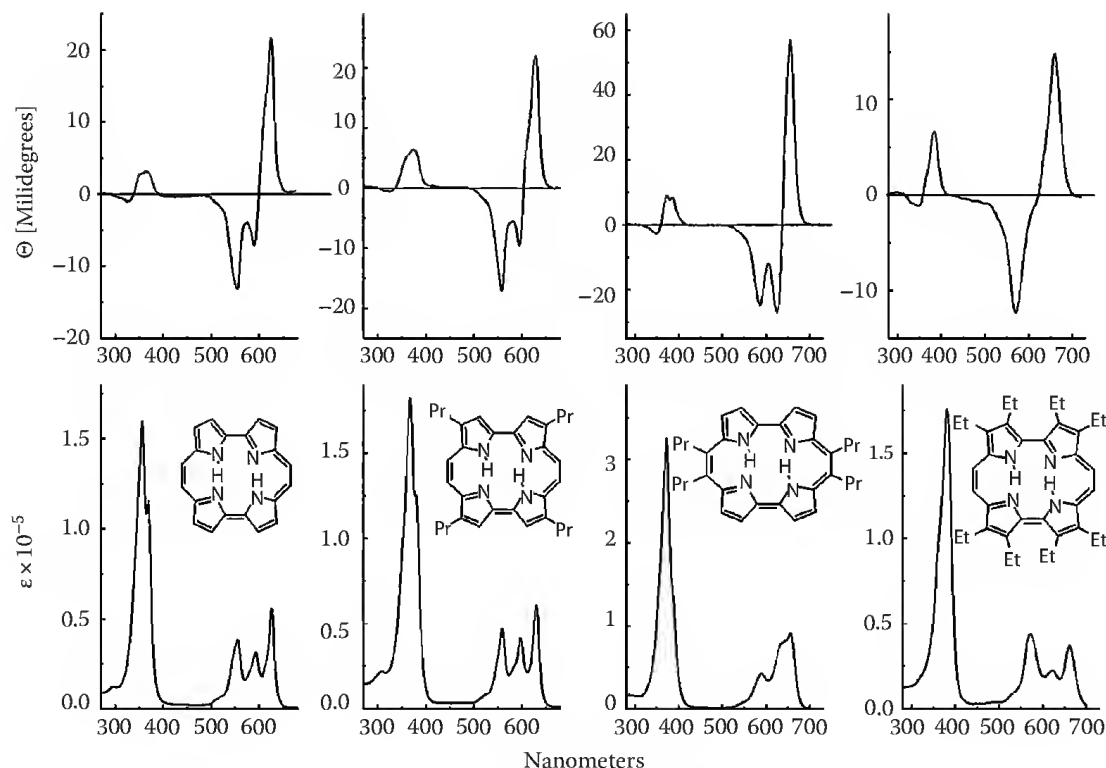

FIGURE 33.6 Bottom, absorption, top, MCD spectra recorded in acetonitrile at 293K. From left to right: parent porphycene, 2,7,12,17-tetra-*n*-propylporphycene, 9,10,19,20-tetra-*n*-propylporphycene, and 2,3,6,7,12,13,16,17-octaethylporphycene.

those of the former should be similar to the spectral properties of porphyrin. This was first predicted theoretically² and confirmed experimentally a decade later for corrphe⁴⁴ and hemiporphycene,⁴⁵ when both compounds became available.

33.3 Photophysics

The photophysical properties of metalloporphycenes or free base porphycenes substituted by heavy atoms are similar to the properties of porphyrin analogues. Fluorescence is weak, and the dominant channel of S_1 deactivation is the intersystem crossing to the triplet state.^{46–48} Usually, singlet oxygen formation is very efficient and its yield is close to that of triplet formation. The differences between porphyrins and porphycenes are more pronounced for free bases not containing heavy atoms. Fluorescence quantum yields of free base porphyrins are usually a few percent, whereas the lifetime is about 10 ns. The dominant depopulation channel of the lowest excited singlet state is the intersystem crossing to the triplet manifold. In free base porphycenes, fluorescence quantum yield and lifetime depend strongly on the position of substitution. In the parent, unsubstituted porphycene, quantum yields of fluorescence and intersystem crossing are similar, about 40%; this implies that about 20% of the molecules decay via internal conversion to the ground state. Very similar photophysical parameters are observed for porphycenes substituted by alkyl groups in the β positions (2,7,12,17, cf. Figure 33.3); substitution by phenyl leads to about two-fold decrease in fluorescence intensity.⁴⁷ Octuple alkyl substitution in the β and β' positions (2,3,6,7,12,13,16,17) leads to the decrease of fluorescence intensity and lifetimes by a factor of 20–50. Even more drastic effects are observed for *meso*-substituted tetraalkylporphycenes: in liquid, nonviscous solutions fluorescence intensity and lifetime are several hundred times lower than those of the parent compound. The dominant radiationless process is the S_1 – S_0 internal conversion. An important observation is that for weakly emitting *meso*-tetraalkylporphycenes and octaethylporphycenes the emission characteristics are strongly viscosity dependent. In rigid

FIGURE 33.7 Correlation of electronic states in *trans* and *cis*-2 tautomeric forms of porphycene, resulting in the appearance of conical intersection (CI). The dashed arrows indicate the excited state radiationless deactivation pathway along the hydrogen transfer coordinate. (Adapted from Sobolewski, A., Gil, M., Dobkowski, J., and Waluk, J., *J. Phys. Chem. A* 113, 7714–7716, 2009. Copyright 2009 American Chemical Society.)

environments such as polymer films, both fluorescence yield and decay time increase, approaching the values observed for low-temperature glassy solvents. This finding, combined with *ab initio* calculations, has led to the suggestion that the origin of the radiationless process responsible for deactivation is the conical intersection along the hydrogen transfer path corresponding to *trans*–*cis*-2 conversion (Figure 33.7).⁴¹ Interestingly the *cis*-2 tautomeric structure, with protons localized on the pyrroles linked to the same ethylene bridge lies much higher in energy than the other, *cis*-1 form, with protons on the same bipyrrrole unit (see Figure 33.2). The calculations showed that the lowest energy structure of the *cis*-2 tautomer corresponds to an open-shell configuration. The closed-shell configuration is slightly higher in energy. The latter has to be correlated with the ground state of the *trans* tautomer while analyzing the *trans*–*cis*-2 reaction, whereas the former should be correlated with the excited *trans* structure. As a consequence, conical intersection should exist along the hydrogen transfer path. The open-shell *cis*-2 structure is strongly distorted from planarity, by twisting of the two protonated pyrrole units. Therefore, the *trans*–*cis*-2 tautomerization involves not only proton translocation, but also twisting, a large amplitude motion. This explains the experimentally observed decrease in the rate of radiationless depopulation while increasing the viscosity of the environment. The activation barrier values were predicted by calculations to decrease for a series of differently substituted porphycenes in the order: (i) the parent, unsubstituted compound; (ii) 9,19-dimethylporphycene; (iii) 2,3,6,7,12,13,16,17-octamethylporphycene; (iv) 9,10,19,20-tetramethyl porphycene. These predictions perfectly match the experimentally observed changes in the radiationless depopulation rates. It remains to be seen whether this model can be generalized to include other derivatives, for example, 2,7,12,17-tetraphenyl- or 2,7,12,17-tetrakis(*p*-substituted phenyl)-3,6,13,16-tetraazaporphycenes. For the latter, S_1 – S_0 internal conversion values exceeding 90% have been reported.⁴⁷

33.4 Tautomerism

While comparing free base porphycenes with their porphyrin analogues, one should take into account different sizes and symmetries of the inner cavity: a slightly distorted rectangle in the former, the square in the latter (Figure 33.1). This difference significantly influences the intramolecular hydrogen bond

parameters. The smaller $\text{NH}\cdots\text{N}$ distances (2.63 vs. 2.89 Å) and larger angles (152° vs. 116°) leave no doubt that the hydrogen bonds in porphycene should be much stronger. Moreover, the energy difference between the dominant *trans* tautomers and *cis* tautomers is also much smaller: B3LYP/TZ2P calculations predict for porphyrin the *cis*–*trans* energy difference of 8.3 kcal mol^{-1} ,⁴⁹ whereas for porphycene the *cis*-1 –*trans* separation is much lower, 2.4 kcal mol^{-1} .⁵⁰ On the other hand, the other, *cis*-2 tautomer of porphycene lies very high in energy. However, as discussed earlier, it should not be neglected, due to its possible role in the radiationless deactivation of the excited state.

33.4.1 Condensed Phase Studies

33.4.1.1 Ground State Tautomerization in Polycrystalline Porphycenes

Ground state tautomerization in porphyrin, involving two chemically identical *trans* tautomers as the substrate and the product, has been intensely studied for years, mostly by NMR techniques. It is now recognized that the reaction proceeds in a stepwise fashion (Figure 33.8).⁵¹ First, the molecule is thermally activated to a level from which *trans*→*cis* tunneling can occur. Subsequently, the *cis* structure undergoes a second hydrogen transfer, which leads either to the other *trans* tautomeric form or back to the substrate. The *cis* structure of porphyrin has never been experimentally detected.

Comparison of ^{15}N -CPMAS-NMR spectra of ^{15}N -enriched crystalline porphycene and porphyrin²⁰ revealed that the ground state tautomerization is much faster in the former. For porphyrin, lowering of temperature results in broadening of a narrow, single line observed at 356 K. For sufficiently low temperatures ($<250\text{ K}$), two lines are observed, corresponding to N and NH nitrogens. Line shape simulations allowed estimating the rate constant of the double hydrogen exchange: it drops from a value larger than $30,000\text{ s}^{-1}$ at 356 K to 500 s^{-1} at 244 K. For porphycene, such approach was not possible. Upon temperature decrease, a single line does not reveal broadening. Instead, it becomes split into four narrow lines. This was interpreted as indication of very rapid hydrogen exchange on the NMR time-scale. The process is not slowed even at temperatures as low as 107 K. The origin of four lines may be alternatively explained by the following: (i) the existence of two different molecules in the crystal lattice, of which each has access to two proton transfer systems; and (ii) the presence of only one molecule, but with access to four tautomeric species. One should note that the crystal field removes the degeneracy of two *trans*–*trans* or *cis*–*cis* minima. Further studies of crystalline porphycene using ^{15}N and ^2H NMR spectroscopy and longitudinal relaxometry allowed estimating the tautomerization rate.³⁷ Quite surprisingly, it was found to increase dramatically—from a microsecond to a nanosecond range—at lower temperatures, below 255 K. A phase transition was suggested to occur at that temperature. Low temperature studies revealed the presence of two inequivalent molecules in

FIGURE 33.8 Stepwise mechanism of double hydrogen transfer in porphyrin: 1, thermal activation, 2, tunneling.

a unit cell, each with access to two *trans* tautomeric states. The Arrhenius plots in the low temperature range were typical for tunneling. It was postulated that tautomerization occurs in a concerted fashion at high temperatures and as a step-wise process at low temperatures, due to lowering in energy of one of the *cis* intermediates.

Rapid ground state tautomerization in the solid state was also demonstrated for three porphycene derivatives: 2,3,6,7,12,13,16,17-octaethyl-, 9,10,19,20-tetrapropyl-, and 2,7,12,17-tetrapropylporphycene by variable temperature ^{13}C - and ^{15}N -CPMAS NMR measurements.⁵²

33.4.1.2 Ground and Excited State Tautomerism in Solutions, Glasses, Polymers, and Rare Gas Matrices

An indication that the ground state hydrogen exchange in porphycene cannot be frozen even at liquid helium temperature was the failure to photo-orient this molecule by irradiation of rare gas matrices with polarized light. Such procedure, successfully performed for porphyrin at temperatures below 80 K,⁵³ requires that the ground state tautomers do not interconvert on the time scale of the experiment. This is not the case for porphycene, as was confirmed later on, by low temperature studies of 9-acetoxy-2,7,12,17-tetra-*n*-propyl derivative.²⁵ In this molecule, the two *trans* tautomers are no longer equivalent, but their ground state energies are very similar. Both *trans* tautomeric forms were observed even at cryogenic temperatures, with their ratio remaining practically constant between 20 and 100 K. Most important, this ratio was not changed upon selective excitation of only one form, which was transformed to the other in the excited state. These results proved that ground state interconversion occurs, most probably by tunneling.

A clear demonstration that tautomerization occurs in the lowest excited electronic state of porphycene was provided by fluorescence anisotropy studies.^{21,22} The value of fluorescence anisotropy measured for excitation into S_1 was much lower than the “normal” value of 0.40, expected for collinear arrangement of absorption and emission transition moments. On the other hand, the value obtained while exciting into S_2 was much higher than expected, since the calculations predict that the S_0 – S_1 and S_0 – S_2 transition moments are orthogonal (Figure 33.9). Such unusual behavior could be explained by assuming rapid *trans*–*trans* tautomerization in S_1 . In the “fast” reaction regime, when the exchange occurs in a time shorter than the S_1 lifetime, the value of the fluorescence anisotropy obtained upon S_1 excitation of the chromophore embedded in a rigid matrix is determined by the angle formed between the transition moments of two chemically equivalent, but spatially differently oriented species (Figure 33.10).^{33,36} By now, the same value of 0.12 ± 0.01 , corresponding to the angle of 75° has been obtained independently using three different techniques: (i) stationary emission anisotropy measurements³⁶; (ii) anisotropy of transient absorption³⁹; and (iii) single molecule spectroscopy of porphycene and its derivatives.^{26,54} This value is in excellent agreement with 76° , the value predicted by TDDFT B3LYP/6-31G(d,p) calculations. Using fluorescence anisotropy measurements, it was also possible to determine transition moment directions for the higher excited singlet electronic states.²² It has to be noted that, because of the low (C_{2h}) symmetry of porphycene, the electronic $\pi\pi^*$ transitions can be polarized along any direction in the molecular plane, and therefore the determination of transition moments by other techniques, such as standard linear dichroism, would be difficult and less accurate. Finally, the depolarization of fluorescence proved that the *trans* tautomers are dominant, both in S_0 and S_1 . No depolarization should be expected for *cis*–*cis* conversion, whereas for a *cis*–*trans* reaction, the anisotropy values should be higher than observed.

Stationary measurements of the emission anisotropy performed for several alkyl-substituted porphycenes provided the first evidence of a strong dependence of the tautomerization rate on the $\text{NH}\cdots\text{N}$ distance, that is, the hydrogen bond strength.²² In glassy propanol matrices at 113 K, fluorescence was found to be depolarized for parent porphycene and two tetra-*n*-propyl derivatives substituted at β and *meso* positions. In contrast, no depolarization was observed for 2,3,6,7,12,13,16,17-octaethyl derivative (Figure 33.9). The X-ray data for the latter show the largest $\text{NH}\cdots\text{N}$ distance compared to the other three (2.80 vs. 2.63, 2.62, and 2.53 Å). Also, large differences in the proton chemical shifts (0.65 vs. 3.15, 3.15, and 6.82) indicate a weaker hydrogen bond in the octaethyl derivative.

FIGURE 33.9 Bottom, fluorescence and fluorescence excitation spectra; top, anisotropy of fluorescence excitation for porphycene and 2,3,6,7,12,13,16,17-octaethyl-porphycene in *n*-propanol glass at 113 K. The inset shows the calculated transition moment directions for the transitions into the first and second lowest excited singlet states. The horizontal dashed lines represent the anisotropy values expected for orthogonal S_0 - S_1 and S_0 - S_2 transition moments in the absence of phenomena leading to depolarization.

FIGURE 33.10 S_0 - S_1 transition moment directions in the initially excited *trans* tautomer (left) and in the tautomerization product. α is the angle between the transition moments in the two forms.

A procedure that enabled determining the excited state tautomerization rate from the analysis of fluorescence anisotropy values, measured either in stationary or time-resolved modes, was developed and applied to the parent porphycene.³⁶ The Arrhenius plot yielded a surprisingly low value of the activation barrier, 0.55 ± 0.05 kcal mol⁻¹. To explain this result, a mechanism of thermally activated double hydrogen tunneling was proposed. The apparent activation barrier corresponds to 181 cm⁻¹, the frequency of a

vibration that simultaneously shortens the $\text{NH}\cdots\text{N}$ distance in both intramolecular hydrogen bonds. In this way, a barrier for concerted *trans-trans* tautomerization becomes lower. This hypothesis was subsequently confirmed by measurements of mode-selective tunneling splittings, discussed below.

Further development of methodology based on using polarized light to determine tautomerization rates resulted in the formula which links the kinetic profiles of the anisotropy of transient absorption with the hydrogen exchange rates in both the ground and lowest excited singlet states. Depending on the choice of pumping and probing wavelengths, it is possible to separately determine the rates in S_0 and S_1 . This was achieved at 293 K for parent porphycene and four alkyl derivatives using polarized pump-probe spectroscopy with tunable femtosecond laser pulses.³⁹ The results demonstrated a huge dependence of the rate on the hydrogen bond strength, expressed in terms of $\text{NH}\cdots\text{N}$ distances or proton chemical shifts. The tautomerization rates differ by about four orders of magnitude between the derivatives with the strongest (*meso*-substituted) and the weakest (octaethyl) hydrogen bond (Figure 33.11). In the former, the reaction proceeds in S_0 in < 100 fs, whereas in the latter it takes > 100 ps. For parent porphycene dissolved in ethylene glycol, tautomerization at 293 K occurs in 1.7 ± 0.1 ps and 14 ± 2 ps in S_0 and S_1 , respectively. In general, for all the porphycenes measured so far, the S_1 rate is about an order of magnitude lower

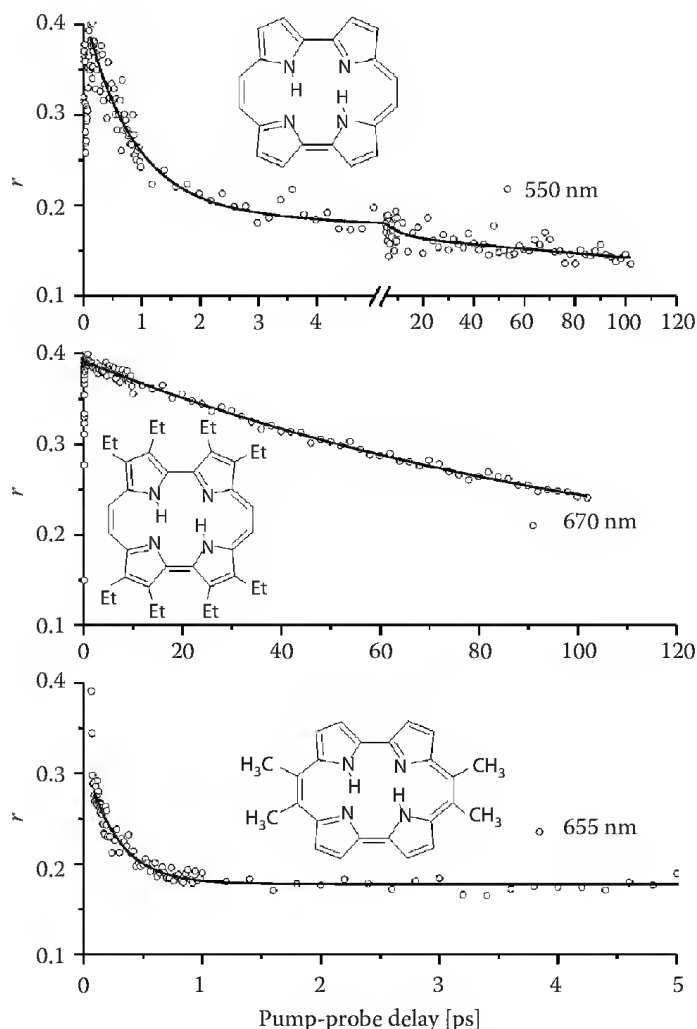

FIGURE 33.11 Decay profiles of anisotropy measured at 293 K for ethylene glycol solutions using femto-second pump-probe spectroscopy. Top to bottom: porphycene, 2,3,6,7,12,13,16,17-octaethyl-porphycene, and 9,10,19,20-tetramethyl-porphycene. Very different decay times reflect different tautomerization rates. Pump and probe wavelength indicated for each compound ($\lambda_{\text{pump}} = \lambda_{\text{probe}}$).

than in S_0 , due probably to an increase in the $NH \cdots N$ separation upon excitation; such behavior has been predicted by calculations. The H/D isotope effects were determined for both ground and excited states. The values of 4.3 ± 0.3 and 8.0 ± 0.5 were obtained for parent porphycene. For 2,7,12,17-tetra-*tert*-butyl derivative, the isotope effects are 5.0 ± 0.4 and 7.7 ± 0.4 for S_0 and S_1 , respectively.³⁹

Using the same pump-probe methodology, it was possible to determine the rates of the intermolecular exchange of the inner protons in porphycene for deuterons, by dissolving the porphycenes in deuterated ethanol and butanol-1.³⁴ The rates of the first and second proton/deuteron exchange turned out to be the same and about 17 orders of magnitude slower than that of intramolecular tautomerization. This provided another proof of exceptionally strong intramolecular hydrogen bonds in porphycene.

Tautomerization in the parent porphycene has also been studied in the lowest triplet state in a wide temperature range using time-resolved EPR and electron spin echo techniques.⁵⁵ It was concluded that porphycene has a *trans* configuration in both S_0 and T_1 . The NH tautomerism was suggested to occur in T_1 at 100 K with the lower and upper limits of the rates of 9×10^6 and 7×10^8 s⁻¹, respectively. The value of the tautomerization rate in S_1 at this temperature, determined from stationary fluorescence anisotropy³⁶ is 2×10^7 s⁻¹, and thus fits well into the range estimated for the reaction in the triplet state.

In summary, the results obtained from condensed phase studies allowed determining the *trans-trans* conversion rates in both S_0 and S_1 electronic states. Several findings suggest an important role of tunneling and its possible sensitivity to the mode of vibrational excitation. These issues have been studied in detail by measurements of porphycenes isolated in molecular beams and helium nanodroplets, discussed in the next section. The problem that remains to be explained is the large difference obtained for the values of exchange rates at 293 K using different methods for porphycenes in different environments. The values obtained for polycrystalline porphycene using NMR techniques are several orders of magnitude lower than those provided by polarized spectroscopy studies in liquids and polymeric films. It is interesting to note that the low temperature data provided by the two techniques agree with each other. Another question that awaits a definitive answer is that of concerted versus stepwise mechanism. The *cis* tautomer has not been detected for parent porphycene, but it may exist as a very short-lived species, difficult to pinpoint experimentally. Careful studies of the temperature dependence of kinetic isotope effects may help in solving this issue.

33.4.2 Coherent Double Hydrogen Tunneling in Isolated Porphycenes

In the condensed phase, the tautomerization in porphycene can be described as a rate process. On the other hand, in an isolated molecule the wave function is delocalized. Coherent double hydrogen transfer tunneling is manifested by line splittings (Figure 33.12), of which the value is the function of the effective barrier height and its shape, as well as of the mass and the distance the tunneling particle has to travel.

Fluorescence excitation spectrum recorded for free base porphyrin isolated in a supersonic jet consists of single lines.⁵⁶ In contrast, the spectra of parent porphycene for which the tautomerization barrier is lower than in porphyrin, show doublets, separated by 4.4 cm⁻¹ (Figure 33.12).²³ Single line pattern is recovered when one or both internal protons are replaced by deuterons, indicating that the splitting is due to hydrogen tunneling. The doublet structure is also not observed for complexes with water or alcohol, which suggests that the double minimum potential is no longer symmetrical, which leads to localization of inner hydrogens.

On the basis of a constant value of the splitting across all vibronic bands and the red shift observed in the fluorescence excitation spectra of singly and doubly deuterated chromophores, which indicates a weaker hydrogen bonding in S_1 compared to S_0 , the observed separation of lines by 4.4 cm⁻¹ was attributed to the tunneling splitting in the ground state vibrationless level, from which the transitions observed in the fluorescence excitation spectrum originate. In consequence, the splitting in S_1 should be lower than 0.1 cm⁻¹, the resolution of the jet spectrometer. These results were confirmed, first by recording the dispersed fluorescence from jet-isolated porphycene and then, with much better spectral resolution, by measuring fluorescence spectra for porphycene embedded in helium

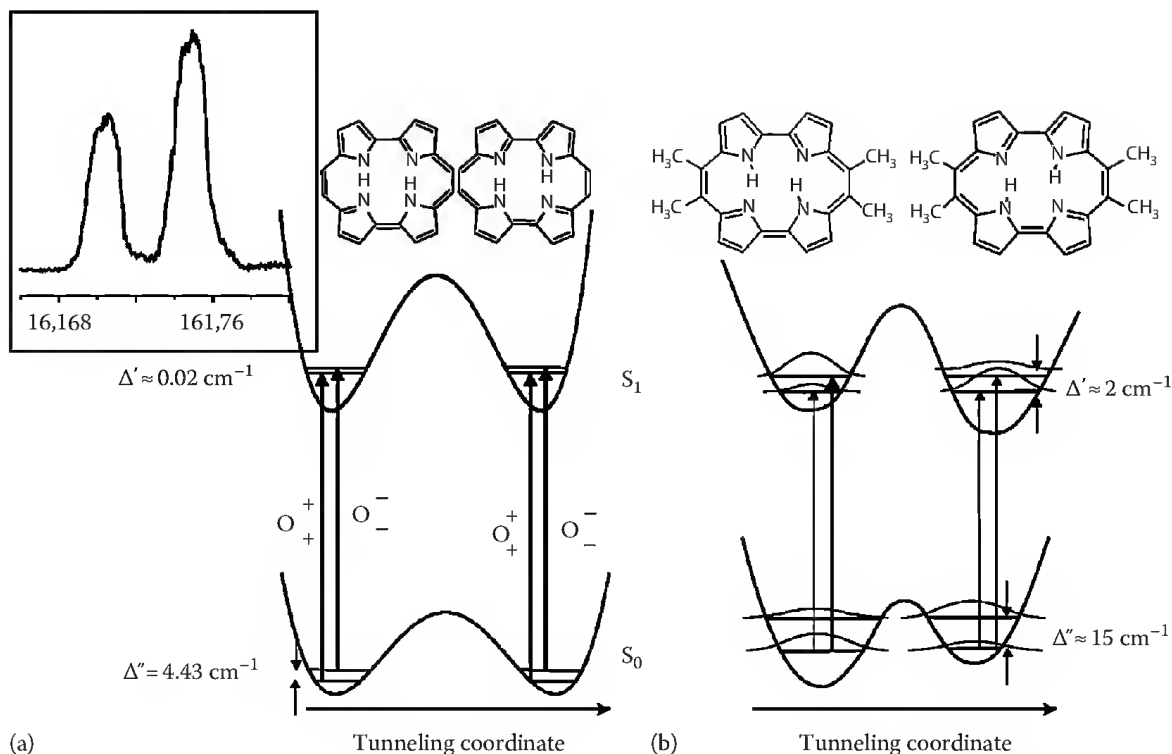

FIGURE 33.12 Double minimum potential energy curves for ground and excited state tautomerization in porphycene (a) and 9,10,19,20-tetramethylporphycene (b). The inset shows the doublet splitting observed in the fluorescence excitation spectrum for the 0–0 transition of porphycene isolated in a supersonic jet.

nanodroplets.³⁸ In the latter experimental regime, the temperature of 0.37 K ensures that the upper tunneling level of the ground state molecule is not accessible. Under such conditions, only one of the lines of the doublet is observed. On the other hand, a doublet was observed for singly deuterated porphycene, its components separated by 0.58 cm^{-1} . This value corresponds to ground state tunneling splitting reduced by single H→D substitution. Replacement of the second hydrogen results in further reduction of the splitting, so that it could not be resolved. The helium droplet experiments established that the ground state splitting in parent porphycene is 4.43 cm^{-1} , whereas the splitting in S_1 amounts to about 0.02 cm^{-1} .

Measurements of the emission spectra of porphycene in helium droplets allowed determining the values of tunneling splittings for various ground state vibrational levels. Since each vibronic line in the fluorescence originates from the same tunneling doublet in S_1 , of which the components are nearly degenerate, the observed energy differences between the doublet components correspond to the ground state splittings for each particular vibration, or that of the vibrationless level. The splittings have been found to be very much different for different vibrations. Some modes reveal splittings of about 4.4 cm^{-1} , the value obtained for the S_0 vibrationless level. They can be, therefore, labeled “neutral” with respect to their influence on the effective tautomerization barrier. The most interesting ones are (i) a 182 cm^{-1} mode revealing a much larger splitting, 12 cm^{-1} ; practically the same value is observed for combinations of this vibration with two “neutral” modes; (ii) a 145 cm^{-1} mode, for which the splitting is too small to be resolved. Thus, for the 182 cm^{-1} mode the reaction barrier is smaller than that for the vibrationless level, whereas it becomes larger for the 145 cm^{-1} vibration. In other words, the former mode promotes and the latter hinders the reaction. These vibrations can be readily assigned. The promoting mode corresponds to a vibration in which both $\text{NH}\cdots\text{N}$ distances change in phase. This leads to simultaneous strengthening of both intramolecular hydrogen bonds. It is the same vibration that was postulated to activate the excited state tautomerization observed in S_1 in condensed environments.³⁶ The hindering mode involves

FIGURE 33.13 The forms of two low frequency modes of porphycene, of which one hinders, the other accelerates tautomerization (a and b, respectively). Calculated using B3LYP/6-31G(d,p).

out-of-phase rocking motion of the two bipyrrrole units (Figure 33.13). The splitting patterns observed for these two modes strongly suggest a concerted character of hydrogen transfer.

Tunneling splittings have also been observed for jet-isolated *meso*-substituted tetramethyl and tetra-*n*-propyl-substituted porphycenes.²⁸ Since this pattern of substitution leads to an increase in hydrogen bond strength, larger splittings than in the parent compound could be expected. This is indeed the case (Figure 33.12). From the analysis of fluorescence and fluorescence excitation spectra, the values of about 15 and 2 cm^{-1} were obtained for S_0 and S_1 , respectively. Moreover, the potential was found not to be symmetric, with the ordering of energy minima reversed upon excitation. The origin of this effect was attributed to the coupling of hydrogen motion with the rotation of alkyl substituents, an effect previously detected for methyl-substituted tropolone⁵⁷ and hydroxyphenalenone.⁵⁸

The experiments for *meso*-substituted porphycenes revealed the presence of two different forms. One of them disappeared in the colder part of the jet, away from the nozzle. It was assigned to the *cis*-1 tautomeric form, of which the calculated energy is only less than 1 kcal mol^{-1} higher than that of the dominant *trans* tautomer. The presence of two tautomeric forms has also been revealed for condensed phases by observing biexponential fluorescence decays. Interestingly, the values of tunneling splittings, deduced from supersonic jet spectra, are very similar for both forms. A more detailed analysis of mode-specific tunneling is difficult, because fluorescence disappears at very low excitation energy excess. The onset of efficient radiationless deactivation is in line with condensed phase studies discussed earlier, which demonstrated that this channel becomes most efficient in low-viscosity media. Supersonic jets represent exactly such an environment.

33.4.3 Tautomerization in Single Molecules of Porphycenes

Polarized spectroscopy studies of porphycene demonstrated that, owing to its tautomeric properties, porphycene is a special chromophore. The self-exchange of the inner hydrogen atoms results in the rotation of the S_0 – S_1 transition moment by a large angle, exceeding 70° (Figure 33.10). This effect has been exploited to detect tautomerization in single molecules of porphycene embedded in polymeric matrices.^{26,54} On the time scale of the experiment (seconds), the molecule is a “dual emitter,” composed of two nearly orthogonal dipoles. For such a case, the spatial pattern of fluorescence intensity should be different from that of a “normal” molecule, considered as a single emitting dipole. Indeed, using the azimuthal polarization mode of the exciting laser beam, it was possible to observe a pattern which cannot correspond to a single dipole: a nearly perfect ring (Figure 33.14). This pattern could be reproduced by simulations, which assumed two equally emitting dipoles. An angle of $72^\circ \pm 3^\circ$ provided the best fit, in excellent agreement with the value first obtained from fluorescence anisotropy studies of bulk porphycene in polymer films,³⁶ and then reproduced by femtosecond transient absorption spectroscopy.³⁹

In some single molecule emitters, a different pattern was observed, consisting of double lobes (molecule B, Figure 33.14). Two explanations of such behavior are possible: (i) freezing of tautomerization by the

FIGURE 33.14 Left, spatial distribution of fluorescence intensity from two single molecules of porphycene embedded in poly(methyl methacrylate) at 293 K. Right, simulation of the distribution. (Adapted from Piwoński, H., Stupperich, C., Hartschuh, A., Sepioł, J., Meixner, A., and Waluk, J., *J. Am. Chem. Soc.*, 127, 5302–5303, 2005. Copyright 2005 American Chemical Society.)

environment or (ii) orientation of molecular plane perpendicular to the sample surface. The issue was resolved by comparing spatial patterns of the emission obtained for the same single molecule by using azimuthally and radially polarized laser beams.⁵⁴ Besides parent porphycene, three derivatives have been studied. The dual dipole character of the emission was confirmed, proving that tautomerization does occur and that different spatial patterns originate from different orientation in polymeric matrices. In fact, it was

FIGURE 33.15 Fluorescence images of three differently oriented single molecules of 2,7,12,17-tetra-*tert*-butylporphycene in poly(methyl methacrylate) at 293 K. The insets show the directions of S_0 – S_1 transition moments with respect to the sample support plane. Top, azimuthal; bottom, radial polarization of the exciting 632.8 nm laser beam. Left, experimental; right, simulated patterns. (Adapted from Piwoński, H., Hartschuh, A., Urbańska, N., Pietraszkiewicz, M., Sepioł, J., Meixner, A., and Waluk, J., *J. Phys. Chem. C*, 113, 11514–11519, 2009. Copyright 2009 American Chemical Society.)

not only possible to distinguish between the molecules lying flat on the sample surface but also those perpendicular to it. For the latter case, use of two different polarization modes allowed separating molecules with both dipoles forming approximately the same angle with the surface from those with one dipole parallel and the other, approximately perpendicular to it (Figure 33.15). Once again, tautomerization in porphycenes served as a tool for spectroscopy, this time enabling exact molecular orientation.

33.5 Summary and Outlook

Structural, spectral, and photophysical characteristics of porphycenes make them equally attractive for fundamental research and applications. With regard to the latter, the results described in this work provide a basis for custom-designing porphycene-related chromophores for a specific purpose. For instance, the finding that the fluorescence intensity of *meso* derivatives is strongly viscosity dependent suggests their use as local microviscosity probes. Probing the interior of a cell is a challenging perspective, especially because the same porphycene chromophore could be, in principle, used not only as a viscosity reporter, but also as a phototherapeutic and/or photodiagnostic agents. The effectiveness of porphycenes in phototherapy has been convincingly demonstrated for numerous derivatives.^{18,59} The main obstacle to general applications lies in difficult and costly synthesis, but progress is being reported.^{60–62}

Studies of tautomerization in porphycenes are closely linked to the investigations of hydrogen bond. In this respect, porphycenes are unique for several reasons. First, using “mild” alkyl substituents, one is able to manipulate the dimensions of the inner cavity, and thus the strength of intramolecular hydrogen bonds. This enables systematic studies of double hydrogen transfer rates as a function of hydrogen bond properties expressed in terms of such parameters as distances, angles, or chemical shifts. These studies have brought spectacular results. Changing the N–N separation by 0.27 Å, from 2.80 Å in 2,3,6,7,12,13,16,17-octaethylporphycene to 2.53 Å in 9,10,19,20-tetramethylporphycene results in more than three orders of magnitude increase in the tautomerization rates, both in the ground and lowest excited electronic states. Such behavior is strongly suggestive of tunneling, a phenomenon whose occurrence is not easy to prove in condensed phase studies. On the other hand, coherent double hydrogen tunneling has now been demonstrated in the isolated molecule regime for parent porphycene and two *meso* alkyl-substituted derivatives. Moreover, these studies have revealed the mode-selective character of tunneling by showing that the values of tunneling splitting are strongly vibration dependent.

Of particular value is the possibility to study the same phenomenon in the same molecule in two completely different regimes. A challenging problem is to interpret the tunneling splitting data, obtained for isolated molecules, along with the rates determined from condensed phase studies. In a simple 1D picture, the residence time of a particle oscillating between two wells is given by \hbar/Δ , where Δ is the tunneling splitting. Assuming $\Delta = 4.4\text{ cm}^{-1}$, the value obtained for porphycene yields the residence time of 7.6 ps, of the same order as the lifetime of 1.7 ps obtained for porphycene in solution at 293 K. For $\Delta = 12\text{ cm}^{-1}$, the value observed for the 181 cm^{-1} mode, the residence time decreases to 2.8 ps. There is no doubt that tautomerization in porphycenes is a multidimensional phenomenon, and therefore, the process may be crucially dependent on the mode of vibrational excitation. This opens up a field for designing experiments that could result in laser control of the reaction. It should be noted that the techniques for monitoring the process in the condensed phase are based on pump-probe polarized spectroscopy, and the reaction kinetics is directly related to the measured temporal anisotropy profile. This is in contrast to an alternative technique, NMR relaxometry, which relies on the assumed values of hydrogen bond distances and angles. We also note that the tautomerization rate in porphycene is larger than the rate of vibrational cooling. This provides an opportunity to study hydrogen transfer rates in a nonequilibrated system.

The data accumulated so far strongly suggest that the tautomerization occurs in a concerted fashion. This is in line with cooperative coupling of the two intramolecular hydrogen bonds, demonstrated by NMR³⁰ and theoretical³¹ studies of geometric H/D isotope effects. However, the movement of the two inner hydrogens need not necessarily be synchronous. The exact description of the transfer is a

challenge for both experiment and theory. For the latter, it should be kept in mind that tunneling cannot be neglected, even when considering the system at room temperature.

Another challenge for the theory is to properly characterize the tautomerization path, both for the ground and electronically excited states. So far, the theory succeeded in predicting very different energy values for the stationary and transition states in porphyrin and porphycene. These results allowed explaining different tautomerization mechanisms in the two isomers.³⁶ The concerted mechanism of double hydrogen transfer in porphycene results from the fact that the energy required for the *trans-trans* conversion (most probably, with tunneling involved) is lower than the *cis-trans* energy difference. In the case of porphyrin, it is more favorable to first populate the *cis* tautomer, from which the second hydrogen transfer can occur.

The methodologies developed for studying the self-exchange processes are relatively simple and can be extended to all processes that lead to a change of transition moment directions. They are also not limited to electronic absorption/emission measurements, but can be applied in other areas, such as IR spectroscopy.

Finally, porphycenes turned out to be good chromophores for single molecule spectroscopy experiments. This fact, combined with their spectroscopic, photophysical, and phototherapeutic properties, makes this class of molecules very promising for future biology and medicine-related studies.

Acknowledgments

I am indebted to many colleagues who contributed to the results presented in this work: Michał Gil, Hubert Piwoński, Natalia Urbańska, Alexander Vdovin, Piotr Fita, Czesław Radzewicz, Oksana Pietraszkiewicz, Marek Pietraszkiewicz, Jerzy Sepioł, Alfred Meixner, Alkwin Slenczka, Bernhard Dick, Achim Hartschuh, Clemens Stupperich, Jacek Dobkowski, Paweł Borowicz, Grażyna Orzanowska, Sylwester Gawinkowski, Andrzej Mordziński, Alexander Starukhin, Alexander Kyrychenko. I am especially grateful to Emanuel Vogel and Josef Michl, who stimulated my interest in porphycenes. This work was partially supported by the grant N20414132/3545 from the Polish Ministry of Science and Higher Education.

34.1 Introduction

Photochemistry of the porphyrins and their relatives has been largely inspired by photosynthetic processes in nature. As a result of this, most current studies generally utilize the chemistry of magnesium and zinc porphyrin analogues. Especially, magnesium tetrapyrrole chelates, that is, magnesium porphyrins and phthalocyanines, have found wide interest. This is primarily related to the biological relevance of magnesium porphyrins in nature, notably in photosynthesis and electron transfer (ET), and thus, we will focus on this aspect in this review. Outside these areas, not many “true” photochemical studies have been performed with magnesium tetrapyrroles.

Although porphyrins and especially phthalocyanines are stable compounds, both will undergo photooxidative degradation or photoexcited ET reactions. An additional problem of magnesium complexes is their low stability in aqueous solution, as they are prone to demetallation. As a result of this, many photochemical studies targeted at modeling the natural situation use the more stable zinc complexes. Zinc derivatives exhibit photochemical properties similar to the natural magnesium derivatives while being more stable and easier to synthesize (Li et al. 1997). Secondly, the propensity of zinc to act as an acceptor atom is used in many supramolecular approaches and/or for the modulation of chromophore properties *via* axial ligand binding. Thus, due to their biological relevance, technical importance, and good stability, substituted zinc tetrapyrroles have found significant use as industrial pigments and ET components, for photochemical transformations, and in photobiotechnology. Likewise, industrial attention has been given to the stable copper derivatives and copper tetrapyrroles have found industrial uses for oil desulfurization, as photoconducting agents in photocopiers, deodorants, germicides, optical computer disks, semiconductor devices, photovoltaic cells, optical and electrochemical sensing, and as molecular electronic materials.

However, even in this area, the body of the available literature is overwhelming and we will only use selected examples to highlight the state of the art of this field. A description of syntheses, methodology, or ET reactions with the various associated model systems is outside the purview of this work and the present work aims to give a broad overview and highlights selected examples in this area.

34.2 Basic Photochemistry of Porphyrins and Phthalocyanines

34.2.1 General Concepts and Theoretical Background

Tetrapyrroles are heteroaromatic macrocycles, where the aromatic character of the tetrapyrrole moiety, the central metal, and the reactivity of the functional groups in the side chains govern their chemistry. The tetrapyrrole ligands coordinate almost any known metal with the core nitrogen atoms. Together with the conformational flexibility of the macrocycle and the variability of its side chains, this accounts for their unique role in photosynthesis, medicine, biochemistry, and other applications (Senge 1992a,b, Kadish et al. 2000a,b, 2003).

Porphyrins and phthalocyanines **1–3** are well-known representatives of the tetrapyrrole class of heteroaromatic compounds and they are closely related. Tetraazaporphyrin (or porphyrazine) **2** is the first member of the phthalocyanine class. In phthalocyanines, the carbon atoms of the methine bridges (positions: 5, 10, 15, and 20 in **1**) are replaced by four nitrogen atoms and the parent structure of a phthalocyanine is structure **3**, formally a tetrabenzotetraazaporphyrin.

Tetrapyrroles contain an extended π -conjugated system, which is responsible for their use in many applications ranging from technical (pigments, catalysts, photoconductors) to medicinal (photodynamic therapy) uses. The electronic absorption spectra are controlled by the aromatic 18

π -electron system and typically consist of two main bands. In phthalocyanines, the Q band around 660–680 nm is the most intense one and is accompanied by a weaker Soret band near 340 nm (Nyokong and Isago 2004). In porphyrins, the situation is reversed with an intense Soret band around 380–410 nm and weaker Q bands in the 550–650 nm region. The position and intensity of the absorption bands are affected by the central metal, axial ligands, solvation, substituents and their regiochemical arrangement, and aggregation. The theoretical background has been widely reviewed and established in pioneering works by Gouterman and Stillman (Gouterman 1978, Mack and Stillman 2003). The spectral characteristics strongly depend on the substituent pattern. By now almost all possible combinations of electron donating, electron withdrawing or sterically demanding groups have been prepared. Tetrapyrroles behave like most other organic chromophores. The absorption of light results in the rapid formation of the lowest excited singlet state *via* promotion of an electron from the highest occupied molecular orbital (HOMO) to the lowest unoccupied molecular orbital (LUMO). The excited state can then either relax to the ground state *via* radiative (fluorescence) or nonradiative processes (internal conversion of vibrational relaxation). Another possibility is intersystem crossing to form a triplet state, which again can relax either *via* radiative (phosphorescence) or nonradiative processes. In our context, both types of excited states can take part in photochemical reactions and, in the presence of donor or acceptor units, energy or ET between the chromophores can compete with these processes (Gust and Moore 2000). In addition, metalloporphyrins and phthalocyanines may form ions upon illumination. These are either anion or π -cation radicals and can undergo further photochemical reactions (Senge and Sergeeva 2006, Sergeeva and Senge 2008). Numerous reviews have been published in this area, the most comprehensive ones being by Wasielewski (1992) and by Gust et al. (2001). Recent studies have addressed questions of regiochemistry, theoretical calculations, solubility, and the influence of sterically demanding or heteroatom containing substituents (Flamigni 2007, Lo et al. 2007, Takagi et al. 2006).

34.2.2 Photophysics of Metallated Tetrapyrroles

The basic photochemical behavior of magnesium tetrapyrroles is similar to that of other metallo tetrapyrroles. Magnesium porphyrins (Fajer et al. 1970, Smalley et al. 1983, Slota and Dyrda 2003) and phthalocyanines (Bobrovskii and Kholmogorov 1973, Kim 1986, van Willigen and Ebersole 1987, Ough et al. 1991) may form cation radicals and ions via the triplet state upon illumination. For (phthalocyaninato) magnesium, both photochemical oxidations and reductions have been shown to occur. In the presence of carbon tetrabromide as an irreversible electron acceptor, the mechanism proceeds via the radical cation (Stiel et al. 1994). The suggested mechanism for the photochemical oxidation is through the lowest lying triplet state of the phthalocyanine and is thought to be similar to that of porphyrins such as (2,3,7,8,12,13,17,18-octaethylporphyrinato) magnesium and (5,10,15,20-tetraphenylporphyrinato) magnesium.

Copper ions are known to be excited state quenchers with the partially filled d orbitals. Copper(II) ions are capable of fluorescence quenching through electron or energy transfer. Furthermore, Cu(II), with its d^9 valence electron configuration, is paramagnetic. These special features have a strong influence on the subsequently discussed photochemical tetrapyrrole transformations. Copper(II) porphyrins are interesting complexes from both a theoretical and experimental point of view. The unpaired electron in the $d_{x^2-y^2}$ orbital couples with the normal porphyrin (π, π^*) excited states to form the singdoublet [$^2S(\pi, \pi^*)$], tripdoublet [$^2T(\pi, \pi^*)$], and quartet [$^4T(\pi, \pi^*)$] states (Kim et al. 1984). These complexes do not exhibit the typical fluorescence of closed-shell metalloporphyrins, but rather show moderately strong phosphorescence from the tripdoublet-quartet manifold (Smith and Gouterman 1968, Eastwood and Gouterman 1969, Gouterman et al. 1970, van Dijk et al. 1981, Bohandy and Kim 1983). The relaxation processes in excited copper porphyrins (CuP) have been extensively studied by picosecond transient absorption spectroscopy (Hilinski et al. 1984, Serpone et al. 1984, Kruglik et al. 1995). It was found that photoexcitation of a CuP in the $^2S_0 \rightarrow ^2S_n$ channel was followed by an extremely fast (1 ps) intersystem crossing to the

excited 2T_1 state, thus suppressing porphyrin fluorescence. The equilibrium formation between the 2T_1 and 4T_1 states proceeds within hundreds of picoseconds. The splitting between the excited 2T_1 and 4T_1 states for different Cu-porphyrins varies, depending on the porphyrin macrocycle structure.

Similar to metalloporphyrins, the central metal in metallophthalocyanines has a significant effect on the nature and the lifetime of the excited states. An interesting feature of metallophthalocyanines is their ability to participate in stacked assemblies with others or with metalloporphyrins. Investigations of these assemblies have shown that metallophthalocyanines with transition metals often display an excited-state relaxation pathway associated with the interactions of the macrocyclic π -system and d-orbitals of the central metal. Although H_2Pc and $Zn(II)Pc$ are both strongly fluorescent probes in room-temperature emission experiments, neither fluorescence nor phosphorescence was observed for $Cu(II)Pc$. Implicit in the fluorescence silence is an ultrafast deactivation of the initially excited state of this paramagnetic compound with a d_9 -metal center. A similar mechanism has been proposed for the analogous CuP , which showed, however, activation of moderately strong and long-lived phosphorescence as a result of thermally equilibrated triplet-doublet/triplet-quartet states (Sergeeva and Senge 2010). Due to the comparable nature of the porphyrin and phthalocyanine macrocycles and binding of the transition-metal center (i.e., Cu-N), it is likely that a similar ultrafast deactivation pattern governs the photophysics of copper phthalocyanine ($CuPc$).

Many spectroscopic studies provide details on magnetic interactions and spin dynamics of states with different multiplicities, such as doublets, triplets, and charge-transfer states. The communication between these states strongly depends on the temperature and the solvent, and the spectroscopic studies established the existence of radical species deduced through ps optical experiments and the corresponding theoretical calculations.

34.3 Photosynthesis

The natural photosynthetic process is a rather complex biochemical system that primarily relies on the light absorption by organic chromophores, followed by generation of reduction equivalents and ATP. The main photosynthetic pigments are chlorophylls or bacteriochlorophylls that have very strong absorption bands in the visible region of the spectrum. Together with accessory pigments (carotenoids and open-chain tetrapyrroles), the various photosynthetic pigments complement each other in absorbing sunlight. Photosynthetic bacteria mostly contain bacteriochlorophylls with absorption maxima shifted toward the bathochromic region compared to the chlorin-based pigments.

In its simplest form photosynthesis can be described as the absorption of light through pigments arranged in a light-harvesting complex. These antenna systems permit an organism to increase greatly the absorption cross section for light and the use of light harvesting complexes with different pigments allows for a more efficient process through absorption of more photons and a more efficient use of the whole visible spectrum. The antenna pigments funnel the excitation energy through exciton transfer to a closely coupled pair of (b)chl molecules in the photochemical reaction center (Figure 34.1). The reaction center is an integral membrane pigment-protein that carries out light-driven ET reactions. The excited (bacterio) chlorophyll molecule transfers an electron to a nearby acceptor molecule, thereby creating a charge-separated state consisting of the oxidized chlorophyll and the reduced acceptor.

After the initial ET event, a series of ET reactions takes place that eventually stabilizes the stored energy in reduction equivalents and ATP. Higher plants have two different reaction center complexes that work together in sequence, with the reduced acceptors of one photoreaction (photosystem II) serving as the electron donor for photosystem I. Here, the ultimate electron donor is water, liberating molecular oxygen, and the final electron acceptor is carbon dioxide, which is reduced to carbohydrates. More simple and evolutionary older types of photosynthetic organisms contain only a single photosystem, either similar to photosystem II or photosystem I (Raghavendra 1998, Kadish et al. 2000a,b, van Grondelle and Novoderezhkin 2006). A simplified scheme of the complex photosynthetic apparatus is shown in an adaptation of the Z-scheme in Figure 34.2. The Z-scheme illustrates the two light-dependent reactions in photosynthetic systems of higher plants and exemplifies that two photosystems function in sequence to convert solar energy into chemical energy.

FIGURE 34.1 Cartoon scheme of a photosynthetic system (RC = reaction center, DA = donor–acceptor complex, LHC = light harvesting complex).

FIGURE 34.2 Simplified Z-scheme of the photosynthetic apparatus in higher plants.

In chemical terms the photoinduced electron transfer (PET) results in transfer of an electron across the photosynthetic membrane in a complex sequence that involves several donor–acceptor molecules. Finally, a quinone acceptor is reduced to a semiquinone and subsequently to a hydroquinone. This process is accompanied by the uptake of two protons from the cytoplasm. The hydroquinone then migrates to a cytochrome bc complex, a proton pump, where the hydroquinone is reoxidized and a proton gradient is established via transmembrane proton translocation. Finally, an ATP synthase utilizes the proton gradient to generate chemical energy. Due to the function of tetrapyrrole-based pigments as electron donors and quinones as electron acceptors most biomimetic systems utilize donor–acceptor constructs to model the natural photosynthetic process (Figure 34.3). Variation of the components (donor, bridge, linking group, acceptor),

FIGURE 34.3 Schematic view of a biomimetic ET compound.

their spatial relationship, solvents, and environmental factors then serves to modulate and optimize the physicochemical properties. Several thousand systems of this general type have been prepared and used for investigation of the PET and numerous reviews have been published in this area (Wasielewski 1992, Gust and Moore 2000). Most of the available literature on ET studies in donor–acceptor compounds focuses on porphyrins. Phthalocyanine building blocks have been used more rarely, a result of their low solubility and the lack of appropriate synthetic methodologies to selectively introduce functional groups or for the synthesis of unsymmetrically substituted derivatives. However, this situation is rapidly changing with the renewed interest in solar energy conversion systems. An overview of the various synthetic and structural principles to model the components of the photosynthetic apparatus has been given in the relevant chapter on zinc(II) porphyrins (Senge and Sergeeva 2006).

34.3.1 Chlorophylls and Related Pigments

Chlorophylls (chl) and bacteriochlorophylls (bchl) are the ubiquitous pigments of photosynthetic organisms and the predominant class of magnesium tetrapyrroles in nature. As such they share common structural principles and functions. They are either involved in light harvesting (exciton transfer) as antenna pigments or charge separation (ET) as reaction center pigments. The best-known pigment is chl *a* **4**, which occurs in all organisms with oxygenic photosynthesis. In higher plants it is accompanied in a 3:1 ratio by chl *b* **6**, where the 7-methyl group has been oxidized to a formyl group. Both compounds typically consist of the tetrapyrrole moiety and a C-20 terpenoid alcohol, phytol. Most compounds are magnesium chelates, but the free base of chl *a*, pheo *a* **5**, is also active in ET. Chl *a* and *b* can be obtained easily from plants or algae and their synthetic chemistry has mainly targeted total syntheses and medicinal application in photodynamic therapy (PDT) (Scheer 1991, Senge 1992b).

However, many other similar photosynthetic pigments occur in nature (Scheer 1991, Senge 1992a,b, Senge and Richter 2006, Sergeeva and Senge 2008). All share either a phytychlorin **7** or a 7,8-dihydro-phytychlorin framework and more than 100 related pigments have been isolated (Senge et al. 2006). For example, these compounds include chl *d* **8** from Rhodophytes, the bchls *c* **9**, *d*, and *e* (which are chlorins **12** and show significant variability in their peripheral groups) from Chlorobiaceae and Chloroflexaceae, and bchl *a* **10** and *b* (true bacteriochlorins **13**) found in Rhodospirillales. Other natural pigments are chl *c* and bchl *g*, and many of these are esterified with different isoprenoid alcohols. Chemically related chlorins have also been found in many oxidoreductases, marine sponges, tunicates, and in *Bonella viridis*. The deep-sea dragon fish *Malacosteus niger* utilizes a chl derivative as a visual pigment (Douglas et al. 1998). These compounds are derived from chl and then processed by the plant or animal.

Photosynthetic organisms that utilize chls or bchls containing metals other than Mg were unknown for a long time (Hiraishi and Shimada 2001). Past years have seen increasing evidence that both Mg and Zn chlorophylls do exist in nature. By now it has been satisfactorily demonstrated that a purple pigment occurring in a group of obligatory aerobic bacteria is in fact a zinc-chelated-bchl (Zn-bchl) (Wakao et al. 1996, 1999, Hiraishi et al. 1998). The natural occurrence of Zn-bchl *a* has been proven for a limited group of aerobic acidophilic proteobacteria, including species of the genus *Acidiphilium*. The major photopigment in *Acidiphilium* was first identified tentatively as Mg-bchl *a* on the basis of preliminary spectral analyses (Wakao et al. 1993, Kishimoto et al. 1995). However, more detailed studies revealed that all previously known species of *Acidiphilium* contained Zn-BChl *a* as the major photopigment and showed *Acidiphilium* to be a photosynthetic organism (Wakao et al. 1996, Hiraishi et al. 1998).

The naturally occurring Zn-bchl *a* and Mg-bchl *a* show large structural similarities and have very similar physicochemical characteristics (Scheer and Hartwich 1995). Likewise, Zn-chl *a* exhibits features similar to Mg-chl *a* with regard to redox potential and absorption maxima in organic solvents. The light-harvesting efficiency of Zn-chl *a* and Mg-chl *a* are very similar, although the fluorescence quantum yield of the former is lower than the latter. Compared to other chlorophyll-type pigments, Zn-bchl *a* is much more stable toward acid. For example, the rate of pheophytinization for Zn-bchl *a* is 10⁶-fold slower than for Mg-bchl *a* (Kobayashi et al. 1998). In fact, it is difficult to fully demetallate Zn-bchl *a* to bacteriopheophytin (BPhe) by treatment with 1N HCl, which is commonly used for pheophytinization of Mg-bchl and Mg-chl. Due to the chemical stability of Zn-(b)chl *a* and their photo- and electrochemical similarities with Mg-(b)chl *a*, Zn-(b)chls are an alternative pigment for photosynthetic studies. Thus, it is not surprising that they have been used along with magnesium porphyrins in studies on artificial photosynthetic systems (Wasielowski and Niemczyk 1984, Osuka et al. 1993a,b).

34.3.2 Light-Harvesting Complexes and Reaction Center Models

The propensity of metal tetrapyrroles for aggregation has been widely used to mimic natural antenna systems of photosynthesis. The best studied system is the chlorosome, where bacteriochlorophylls self-organize *without* the use of a protein scaffold. Depending on the light conditions these require constructing arrays with as many chromophores as possible. Thus, many studies on the self-assembly of bacteriochlorophyll model compounds or dendritic/polymeric approaches have been performed (Haycock et al. 2000, Ikeda et al. 2001). Current studies focus on large aggregates and chirality effects (Balaban et al. 2003). A typical example involves perylene monoimide donors that have been used to construct antenna models in which up to 8 perylene units were covalently bound to a zinc(II) porphyrin (Tomizaki et al. 2002). Osuka and coworkers' windmill porphyrins also present excellent antenna complex building blocks (*vide infra*) (Nakano et al. 2001). In addition, several "porphyrin wheel" antenna complexes were prepared by template-assisted synthesis (Yu and Lindsey 2001, Tomizaki et al. 2003) or self-aggregation (Kuramochi et al. 2004). Intramolecular cyclization of porphyrin dodecamers to a porphyrin wheel has also been achieved (Peng et al. 2004).

Classic examples for structural models of the photosynthetic reaction center are the cofacial bisporphyrins or bischlorins (Kalisch et al. 1998), which model the structural arrangement of the

special pair in the reaction center (Pascard et al. 1993, Brettar et al. 2001, Fletcher and Therien 2002). Zinc(II) bisporphyrins with various other geometrical arrangements, for example, skewed (Shultz et al. 1999), have been prepared as well, including those bearing C_{60} acceptor groups (Liddell et al. 2004). The important two-tetrapyrrole-unit found in the special pair has by now been realized in a multitude of different geometrical arrangements. Depending on the porphyrin-porphyrin or porphyrin-acceptor linkage meso-meso, meso- β (Senge et al. 2004), and β - β (Deng et al. 2000) linked systems have been prepared. Similar arrangements are also possible using noncovalent self-assembly. Noncovalent binding of substrates at the zinc(II) center can be used to control the PET in such systems (Yagi et al. 2003)

Today, most reaction center models carry suitable antenna pigments and acceptor groups and in effect are photosystem models. A typical example for a state of the art system that incorporates many aspects of a photosystem consisted of a boron dipyrin covalently linked to a zinc(II) porphyrin, which carried a suitably modified C_{60} derivative as axial ligand. Selective excitation of the boron dipyrin as antenna pigment resulted in energy transfer to a zinc(II) porphyrin followed by ET to the C_{60} acceptor (D'Souza et al. 2004a). These and other photoactive complexes will be discussed in more detail later in the section on ET systems.

34.4 Electron Transfer Systems and Photochemical Reactions

34.4.1 Introduction

Studies on photoinduced energy and ET in supramolecular assemblies have witnessed a rapid growth in the past decade. Most of these studies focused on the mechanistic details of light-induced chemical processes. Researchers attempt to generate systems with ultra fast charge transfer and charge recombination applicable as light-induced switches or with long lived charge-separated states to mimic the photosynthesis or for solar energy conversion (Iseki and Inoue 1994). The development of novel photochemically active systems has focused on polychromophoric, dendritic, supramolecular systems, and novel materials. These endeavors have produced an expanding body of information on porphyrin/phthalocyanine dyads, their design, and energy, exciton, and charge transfer properties. Incorporation of these systems into larger architectures now offers the possibility for applications in molecular photonics, electronics, solar energy conversion, nanomaterials, and quantum optics.

Most ET studies are aimed at the synthesis and investigation of donor-acceptor complexes that mimic the natural processes. Typically, this involves the construction of systems consisting of donor(s), a covalent or noncovalent bridging unit, and acceptor(s) (Figure 34.4). In an ideal situation, all requirements of the natural system would be modeled. These include (1) unidirectional ET \rightarrow redox gradient in subunits; (2) rigid linker groups that do not play a role in ET \rightarrow no heteroatoms, conjugated systems, etc.; (3) defined overall geometry with correct relative orientation of the subunits \rightarrow for example, special pair model with cofacial orientation of the macrocycles \rightarrow use of coupling reactions that give products with defined geometry; and (4) modeling the protein environment \rightarrow scaffold, electronic, and steric effects/reconstituted pigment-protein systems.

FIGURE 34.4 Synthetic model of a natural photosynthetic system.

34.4.2 Donor–Acceptor Electron Transfer Compounds

Most of the available literature on ET studies in donor–acceptor compounds focuses on porphyrins. Phthalocyanine building blocks have been used less often, a result of their low solubility and (until recently) the lack of appropriate synthetic methodologies to selectively introduce functional groups or for the synthesis of unsymmetrically substituted derivatives.

The simplest covalently linked systems consist of porphyrin linked to electron acceptor or donor moiety with appropriate redox properties as outlined in Figure 34.3. Most of these studies have employed free base, zinc and magnesium tetrapyrroles because the first excited singlet state is relatively long-lived, so that ET can compete with other decay pathways. Additionally, these pigments have relatively high fluorescence quantum yields. These tetrapyrroles are typically linked to electron acceptors such as quinones, perylenes (Yang et al. 2001a,b, Fukuzumi et al. 2005), fullerenes (El-Khouly et al. 2005, D'Souza et al. 2005), acetylenic fragments (**11**,**12**), aromatic spacers (Li et al. 1997, Youngblood et al. 2002, Mitzel et al. 2003, Chandra et al. 2003), and other tetrapyrroles (e.g., boxes and arrays).

Biomimetic systems composed of porphyrins and quinones have been studied extensively with regard to their ET and charge transfer properties. Porphyrin-quinone (PQ) model systems in which the quinone is fused directly to the porphyrin periphery therefore have a special relevance for the fundamental understanding of rapid biological ET reactions as they are related to photosynthesis and solar energy conversion. In many cases, the magnitude of the reduction potentials of quinones covalently linked to porphyrins suggests light-induced radical-pair generation. However, use of quinones as acceptors decreases the energy that can be stored in the photoinduced radical pair, thus diminishing the likelihood of a mechanism via radical-pair generation (Connolly 1982). Many artificial systems with wide range of functionalized quinine units have been synthesized and extensively studied (Gust and Moore 2000). Here, we will only highlight selected recent works.

A series of “black” (tris- and tetra- β -quinonoporphyrinato)zinc(II) chelates was prepared via thermolysis of a tetra- β -sulfolenoporphyrin in the presence of excess benzoquinone followed by oxidation with dicyanodichlorobenzoquinone in up to 86% yield. Surprisingly, the absorption spectra of these tetrapyrroles represent broad and intense electronic transitions covering the whole range of visible wavelengths region (Banala et al. 2009).

While most studies utilized quinones as acceptor compounds, these studies almost exclusively used *p*-quinones. Nevertheless, the isomeric, but synthetically less accessible porphyrin-*o*-quinones are much better electron acceptors (Giangiacomo and Dutton 1989). This results in a higher ΔG_{ET} and thus in a higher efficiency of the ET and several *o*-quinone containing zinc(II) porphyrin dyads (e.g., **14–16**), triads, and tetrads have been prepared by us (Speck et al. 1997, 2000, Senge et al. 2003). In order to achieve a variation of ΔG_{ET} , the general strategy in ET studies generally involves the synthesis of different models via chemical modification of the porphyrin donor or the quinone acceptor. However, this also leads to changes in a number of other variables such as distance, solvent term, and electronic matrix element resulting in altered ET rates. Here, the utilization of porphyrin-*o*-quinones as ET systems offers an attractive alternative. With them, a facile and simple variation of ΔG_{ET} can be achieved by using the in situ formed semiquinones for metal chelation (Figure 34.5) (Speck et al. 2002). Some of the sterically hindered parent free base systems (e.g., free base of **6**) can undergo photochemical degradation reactions. However, such side reactions were not observed with the zinc(II) complexes (Speck et al. 1997, 2000).

Although the importance of these compounds as structurally simple models with large electronic donor–acceptor coupling has long been recognized, only few examples of magnesium containing systems have been reported so far. For mechanistic studies, it is essential to have acceptor moieties other than quinones with systematically variable reduction potentials so that the energy of P^+-A^- falls between the energies of the excited singlet and triplet states and beyond. CuP and CuPc play a very important

FIGURE 34.5 Porphyrin-*o*-quinone systems.

role in the ET processes. One example for alternatives to PQ model systems are the copper picryl porphyrins **17** (Maiya and Krishnan 1985). Here, the interaction between the porphyrin and trinitroaryl group is relatively stronger than in PQ systems (Yamada et al. 1983).

Novel systems of zinc porphyrin containing fluorescent dyes attached to the surface of bacteriophage MS2 enabled energy transfer and sensitization of the porphyrin at previously unavailable wavelengths and participated in the photocatalytic reduction reactions at multiple excitation wavelengths (Stephanopoulos et al. 2009).

Viologen (4,4'-bipyridyl) derivatives are attractive electron-accepting units for tetrapyrrole-containing dyads and more complex donor-acceptor systems as they can be easily reduced, conveniently linked to other molecules via *N*-alkylation of precursors, and can be used to vary the solubility in polar solvents by virtue of their charged nature. Based on the fact that the viologen radical monocation absorbs in the visible region they can be used as convenient charge separation indicators. As a result, a number of magnesium porphyrins (Szulbinski 1995, Zakrzewski and Giannotti 1995) and phthalocyanine (Harriman et al. 1981, Ohtani et al. 1984)–viologen systems have been studied. Typically, excitation of a porphyrin-viologen dyad **18** leads to the porphyrin first excited singlet state, which can then induce photoelectron transfer to the viologen or undergo intersystem crossing to yield the porphyrin triplet state. As viologen is easily reduced, the porphyrin triplet state may also act as an electron donor in these systems.

A different strategy involves using a transition metal center linked to an organic chromophore. This greatly expands the number of electron/energy transfer reactions that can take place within the assembly compared to pure organic or inorganic–organometallic systems. Covalently linking metal complexes to porphyrins yields a cornucopia of candidates for photosynthesis-related studies. Again, only a few examples of photoinduced processes based on magnesium phthalocyanine (Kobyshev et al. 1963) and porphyrins (Monnereau et al. 2005, Gabrielsson et al. 2006) have been reported so far (e.g., compounds **19** and **20**).

For example, in 1963, the photochemistry of magnesium phthalocyanine with coordinated uranium cations was studied in pyridine and ethanol and indicated the occurrence of PET to the uranium complex (Kobyshev et al. 1963). A rapid PET (2–20 ps) followed by an ultra fast charge recombination was shown for various zinc and magnesium porphyrins linked to a platinum terpyridine acetylide complex (Monnereau et al. 2005). The results indicated the electronic interactions between the porphyrin sub-unit and the platinum complex, and underscored the potential of the linking *p*-phenylene bisacetylene bridge to mediate a rapid ET over a long donor–acceptor distance.

Complexes of rhenium(bipyridine)(tricarbonyl)(picoline) units linked covalently to magnesium tetraphenylporphyrins via an amide bond between the bipyridine and one phenyl substituent of the porphyrin **20** exhibited no signs of electronic interaction between the Re(CO)₃(bpy) units and the metalloporphyrin units in their ground states. However, emission spectroscopy revealed a solvent-dependent quenching of porphyrin emission upon irradiation into the long-wavelength absorption bands localized on the porphyrin. The presence of the charge-separated state involving ET from Mg(II)/TPP to Re(bpy) was shown by time-resolved IR spectroscopy (Gabrielsson et al. 2006).

The system is reversible in the absence of an added electron donor but undergoes irreversible reaction at the reduced rhenium bipyridine center in the presence of added triethylamine. The observation of

reaction at the rhenium site upon excitation in the absorption band of the metalloporphyrin site is compatible with an ultra fast back ET provided that the triethylamine coordinated to the magnesium prior to absorption and that the ET from the metalloporphyrin to the bipyridine was followed rapidly by irreversible ET from the triethylamine to the metalloporphyrin. The experiments graphically demonstrated the benefits of the incorporation of carbonyl ligands at the electron acceptor as they allowed a tracking of the sequence of charge separation and back ET via time-resolved IR data (Gabrielsson et al. 2006).

Applications of fullerenes in PET studies derive from the fact that back ET is inhibited in donor-acceptor systems incorporating [60]fullerene (C_{60}). Fullerenes can accept up to 6 electrons and exhibit small reorganization energies while the photoinduced charge separation is accelerated and charge recombination is slowed. The effect of the introduction of C_{60} as an electron acceptor into tetrapyrrole molecules should enhance our knowledge of the dependence of PET dynamics on molecular topology. Thus, relatively long-lived charge-separated states are obtained without a special environment such as an apoprotein (Imahori et al. 2002a). Several self-assembled donor-acceptor systems containing fullerenes as three-dimensional (3-D) electron acceptors and porphyrins as electron donors have been described. A recent system consisting of a ferrocene, two porphyrins, and one C_{60} unit exhibited a life-time of 1.6 s (!), comparable to bacterial photosynthetic reactions centers. The quantum yields for charge separation in complex biomimetic systems can reach unity. Recent advances in their synthetic methodologies allow the functionalization of fullerenes and linking them to other pigments.

Fullerenes [mostly C_{60} but also C_{70} (Kesti et al. 2003)] have been incorporated into multicomponent systems with step-wise charge separation (Bell et al. 2002, Imahori et al. 2002a,b, 2004, Kesti et al. 2003, Imahori 2004, Imahori and Fukuzumi 2004) and used as core groups for dendrimers with zinc(II) porphyrin donors (Camps et al. 1999). Already, C_{60} has also been linked to chlorins and phytychlorin derivatives (Helaja et al. 1999, Fukuzumi et al. 2001) and carotenoid-porphyrin- C_{60} systems are under investigation (Kodis et al. 2004). Many of these systems utilize a pyrrolidine linkage, but bislactone (Montforts et al. 2003), or Diels-Alder derived cyclohexene-linked systems (Fukuzumi et al. 2001, Bell et al. 2002) have also found wide applications. Currently, nanostructured systems are emerging (Yamaguchi et al. 2003) and new attention has been focused on combining the utility of fullerene acceptor groups with rotaxane systems (Watanabe et al. 2003, Schuster et al. 2004, Li et al. 2004a,b). Zinc(II) porphyrins have been used in many systems for complexation studies (Guldi et al. 2001) and to modulate the ET properties by using axial coordination effects (D'Souza et al. 2001, 2002a,b) or to construct self-assembled donor-acceptor systems (D'Souza et al. 2002a, 2003, 2004b).

For example, pyridinofullerenes were used as axial ligands for Zn(II)TPP or Zn(II)OEP and the formation of the noncovalent porphyrin-fullerene dyads was indicated by fluorescence quenching of Zn(II)TPP (Wilson et al. 2004). This PET is an exergonic process (D'Souza et al. 1999). PET in nonpolar media was reported for porphyrin tripod fullerene systems synthesized via "click" chemistry (Takai et al. 2010). Likewise, a photoactive [2]catenane containing zinc(II)-porphyrin (ZnP) and/or [60]fullerene (C_{60}) as appended groups also prepared via "click" chemistry was described as well (Megiatto et al. 2010). For a related triad (C_{60} + 2Zn(II) porphyrins), it was shown that the main quenching pathway involved charge separation from the excited singlet state Zn(II)TPP to the C_{60} unit in noncoordinating solvents and from the triplet excited state of Zn(II)TPP in coordinating solvents (El-Khouly et al. 2003). Porphyrin-fullerene dyads with an azobenzene linker were synthesized, and the photophysical-chemical properties were investigated using steady-state and time-resolved spectroscopic methods (Schuster et al. 2007). Photosynthetic models containing dendritic C_{60} - H_2P -(ZnP)₃ conjugates were analyzed in relation to the primary events in photosynthesis, that is, light harvesting, unidirectional energy transfer, charge transfer, and charge-shift reactions (Schludt et al. 2009). Similar approaches have been used with zinc(II) phthalocyanines (Guldi et al. 2002). Some of the characteristics of fullerene containing systems, for example, recombination to the triplet state, were also observed with specifically designed triads without a fullerene unit (Gould et al. 2004).

In line with the general development in the field noncovalently and covalently linked Mg porphyrin-fullerene, dyads have been synthesized and investigated spectroscopically (El-Khouly et al. 2005,

D'Souza et al. 2005). For example, a covalently linked magnesium porphyrin-fullerene (MgP-C_{60}) dyad with a flexible ethylene dioxide bridge (El-Khouly et al. 2005) was compared to a self-assembled noncovalently linked dyad ($\text{MgP}\cdots\text{C}_{60}\text{Im}$, **21**). In the latter, axial coordination of an imidazole (Im)-functionalized fullerene (D'Souza et al. 2005) to the magnesium porphyrin was used for bonding. Significant increases in the lifetime of the charge-separated states were observed upon coordinating nitrogenous axial ligands to the latter.

Likewise, different types of noncovalently and covalently linked CuPc-fullerene dyads have been prepared (Nierengarten et al. 2000, El-Khouly et al. 2002, Li et al. 2004b). An example is a series of fulleropyrrolidinophthalocyanines containing free base, Zn, and Cu used as electron-donating building blocks in fullerene dyes of type **22** (Guldi et al. 2004). These experiments support the view that the $\text{C}_{60}/\text{C}_{60}^{\bullet-}$ couple exhibits the strongest electron affinity, while the different Pc/Pc $^{++}$ couples play the role of electron donors.

Further investigations showed that the donor ability increases in the following order: $\text{CuPc} < \text{H}_2\text{Pc} < \text{ZnPc}$. In other words, starting from the free base (H_2Pc), addition of either Cu (CuPc) or Zn (ZnPc) increases or decreases the electron density on the phthalocyanine, respectively. Similarly, the energy for the radical ion pair $\text{CuPc}^{\bullet-}-\text{C}_{60}^{\bullet+}$ formed in a PET reaction (*vide infra*), decreases in the following order: (1.40 eV) $>$ $\text{H}_2\text{Pc-C}_{60}$ (1.36 eV) $>$ ZnPc-C_{60} (1.23 eV).

Many other building blocks have been developed for use in photochemically active compounds. Perylene units have attracted attention as energy transfer donors, as they increase the light-harvesting efficiency in the green spectral region (where porphyrins are relatively transparent). Classic cases of magnesium porphyrins are **23** and **25**. They represent a family of closely related bichromophoric systems with properties designed to utilize PET strategies (Yang et al. 2001a,b, Fukuzumi et al. 2005). A typical example for zinc tetrapyrroles is **23** (Prathapan et al. 2001) but larger arrays including some with phthalocyanine units have been described as well and perylene units have been used as bridging units in D-B-A systems (Hayes et al. 2000, You and Würthner 2004).

34.4.3 Heteroligand Systems

The PET between metalloporphyrins and free bases in dimeric, trimeric, and oligomeric porphyrin systems has been studied extensively. Depending on the choice of the donor and acceptor unit, ET from either singlet or triplet states may be observed. ET studies in systems based on heterodimers with covalent or electrostatic bonds are of particular interest as it relates directly to the natural photosynthetic process.

For systems such as the magnesium free base porphyrin heterodimer **26**, electron paramagnetic resonance (EPR) spectroscopy is an essential analytical tool that provides information not available from optical studies. It provides details on the magnetic interactions and spin dynamics of states with different multiplicities, such as doublets, triplets, and charge-transfer states. The communication between these states strongly depends on the temperature and the solvent, and the EPR results established the existence of the radical species deduced in ps optical experiments and the corresponding theoretical calculations (Zaleski et al. 1993, Levanon et al. 1993, Zhang et al. 1995).

A series of conformationally restricted magnesium free base hybrid arrays bridged linearly via aryl-spacers to form di- (**27**) or trimeric porphyrins was used to study the intramolecular ET reactions from the singlet excited state of the remote doubly strapped free base porphyrin to the pyromellitimide acceptor by time-resolved ps fluorescence and transient absorption spectroscopy (Osuka et al. 1993b, 1994a,b). The ET was more effective in magnesium-porphyrin bridged models than in the related zinc-porphyrin bridged ones, indicating that the past reliance on the use of zinc-based biomimetic models is not always sufficient. Remarkably, the ET rates over two porphyrins were almost similar to those for the ET over one porphyrin independent of the bridging metalloporphyrin. Compound **28** is an example of multichromophoric systems that are now more frequently used to study the intramolecular electronic communications between chromophore subunits (Li et al. 1997, Youngblood et al. 2002).

Another example involving dimeric systems linked through noncovalent bonds used (5,10,15,20-tetrakis(4-sulfonatophenyl)porphyrinato)zinc(II) and (5,10,15,20-tetrakis(4-*N,N,N*-trimethylanilinium)

porphyrinato)magnesium(II) with complementary charge results in dimerization in solution. Continuous wave time-resolved EPR spectroscopy demonstrated that intramolecular electron and/or energy transfer in electrostatically bound metalloporphyrin dimers can be controlled via simple metal and substituent effects. Although the metal constituents were identical in these two dimers, the peripheral charged substituents governed the fate of the ET, whereas the energy transfer is controlled via the metal substituents (Murov et al. 1993, Berg et al. 1996).

ET from CuP to its free base partner was observed in the CuP-H₂P hybrid dimer **29** (Asano-Someda et al. 1994). Clearly, the advantage of a hybrid system is that the energy donor and an acceptor are distinct. The lowest excited singlet and triplet states of the free base porphyrin monomer are lower than those of the CuP. Based on T-T transient absorption spectra, the triplet yield of the free base porphyrin was found to be increased in the hybrid dimer compared to a monomeric free base porphyrin. Time-resolved ESR showed that the intermolecular energy transfer occurs between the triplets. The lowest excited triplet state of the CuP-H₂P dimer is generated both by energy transfer processes from the triplet manifolds in the CuP moiety and by intersystem crossing from the lowest excited singlet state of the free base moiety. As a result of the paramagnetic perturbation, intersystem crossing in CuP is remarkably accelerated and seems to prevent singlet-singlet energy transfer to another porphyrin moiety.

Electrostatically linked dimers can easily be produced by a coupling of two monomers with oppositely charged substituents in the liquid phase. An example of such systems has been illustrated by Tran-Thi et al. (1992), where Zn-porphyrin units were linked with Cu-phthalocyanines. Drastic changes in the ground-state absorption of the electrostatically linked dimer compared to the corresponding monomers indicate a strong interaction between the two chromophores. According to femto- and nano-second absorption spectroscopy, very efficient intersystem conversion takes place in the excited ZnP-CuPc, leading to the final 'triplet' state. In contrast, excitation of a ZnP-AlPc dimer led to an ET from the porphyrin to the phthalocyanine moiety. The different behavior in ET can be explained by the peculiar properties of the paramagnetic CuPc.

For systems such as the copper-copper dibenzofuran-bridged cofacial bisporphyrins **30** and **31**, EPR spectroscopy has been shown to be an essential analytical tool that provides information not available from optical studies. It also complements crystallographic studies by probing intramolecular metal-metal arrangements in frozen solution (Chang et al. 2002).

Mixed cyclization of porphyrin containing phthalonitrile compounds with an europium(III) half-sandwich phthalocyanine complex in the presence of 1,8-diazabicyclo[5.4.0]undec-7-ene (DBU) gave a series of porphyrin-appended europium(III)bis(phthalocyaninato)complexes. These mixed tetrapyrrole triads and tetrad were spectroscopically characterized with steady-state and transient spectroscopic methods. The porphyrin fluorescence was effectively quenched by the double-decker unit through an intramolecular PET process. Both the PET and recombination of the charge-separated state depended on the number and position of the porphyrin units attached to phthalocyanines (Bian et al. 2007).

Many systems were prepared and detailed photophysical analyses were carried out for zinc tetrapyrrole systems (Senge and Sergeeva 2006). Other examples for hybrid systems are slipped-cofacial dimers consisting of directly linked zinc porphyrin–zinc phthalocyanine units (Ito et al. 2006).

34.5 Photochemical Reactions

34.5.1 Porphyrins

Photoinduced metallation of porphyrin was reported first in the 1970s (Bluestein and Sugihara 1973). Various porphyrins, geoporphyrins, and Cu(II) 1,3-diketonates underwent a quantitative conversion into Cu(II) porphyrins in a short period of time (depending on the light intensity) upon light irradiation (~400 nm). Dark experiments required several hours or days to achieve a comparable conversion. Since the photochemical reaction occurred upon irradiation by light (~400 nm) in the Soret band, the formation of a porphyrin-excited form may be assumed.

Another example for photochemical transformations involved the copper(II) porphyrins **32** and **33**. These compounds were shown to undergo an unusual self-sensitized photo-oxygenation reaction (Jiao et al. 2006). While stable in the dark under inert gas, they were rapidly transformed into oxygenated adducts upon exposure to both light and air. Compound **33** was less stable and its major photooxygenation product was the α,β -unsaturated ketone **34** (52%). In contrast, the cofacial bis-porphyrin **35** was isolated from the reaction of **32** in the presence of DBU in good yield (60%) and its structure was confirmed by x-ray analysis

One of the few true photochemical reactions described for Mg(II) phthalocyanines involved a wavelength dependent photocyclization of **36**–**37**. Together with the back reaction, this system was developed as a photochromic readout system (Luo et al. 2007). A related example involving molecular motion used a “scissor”-like porphyrin dyad with flexible ferrocene-azabenzene-linkers where light-induced change in conformation of the host molecule forced a noncovalently bound guest to change its conformation as well (Muraok et al. 2006).

34.5.2 Photoinduced Ring-Opening Reactions

The photochemistry of chlorophylls is one of the oldest photochemical topics involving tetrapyrroles. The formation of long-lived excited states of chlorophyll and its function as energy-storage and catalytic material in photosensitization reactions has been postulated for some time on the basis of indirect evidence. For example, in the 1930s, Rabinowitch and Weiss performed spectro-photoelectrochemical studies on the reversible oxidation and reduction of chl (Rabinowitch and Weiss 1936, 1937). An ethyl chlorophyllide solution was reversibly oxidized by FeCl_3 to a yellow, unstable intermediate from which the green solution was regenerated by reduction with FeCl_2 . The oxidation was greatly favored by illumination and the equilibrium was shifted by light toward the yellow form. The nature of the reversible reaction with Fe^{3+} was considered to be an oxidation in which Fe^{3+} was reduced to Fe^{2+} and chlorophyll was oxidized to a chl cation or a dehydrochlorophyll species.

About a decade later, Calvin and coworkers reported photochemical reactions of simple chlorins and either oxygen or various *ortho/para* quinones that led to the corresponding porphyrins and unidentified products. Based on kinetic experiments, they proposed a mechanism for the photochemical oxidation of 5,10,15,20-tetraphenylchlorin (H_2TPC) and β -naphthoquinone involving the triplet state of the chlorin molecule as an intermediate (Calvin and Dorough 1948). The production of P^+ and P^- ions from the first excited triplet state (T) of $\text{Mg}(\text{II})\text{OEP}$ (P) predominantly involves triplet-triplet annihilation. Evidence indicated that the reaction of T with ground-state P is not a significant source of ions. On the other hand the two triplets initially can combine to form an excited charge-transfer complex. Less extensive experiments were carried out with $\text{Mg}(\text{II})\text{TPC}$ due to its instability. However, the data obtained confirmed the existence of a phosphorescence state (Huennekens and Calvin 1949a). The photooxidation rates for the magnesium chlorins were significantly lower (~ 8 times) than for the corresponding zinc complexes.

The magnesium and zinc complexes of TPC can also be photooxidized using quinones as hydrogen acceptors. More detailed studies showed that the reaction between quinones and $\text{Zn}(\text{II})\text{TPC}$ resulted in the formation of $\text{Zn}(\text{II})\text{TPP}$ (Huennekens and Calvin 1949a). Subsequent work showed that $\text{Mg}(\text{II})\text{TPC}$ and $\text{Zn}(\text{II})\text{TPC}$ can be photooxidized by molecular oxygen and *o/p*-quinones. Oxygen is reduced to hydrogen peroxide with a concomitant reduction of quinones to hydroquinones. However, oxygen differs from quinones, as the primary formation of oxidation to porphyrins here is followed by secondary reactions. This second reaction involves H_2O_2 that can react either directly or as an initiator of Haber-Weiss processes and resulted in the formation of unidentified products (Huennekens and Calvin 1949b) similar to those obtained by "bleaching" of chlorophyll in the presence of oxygen (Rabinowitch and Weiss 1936, 1937).

Subsequent work in this area clarified some aspects of the photooxidation of magnesium porphyrins. Barrett found no alteration in the spectral and chromatographic properties of nonfluorescent protoporphyrin complexes of Fe, Ni, Co, Cu, and Ag upon irradiation (Barrett 1967). However, irradiation of (protoporphyrinato dimethyl ester)magnesium(II) **38** in various organic solvents resulted in rapid photooxygenation to green-brown products that did not contain magnesium. Moreover, spectroscopic data indicated an interruption of the aromatic ring system, showed no fluorescence and the appearance of a strong band at 1680 cm^{-1} (CCl_4) in the IR spectrum of the newly formed compound. This green pigment was very photolabile and quickly decomposed to yield 15,16-hydrobiliverdin **39**. Magnesium porphyrins without vinyl side chains were photooxidized to similar green compounds with the band at 1680 cm^{-1} , confirming no oxidation of the vinyl group. The UV/vis spectra of these green products were similar to those of the phlorins obtained by photoreduction of uro-, copro- and hematoporphyrins (Mauzerall 1962). Thus, photooxidation of magnesium protoporphyrins resulted in the formation of 15,16-hydrobiliverdins upon ring cleavage. This is in contrast to the enzymatic breakdown of heme that proceeds through biochemical transformations *via* biliverdin **40** toward the phycobilins (Beale and Cornejo 1991a–c).

SCHEME 34.1 Photochemical ring-opening reactions of Mg(II)OEP.

The reaction of porphyrin ligands with molecular oxygen is related to catabolic processes of naturally occurring porphyrins and drugs and is of great medical relevance. Various metalloporphyrins, particularly the chlorophylls present in photosynthetic organisms, can be rapidly destroyed by light and oxygen. In fact, without the presence of photoprotective pigments such as carotenes, no natural chlorophyll-based photosynthetic system would be stable. Initial studies on the photooxygenation of Mg(II) OEP (41) (Fuhrhop and Mauzerall 1971, Fuhrhop 1974, Fuhrhop et al. 1974), Mg(II)TPP (Matsuura et al. 1980, Smith et al. 1980), and Mg(II)protoporphyrin and Mg(II)(tetrabenzoporphyrin) (Goedheer 1967, Goedheer and Siero 1967) were reported in the 1970s and 1980s.

For example, exposure of Mg(II)OEP to visible light in the presence of air in benzene solution, resulted in the quantitative conversion of the porphyrin into a chromophore with an intense absorption band above 800 nm. This reaction proceeded uniformly and no intermediates with lifetimes of more than 10s were observed. The primary product was an open-chain magnesium formylbiliverdin complex 42 that can be easily demetallated to the formylbiliverdin. A similar photooxidation pathway was found for Mg(II)TPP. It reacted readily with molecular oxygen to yield the corresponding 15,16-dihydrobiliverdin similar to the one shown for Mg(II)OEP in Scheme 34.1. Further studies have proposed that the photooxygenation of metallo-*meso*-tetrasubstituted porphyrins proceeds *via* a one-molecule mechanism involving only one oxygen molecule. Most likely, the first intermediates formed upon photooxygenation are short-lived peroxides. Such compounds are very instable and a possible dioxetane structure is shown in formula 43.

34.5.3 Reactions of Chlorophyll

The most obvious chemical reaction involving chlorophyll is the chlorophyll breakdown in fall during senescence. This process involves annually more than 10^9 tons of chlorophyll and despite its obvious prominence in the natural beauty of the fall season remained unknown until about 25 years ago (Hendry et al. 1987). Different groups have shown that the central step is a ring-opening reaction at the 5-position (Iturraspe et al. 1995, Gossauer and Engel 1996, Kräutler and Matile 1999).

SCHEME 34.2 Photochemical reactions of chlorophyll.

This is in contrast to the situation encountered for heme, which is oxidatively cleaved at the 20-position. As shown in Scheme 34.2, the crucial steps during chl degradation are the conversion of chl *a* into pheophorbide *a* 5, followed by enzymatic transformation into the bilinone 44. During this step, the macrocycle undergoes oxidative C5 ring-opening, incorporates 2 oxygen atoms (the CHO one from O₂), and is saturated at the 10-position. This reaction is catalyzed by a monooxygenase and the red compound 44 is further converted to the still fluorescing compound 45, and finally into the nonfluorescing derivative 46 along with some changes in the side chains directed to increase the hydrophilicity of the breakdown products. Chl *b* 6 is first converted into chl *a* 4 and then subjected to the same reactions. Note that this is an enzymatic process not a simple photochemical reaction and should not be confused with the photooxidative ring-opening reactions.

A second reaction involves the classic chlorin to porphyrin conversion. Any chlorin that has hydrogen atoms at the sp³-hybridized centers of the reduced ring can be oxidized to the respective porphyrin. Oxidation may be achieved by various oxidants including oxygen (Inhoffen 1968). Likewise, reductions to hydroporphyrins and other reactions of the macrocycle are possible. However, most of these are of interest only for the specialist. The best known reaction is probably the Krasnovskii photoreduction to 47 (Scheer and Katz 1974).

Similar to porphyrins chls undergo photooxygenation (Hynninen 1991, Gurinovich and Tsvirko 2001). Chls are potent photosensitizers and will produce singlet oxygen in the presence of air or triplet oxygen (Inhoffen 1968). Thus, chls can undergo self-destruction. The chemistry of this photooxygenation is heavily involved and differs somewhat for individual types of (b)chls (Inhoffen 1968, Troxler et al. 1980, Llewellyn et al. 1990a,b, Iturraspe et al. 1995). While being partially responsible for the low stability of chls in solution (Peled et al. 2000) and for unwanted side reactions in food stuff (Min and Boff 2002), the same reaction also offers potential for future applications. Chl and derivatives thereof may be used as photosensitizers to affect desired chemical transformations and they have been utilized for applications in PDT (Nyman and Hynninen 2004).

As lipophilic pigments, where the (b)chls are embedded in natural systems in apoproteins, photosynthesis in general is a transmembrane process. Thus, PET reactions in lipid membranes have been investigated

extensively. Many reports have been published on photo-initiated (i.e., the photo-initiated species acts as a catalysts to mediate thermodynamically favored reactions) and photo-driven (i.e., some of the light energy is converted into the products) processes (Tunuli and Fendler 1981). Typical examples are Mg(II)OEP (2,3,7,8,12,13,17,18-octaethylporphyrin) sensitized ET reactions across lipid bilayer membranes (Ilani et al. 1989). The reaction mechanism involves a reduction of photoexcited Mg(II)OEP at the reducing (ascorbate) side of the bilayer with the charge carrier most likely being a neutral protonated Mg(II)OEP anion. Thus, the magnesium porphyrin participated as a sensitizer and a transmembrane redox mediator.

A well-studied system is an Mg-substituted horseradish peroxidase. This system can form stable porphyrin π -cation radicals in the presence of oxidants (Kuwahara et al. 1982, Deguchi et al. 1985) and photooxidation and photoreduction occur through direct reaction of the excited-state porphyrins with oxidants and reductants, respectively. In general, porphyrins appear to be photooxidized both via ET and $^1\text{O}_2$ mechanisms. Thus, photoirradiation of the Mg-substituted horseradish peroxidase under aerobic conditions results in two simultaneously occurring reactions. A porphyrin π -cation radical is generated through ET from excited porphyrin to O_2 and a so-called the 448 nm compound via a singlet oxygen mechanism. A species with an absorption band at 448 nm was first formed upon irradiation and was then converted in the dark to a final product with a band at 489 nm, probably via an isomerization reaction.

34.6 Photoinduced Electron Transfer in Applied Photochemistry

Tetrapyrroles have found applications in the different areas of current research targeting highly interesting topics of organic and medicinal chemistry, material, and nanoscience. They have shown to be effective photocatalysts for aquatic wastes and organic pollutants degradation in green chemistry. On the other hand, they can also be used as efficient stabilizing agents for polymers and dyes.

The search for alternative energy sources is one of the most important aims of the present century that has found renewed attention after a lack of interest for several decades. Solar energy conversion, electrophotography, hydrogen production, and photocatalysis are the most popular topics involving tetrapyrroles. Photoenergy conversion systems have been designed using donor-acceptor molecules, polymers, and carbon nanotubes. The mechanism of PET is extensively studied and a variety of the artificial systems applying PET are examined for use as molecular devices. Here we will highlight the future potential of these materials as molecular devices in emerging areas of nanoscience, especially in the utilization as prospective (photo)catalysts in areas of green chemistry and hydrogen production, and in solar energy as photovoltaic cells and junctions.

34.6.1 Nanomaterials: Molecular Electronic Devices

The discovery of charge transfer across donor-acceptor systems opened an effective way to improve the photooptical response of organic materials. Here, the development and use of organic ultrathin monolayers as potential models for optoelectronic devices and catalysts in solid photochemistry has attracted great attention. Some studies focused on the fabrication of CuPc and CuP thin films using photoinduced deposition methodologies (Yamanouchi and Saji 1996, Hoshino et al. 1996, Bearinger et al. 2008) and investigated their optical (Yamada et al. 1995), optical memory and photoswitching (Liu et al. 1994), and xerographic properties (Xu et al. 2002).

Many memory and switching phenomena in organic solid films have been described as prototypical candidates for molecular electronic devices and photogeneration in these organic superlattices under an applied electric field may play a fundamental role. Some work has been reported on PET and back ET (charge recombination) of hetero-Langmuir-Blodgett films with phthalocyanines as a sensitizer. For example, a transient electric current was observed upon the selective photoexcitation of CuPc and the

resulting charge-separated state in the device survived for a few minutes. Applying electric biases and/or lowering temperatures caused the charge-separated state to last much longer (Naito and Miura 1993).

Disk-shaped like monomers can form rod-like aggregates (discotic mesophase materials) and they exhibit long-range order, large electrical anisotropies. The high interest in these materials stems from their promise as organic electronic devices requiring high charge mobility and dense integration (e.g., organic field effect transistors, organic light-emitting diodes, and photovoltaic cells).

Tetrapyrroles, especially with flexible hydrocarbon chains, exhibit a remarkable feature to form discotic mesophase architectures. An example are the octa-substituted phthalocyanines **48–50** with and without polymerizable styryl side chains: CuPc(OC₂H₄OCH=CHPh)₈ (**48**) with styryl groups at the termini on the side chains, or with one alkoxy group removed CuPc(OC₂H₄CH=CHPh)₈ (**50**) (Drager et al. 2001) and CuPc(OCH₂)₂OBz)₈ (**49**). The latter compound **49** formed highly coherent rodlike aggregates in Langmuir-Blodgett films with excellent control of rod orientation (Smolenyak et al. 1999, Zangmeister et al. 2001). Irradiation of the styryl π - π^* absorbance bands with $\lambda \sim 254$ nm for horizontally transferred LB films of **48** and **50** resulted in a stabilization of their rodlike aggregates, through formation of cyclobutane links between adjacent side chains (through common [2 + 2] cycloaddition (Donley et al. 2003). Polymerized thin films have shown a long-range order that was confirmed by atomic force microscopy and x-ray reflectometry. The differences in the orientation of individual Pc's, between films of **48** and **49**, were determined by transmission and reflectance. Higher dark photoconductivities and electrical anisotropies were observed in films of **48** after annealing and polymerization, compared with those found for films of **49**.

Several studies were aimed at the fabrication of molecular-based photoelectrodes and special attention has been given to the efficient uptake of visible light and conversion into output of the photosystems. Typical examples are the construction, determination of photoelectric characteristics, and an evaluation of the photoelectrodes (Meshitsuka and Tamaru 1977, Ichikawa et al. 1994). For example, photoelectrode devices constructed from CuPc as a p-type semiconductor in combination with *N,N'*-diphenylglyoxaline-3,4,9,10-perylenetetracarboxylic acid bisbenzimidazole as n-type semiconductor in the water phase were investigated in terms of kinetics. Each film of the p/n bilayer presents a photoanode, where the photoinduced oxidation of thiol occurs. The holes originate on account of the photophysical events in the p/n interior, involving the charge separation of excitons at the p/n interface (Abe et al. 2008).

Gas-sensitive electrodes can be fabricated by use of CuPc incorporation into a polypyrrole backbone. The photoresponse in electrochemical mode increases due to the presence of phthalocyanine in the films and enhanced sensitivity toward nitrogen gas as compared to pure polypyrrole film was observed (Radhakrishnan and Deshpande 2001).

Molecular conductance junctions (Nitzan and Ratner 2003) are another important utilization of phthalocyanines. Here, a molecule or a small cluster of molecules conduct electrical current between two electrodes. CuPc has been used in silicon-based molecular nanotechnology to integrate molecular electronic function with silicon surfaces (Hersan et al. 2000). The knowledge about the mechanisms of

charge transfer and the role of the outer phenyl ring is important to understand the interaction with the surrounding substrate when the CuPs molecule is bound to the surface *via* its central copper atom (Abramczyk et al. 2006). One example is the intercalation of CuPc pyridinium complex and iron phthalocyanine into two-layered titanates from $\text{Na}_2\text{Ti}_3\text{O}_7$ to study the microstructure control (Kaito et al. 2002).

34.6.2 Solar Energy

The current targets in solar energy conversion are reaching 10% conversion efficiency. This is within reach and has caused an intensive development of organic and hybrid thin film photovoltaics (third generation solar cells). Substantial improvements have been made resulting in new device concepts and improved understanding of energy conversion processes. Films of tetrapyrrole semiconductors are promising candidates for stable and low cost electrode materials that can be used for solar energy conversion. Various CuPcs have been investigated as thin-film electrodes in photoelectrochemical cells (Osada and Mizumoto 1986, Yanagi et al. 1993). Most likely, due to their stability, this field will be dominated by phthalocyanine derivatives although porphyrin systems are continuously advancing (Yamashita et al. 1989).

Zinc porphyrin dimers have been incorporated into solar cells to improve their light harvesting efficiency to yield enhanced performance. Such materials have potential in next generation solar energy conversion systems as 3-D light harvesting arrays (Mozer et al. 2009). Photochemical solar cells constructed from organized assemblies of single-walled carbon nanotubes and a protonated porphyrin on nanostructured SnO_2 electrodes are photoactive and absorbed in the entire visible region (Hasobe et al. 2006). Organic-inorganic hybrid cells also demonstrated enhanced performance through use of nanoporous Si as *n*-type and CuPc (Levitsky et al. 2004).

Other studies reported the construction and analysis of photovoltaic cells fabricated with CuPc and TiO_2 (Arbour et al. 1990, Grätzel and Halmann 1990, Ding et al. 2005, Doherty et al. 2007) or ZnS (Zhang et al. 2005) nanoparticles. The dye-sensitized TiO_2 solar cell showed conversion efficiencies of 7%–10% under standard solar conditions. These high efficiencies are associated with ultrafast charge transfer from the dye to TiO_2 , the high internal surface area of the TiO_2 films, the broad absorption of the dye, and the efficient separation of opposite charges between the domains. Recently, some attention has been given to composites of metal phthalocyanines and carbon nanotubes due to their high quantum efficiency facilitated by charge transfer between them and the complementary properties of the composites. These are regarded as promising candidates for the fabrication of donor-acceptor heterojunction diodes and photovoltaic devices. An example of such constructions has been reported recently for a CuPc with long dodecyl chains covalently attached to modified multiwalled carbon nanotubes (Wang et al. 2005).

34.6.3 Hydrogen Production

Photochemical processes capable of the evolution of molecular hydrogen are one of the most important areas of current research. Considerable interest has followed after Fujishima and Honda reported the photoelectrochemical water splitting using a UV-responsive TiO_2 electrode (Fujishima and Honda 1972). At present, dihydrogen (H_2) energy is attracting significant attention as a “clean energy” source with water photolysis being one of the most promising procedures to produce H_2 . Some of the strategies are based on the development of the an efficient solid/water interface to achieve the (photo)chemical energy conversion under solar irradiation.

A number of photosensitization reactions have been described that offer potential use in chemical applications or are of fundamental interest. One of the oldest photochemical reactions that involves tetrapyrrole photosensitizers is the photoreduction of methyl viologen (MV). Being *p*-type of semiconductors, CuPcs can be used to construct *p/n* type of organic bilayers as photoelectrodes and used in water phase (Abe and Nagai 2007). Copper tetrapyrroles can be used in aqueous solution to reduce MV from MV^{2+} to $\text{MV}^{•+}$ that is capable of decomposing water in the presence of a catalyst. Three-component

system [chromophore/donor/MV] for hydrogen production was analyzed using CuPc as a chromophore (Yarnaguchi et al. 1986). However, sulfonated phthalocyanines compared unfavorably to metalloporphyrins (Harrimana and Reichoux 1980). Some studies were carried out on the photodynamics of these systems for future applications (Ichikawa et al. 1995). In addition, studies on the photoexcitation of zinc porphyrin-viologen systems showed their potential use in hydrogen production (Petersson et al. 2009).

Another approach used hydrogenase active site models and metalloporphyrins. Visible-light-driven hydrogen generation was observed from noncovalent assembly of a pyridyl-functionalized hydrogenase active-site model complex and zinc tetraphenylporphyrin (Li et al. 2008a). Others examples included two kinds of light-sensitive, electro- and enzyme-active electrodes modified with zinc porphyrins, hydrogenase, and viologen triad multilayers. Here, the first zinc porphyrin or viologen layer was covalently immobilized on the substrate surfaces followed by hydrogenase and polyviologen layers or electrostatically adsorbed positively charged porphyrin (Liu et al. 2008).

34.6.4 Dye Industry

Improvements in the lightfastness of disperse dyes is a major goal in dye industry. The relationship between chemical structure and lightfastness of dispersed dyes and complete determination of the reaction mechanisms that characterize the photofading of disperse dyes on polyamide and PET substrates is of great interest. Many studies have been focused on investigating the light-induced reduction, photo-oxidation by singlet oxygen, and wavelength-dependent of photo-reduction in various organic solvents, to name a few.

Himeno et al. (2000) reported that reductive fading of monoazo disperse dyes combined with vinyl-sulfonyl CuPc on nylon or polyester substrates was decreased compared to the rate of reductive fading of disperse dyes without the CuPc dye. Singlet oxygen generated by the photosensitization of CuPc dyes suppressed the reductive fading of disperse dyes. Nylon had a greater tendency to give light-induced reduction and oxidation of disperse dyes than polyester, depending upon the properties of the adsorbed dye. Some investigations were carried out purely on CuPc dyes. Examples are the photosensitized oxidation of CuPc reactive dye on cellulose under different conditions (Okada et al. 1990a,b, Okada 1992) and additives (Hihara et al. 2001), and photochemical reduction of tetrasodium salt of copper tetrasulphonatophthalocyanines with amines (Kaneko et al. 1995, 1996).

Dyes are utilized in polymer materials to enhance their color-changing properties. However, these additives can affect considerably the polymer stability toward degradation. Interestingly, CuPc can play the role of a polymer stabilizer against degradation as well as in some cases to be its trigger. The interaction mechanism of dyes can occur via two pathways (Bamford and Dewar 1949, Allen 1994, Sánchez et al. 2004). In one pathway, after the light absorption in oxygen containing media, the dye produces chemical species such as singlet oxygen and superoxide anions. These reactive species then accelerate polymer degradation. In the other pathway, the dye reaches excited singlet (S_1 , S_2) and triplet (T_1 , T_2) states. The energy absorbed is then transferred to the chemical groups in the polymeric chain via intermolecular energy transference.

For example, CuPc incorporated into polycarbonate resulted in accelerated degradation under UV radiation. As a strong sensitizer, CuPc very likely enhances the formation of reactive species in polycarbonate. Excited states of CuPc may increase the formation of free radicals, which is the beginning for the sequential photooxidation processes leading to the degradation of a polycarbonate. Alternatively, photodegradation of polycarbonate triggered by CuPc may proceed via ET sensitization (Saron et al. 2006). In contrast, a three-component system involving hindered piperidine (known to be effective photostabilizers for some polymers), antioxidant, and CuPc have shown synergistic effects. Interestingly, CuPc alone offered little photoprotection and some enhanced photoprotection was observed for antioxidant-CuPc. These results indicate that CuPc and a hindered piperidine exhibit a highly favorable interaction for photostabilization (Allen and Parkinson 1983). Finally, CuPc dyes can also be used as heterogeneous sensitizers to induce the photopolymerization of trimethylolpropane triacrylate (Rosche et al. 1997).

34.7 Green Chemistry of Tetrapyrrole-Based Dyes: Photodegradation, Stabilization, and Photocatalysis

High levels of environmental contamination have been associated with dye wastewater contents from textile dyeing and finishing industry. Various types of synthetic dyes are used in textile industry including azo, anthraquinone, triarylmethane, and phthalocyanines designed to be highly robust. Moreover, due to the complexity and variety of the dyes used for different purposes, as well as their nonbiodegradability, it is rather difficult to find unique treatment methods that would result in effective degradation of all types of dyes. Azo dyes are the largest class of commercially used colorants, while phthalocyanines are mainly utilized as blue and green dyes. CuPcs (**51**–**54**, **56** are examples of the commercially used CuPc dyes) are the most important derivatives of the phthalocyanine pigment class (Gordon and Gregory 1983). Their commercial success is based on three features: beautiful bright blue to green shades and strength, remarkable chemical stability, and excellent fastness to light. Due to their low tendency to migrate in materials, CuPc are used in inks and printing, coatings, some plastics, textile, and leather. However, environmentally, these advantages as robust and efficient colorants decrease the efficiency of convenient treatment technologies. Additional contamination associates with metals such as copper released during the process from the metallized dyes.

34.7.1 Tetrapyrrole-Based Photocatalysts

Tetrapyrroles are suitable candidates for use in (photo)catalysis, an advanced oxidation process that is used to eliminate organic pollution. The oxidation rates depend strongly on the oxidation potential of the central metal, and thus zinc(II) derivatives typically take up a central position. Some selected

SCHEME 34.3 Photooxidation of phenols.

examples for the use of zinc(II) tetrapyrroles as photosensitizers are the oxidation of isopropyl alcohol (Uchida et al. 1977) or water (Gerasimov et al. 1991), the photochemical dediazonium salts with a zinc(II) phthalocyanine derivative (Becker et al. 1986), the photocatalytic decomposition of CCl_4 (Khairutdinov et al. 1982), trichlorophenol (Kasuga et al. 2000), amino acids (Zhang and Xu 1994, Spikes et al. 1995), and of atrazine (Héquet et al. 2000). Likewise reactions with hydroquinone (Fan and Bard 1979), cellulose (Thomas and Allen 2002), and the photocatalytic destruction of organic matter in effluents from paper industry (Machado et al. 2003) were studied and a variety of antimony porphyrin-based photocatalysts were prepared and analyzed (Shiragami et al. 2005).

Phenol photooxidation can also be performed by an iron porphyrin in the presence of oxygen. The main photooxidation product was *p*-benzoquinone (33%, λ_{max} 245 nm), although some *p*-hydroquinone (6%, λ_{max} 288 nm) was also observed (Silva et al. 2004). This is similar to reports for the degradation of phenols in the presence of phthalocyanines and other photosensitizers (Scheme 34.3).

5,10,15,20-Tetrakis(2,6-dichloro-3-chlorosulfophenyl)porphyrin and its Sn and Zn complexes were also successfully used in the photodegradation of 4-chlorophenol and 2,6-dimethylphenol (Monteiro et al. 2005). Likewise, silica microspheres functionalized with 5-(4-allyloxy)phenyl-10,15,20-tri(2,6-dichlorophenyl)porphyrin were used to oxidize 1,5-dihydroxynaphthalene under visible light irradiation in aerated aqueous solution (Cai et al. 2009). Visible light photocatalysis using SiO_2 immobilized water-soluble and -insoluble tin porphyrins degraded 4-chlorophenol and Acid Orange 7 in water. Interestingly, the visible light activity of the porphyrin photocatalyst was enhanced by increasing the loading of insoluble tin porphyrin (Kim et al. 2008).

Photocatalysts prepared in situ by CuPc immobilization on Al and encapsulated inside zeolite-X showed a remarkable affinity toward CN^- . Here, photooxidation is based on transferring electrons from the zeolite to cyanide ions in solution (Mohamed and Mohamed 2008). Mesoporous catalysts prepared from 3-aminopropyltrimethoxysilane and (hexadecafluorophthalocyaninato)copper(II), followed by cocondensation of tetraethylorthosilicate around a micelle formed by *n*-dodecylamine demonstrated efficacy for photodegradation of organochloride compounds, industrial dyes, and pesticides with unproblematic recuperation from the reaction medium (DeOliveira et al. 2008).

34.7.2 Titanium Dioxide–Based Tetrapyrrole Photocatalysts

Titanium dioxide (TiO_2)–based photocatalysts are being used in photocatalytic technologies for the degradation of organic compounds in water. In the past decades, focus of interest has been on the development of economically and environmentally friendly catalytic systems with enhanced activity of TiO_2 -based catalysts for use in the oxidative degradation of various organic pollutants. Several studies have been also

carried out to investigate the influence of different semiconductor types such as Al_2O_3 or WO_3 and phthalocyanine complexes on the photoactivity. For example, it was found that the photocatalytic activity of the phthalocyanine complexes, supported on TiO_2 or WO_3 was much higher compared to dielectric Al_2O_3 .

Thus, TiO_2 is one of the most popular materials to be used as a photocatalyst for air treatment and degradation of organic pollutants in water. Having a large band gap (3.2 eV with $\lambda \leq 385$ nm), TiO_2 can consume only about 5% (with energy above 3.0 eV, $\lambda \leq 410$ nm) of solar light reaching the earth surface. Thus, to increase the efficiency of solar energy utilization through TiO_2 , it is often doped with transition metal ions or organic dyes to shift the photoresponse of the catalyst into the visible region. In view of its low cost and feasibility, dye sensitization is considered to be an effective method to modify the photochemical properties of TiO_2 particles. Mechanistically, the photosensitization of TiO_2 proceeds via initial excitation of the dye. A PET from excited dye to TiO_2 and the surface reaction of TiO_2 conductive band electron were suggested as the key processes.

Systematic investigations demonstrated the existence of an optimum photoreactivity depending on the amount of impregnated porphyrin. It was shown that TiO_2 impregnated with Cu-based sensitizers is beneficial for the photoactivation of TiO_2 , and CuPs (Mele et al. 2003, 2005, Wang et al. 2007) and CuPcs have shown to improve the photocatalytic activities of these photocatalysts.

Comparative studies showed that TiO_2 samples doped with CuP and FeP are more photoactive than simple TiO_2 (anatase), whereas samples including MnP showed less photoreactivity (Mele et al. 2007a). Free base porphyrins have shown slightly higher photoactivity than TiO_2 , suggesting that the porphyrin macrocycle is photocatalytic as well. However, samples impregnated with CuP exhibited the highest photoactivity. These results, related to the photodegradation of 4-nitrophenol (4-NP) in an aqueous heterogeneous environment, suggest that the Cu(II)-Cu(I) photocatalytic redox cycle plays the main role in the process.

Similar results were shown for a series of TiO_2 -CuPc's systems where different Cu(II)Pc (TiO_2 -CuPc) were examined for their photocatalytic degradation of 4-NP (Mele et al. 2002). The high photocatalytic activity was explained by an ET from the conduction band of the excited Pc to the conduction band of a semiconductor. Recent studies have shown that the photocatalytic activity of polycrystalline TiO_2 samples impregnated with rare-earth-metal diphthalocyanines in the 4-NP photocatalytic degradation show better photoactivity for the complexes of lanthanide metals, such as Nd, Sm, and Ho (Mele et al. 2007b). Improved photocatalytic activity was observed in the decomposition rates of 4-NP for TiO_2 -lanthanide diphthalocyanines over those impregnated with Cu(II)Ps.

Plastic is widely used all over the world and its waste, the so-called "white pollution," has been recognized as one of the central environmental problems. Heterogeneous photocatalytic oxidation can occur under moderate conditions, such as room temperature, atmospheric pressure, and molecular oxygen as the only oxidant. Recently, studies of the solid phase photodegradation of TiO_2 -embedded plastic upon irradiating the composite film for 300 h under air have shown reduction of its average molecular weight by two-thirds and weight by 27% (Cho and Choi 2001). Comparative studies have been carried out on polystyrene incorporated in (TiO_2 /CuPc) and TiO_2 alone. Faster photocatalytic degradation of polystyrene was observed in polystyrene- TiO_2 /CuPc than in polystyrene- TiO_2 . During photocatalytic degradation, activation of polystyrene by the reactive oxygen species attacking neighboring polymer chains leads to chain cleavage and production of new reactive radicals. The higher charge separation efficiency of TiO_2 /CuPc photocatalyst results in more effective generation of reactive oxygen species both on surface and inside thin film; polystyrene undergoes faster and more complete mineralization over TiO_2 /CuPc than over TiO_2 photocatalyst (Shang et al. 2003).

Another serious environmental problem is caused by azo dyes from textile industry. Here, methyl orange is often selected as a reliable model to investigate decolorization and decomposition of azo dyes using photocatalysts. Photo-stable copper 2,9,16,23-tetracarboxyl phthalocyanine (CuTcPc) doped with amorphous TiO_2 (am- TiO_2) hybride photocatalyst exhibits excellent photocatalytic activity toward methyl orange under visible irradiation ($\lambda > 550$ nm) (Chen et al. 2005). In contrast, no photobleaching of methyl orange was observed with bare am- TiO_2 at $\lambda > 550$ nm. Degradation of acid chrome blue K was achieved with TiO_2 -based photocatalysts containing carboxy and nitroporphyrins. Here, the photoexcited sensitizer had remarkable effects on the photodegradation of the dye under natural sunlight (Li et al. 2008b).

34.7.3 Photodegradation of CuP and CuPc Dyes

Although porphyrins and especially phthalocyanines are stable compounds, both will undergo photo-oxidative degradation or photoexcited ET reactions. The phthalocyanine systems are very stable even in advanced catalytic processes such as photocatalytic oxidation. Photoelectrocatalytic oxidation attracts considerable attention as a way to increase the photocatalytic efficiency in degradation of organic pollutants and studies have been carried on to apply this methodology for decolorization of Pc systems.

For example, the decolorization of commercially relevant reactive CuPc-dyes—for example, the *Remazol Turquoise Dyes* family—was studied in aqueous solutions under different conditions. For example, *Remazol Turquoise Blue 15* (**56**) was investigated by direct cathodic reduction on platinum electrode and photoelectrocatalytic oxidation on Ti/TiO₂ as nanostructured semiconductor thin-film electrodes with higher efficiency for combined processes of photoelectrocatalytic oxidation and electrochemical reduction (Osugi et al. 2006).

Some studies on photostable CuPc sulfonates sodium salts were carried out under UV ($\lambda > 320$ nm) or visible light ($\lambda > 450$ nm) in the presence of a TiO₂ semiconductor in an aqueous medium. They underwent photobleaching in the presence of TiO₂. The spectral analysis showed that the dye photobleaching led to complete destruction of the phthalocyanine ring. In addition, the stability of the dye toward visible light was greatly affected by the physical properties of TiO₂ semiconductors, and the dye photostability could be improved through addition of electron sacrificers such as 4-chlorophenol (Sun et al. 2005).

Another example of photodegradation catalyzed by TiO₂ is illustrated for the CuPc dye **54** (*Alcian Blue 8 GX*) (Caliman et al. 2007). This dye is one of the so-called “biological stains,” such as *Eosin Y*, *Auramine O*, *Hematoxylin*, or *Rose Bengal*, etc., which are widely used in biomedical research laboratories and for diagnostic purposes. Some of them are known to be toxic or mutagenic to humans and animals, highly resistant to microorganisms such that biological wastewater treatment processes are very inefficient in treating of these dyes. Decolorization and mineralization of phthalocyanine dye **51** (*C.I. Direct Blue 199*) has been studied using an advanced oxidation process. Decolorization was found to be more difficult than that of an azo dye (*C.I. Acid Black 1*) under the same operating conditions (Shu and Chang 2005).

34.8 Photomedicine

34.8.1 Photodynamic Therapy and Singlet Oxygen Production

The interaction of tetrapyrrole derivatives with oxygen under the influence of light, and their photostability, has been a matter of great interest due to its medicinal relevance. PDT presents the only one clearly established medicinal application of porphyrins and relies on the selective accumulation

of a tetrapyrrole photosensitizer in target tissue where it can be activated with light to produce toxic singlet oxygen resulting in, for example, tumor necrosis. Typically, two different photosensitization processes are discussed. Type I reactions include charge transfer, whereas the type II pathway involves transfer of excitation energy from porphyrin to triplet oxygen. Several porphyrin-based compounds have been approved for medicinal applications and others are in Phase-2 trials (Spikes and Bommer 1991, Dougherty et al. 1998, Kessel and Dougherty 1999, Bonnett 2000, Wiehe et al. 2005, O'Connor et al. 2009). Amongst these tetrapyrroles, chlorophyll derivatives are currently under active investigation and show some promise (Nyman and Hynninen 2004). The use of chlorophyll derivatives in technical applications is still in the early developmental stage.

Although many different derivatives are under investigation the majority of compounds are free base derivatives. The situation is different for zinc(II) phthalocyanines. A classic study on zinc(II)phthalocyanine of type **3** showed that it is an efficient photosensitizer for singlet oxygen with a quantum yield of *ca* 0.4 (Valduga et al. 1988). The efficiency of the photosensitization reaction strongly depends on the macrocycle conformation and substituent pattern (Weitman et al. 2001). Thus, the quantum yield for singlet oxygen generation for tetrasulfonated zinc(II) phthalocyanines (0.7) is almost three times that of the zinc(II) naphthalocyanines (0.25) (Spikes et al. 1995). Phthalocyanine derivatives exhibit some photophysical advantages compared to porphyrins: increased Q-band absorption coefficient, red-shifted absorption bands resulting in deeper light tissue penetration (Ochsner 1996), high triplet quantum yields, long triplet lifetimes and high singlet oxygen, and fluorescence yields (Rosenthal 1993). For specific substituents pattern, this can result in improved photodynamic activities compared to commercial photosensitizers (Ochsner 1996, Ball et al. 1998).

A few current examples are shown in the following and include unsymmetrically substituted derivatives **57** (Kudrevich et al. 1997), the cationic derivative **58** (Fernández et al. 1997), the neutral derivative **59** (Ball et al. 1998), and the classic anionic derivative **60** (Griffiths et al. 1994, 1997). "(Tetrabenzoporphyrinato)zinc(II)," an intermediate structure between that of porphyrins and phthalocyanines, has also been investigated in this respect. However, its quantum yield for singlet oxygen generation in liposomes (0.023) is much lower than that of Photofrin (0.19) (Gross et al. 1993). Other examples are zinc, palladium, copper and free base porphyrin complexes of 5-(4-(trimethylammonium)phenyl)-10,15,20-tris(2,4,6-trimethoxyphenyl)porphyrin iodide (Milanesio et al. 2008) or compounds with photocleavable linkers as photodynamic prodrug systems (Jiang and Dolphin 2008, Bakar et al. 2009). Note that zinc derivatives are not necessarily the best metal derivatives of phthalocyanines for use in PDT (Canti et al. 1992). Taking aspects like tissue clearance and target-specific localization into account, porphyrin derivatives will most likely carry the field in this application. In addition, many of these systems are under scrutiny for their antibacterial action (Segalla et al. 2002).

A series of meso-substituted tetracationic porphyrins have been synthesized and the role of amphiphilicity and zinc insertion in PDT efficacy (such as fluorescence and singlet oxygen quantum yields, uptake by vesicles, mitochondria and HeLa cells, dark and phototoxicity in HeLa cells) were studied (Pavani et al. 2009). Some studies have been carried out to investigate copper tetrapyrroles with regard to singlet oxygen production for use in PDT. For example, the iminium salt of octaethylbenzochlorin copper complex **61** was tested for its tumoricidal effects on the AY-27 N-[4-(5-nitro-2-furyl)-2-thiazolyl] formamide tumor line and was found to be an effective photosensitizer in vivo in combination with noncoherent light sources. Skin photosensitization was found to be minimal when drug-injected mice were illuminated in a solar simulator (Selman et al. 1993). As expected, the photodynamic ability of this complex required the presence of molecular oxygen in order to generate reactive species upon light activation (Hampton et al. 1993, Cavaleiro et al. 2001).

Sometimes, the efficacy of one-photon PDT is limited by hypoxia, which can prevent the production of the cytotoxic singlet oxygen species, leading to tumor resistance for PDT. To solve this problem, two-photon excitation of the photosensitizer can be employed. Excitation of the CuPc triplet state leads to an upper excited triplet state with distinct photochemical properties, which could inflict biological damage independently from the presence of molecular oxygen (Fournier et al. 2004). The potential of a two-photon excitation process was investigated on Jurkat cells incubated with CuPc tetrasulfonate (Mir et al. 2008). Significant advances can be expected from this line of research.

Tetrapyrroles have also found wide use in DNA binding and intercalation studies (Meunier 1992) and type II photosensitized reactions (Foote 1991) offer an intriguing possibility for site-specific photoinduced oxidation of DNA. Most studies were performed with free base porphyrins (Camino and Durantini 2008) but a recent example is the use of a tetra-ruthenated zinc(II) porphyrin (Adam et al. 1997) for the specific photooxidation of 2-deoxyguanosine bases to form 8-oxo-2-deoxyguanosines (Araki et al. 2000).

Other studies showed that copper-based tetrapyrroles can exhibit photonucleolytic activity and may be used for the DNA cleavage. Many copper complexes have been shown to exhibit nuclease activity in the presence of external cooxidants (Hegg and Burstyn 1996, Itoh et al. 1997, Borah et al. 1998, Baudoin et al. 1998, Dhar and Chakravarty 2003, Melvin et al. 2000). Only few reports are available where copper(II) complexes promote DNA cleavage on their own (Reddy et al. 2004, Verma et al. 2004). For example, hexaporphyrin dyads were synthesized from *n*-butyl stannonic acid and 5-(4-carboxyphenyl)-10,15,20-triethylporphyrin ($H_2TTP-CO_2H$) followed by copper insertion as artificial nucleases (Chandrasekhar et al. 2005). The Cu-hexaporphyrin **62** showed high nuclease activity toward DNA supercoils. Interestingly, DNA cleavage did not occur in the presence of the free base hexaporphyrin alone and a monomeric CuP complex also failed to cleave it. Considerable inhibition of DNA cleavage in the presence of singlet oxygen quencher NaN_3 suggests the involvement of reactive oxygen species for cleavage.

**62**R: Ph, SiMe₃**63****64** M: 2H**65** M: Cu(III)

Another example of potentially useful biomolecules is presented by the porphyrin **63** (Chandra et al. 2003) units. Eneidyne (Lee et al. 1987, Golik et al. 1987) themselves are known to undergo rearrangements to form diradicals upon photoactivation leading to H-abstraction from DNA and cell death (Smith and Nicolaou 1996). It is interesting to note that “doubly N-confused” copper porphyrins have also been synthesized and investigated in terms of their singlet oxygen production. The free base “doubly N-confused” porphyrin complex **64** exhibits a low fluorescence quantum yield of 9.1×10^{-3} , which is completely suppressed in the Cu(III)P complex **65**. However, a high singlet oxygen quantum yield ($\phi\Delta = 0.66$) was observed for the Cu(III). These results were explained in terms of enhanced intersystem crossing rates, induced by a heavy atom effect, rather than a redox quenching involving the metal ions in an unusually high oxidation state. The “confused porphyrins” are photochemically stable in oxygen-free solution but are bleached more or less rapidly by photogenerated singlet oxygen in the absence of other quenchers (Engelmann et al. 2004).

Phthalocyanines act as photosensitizers for the production of singlet oxygen in a similar manner to the porphyrins. Besides their catalytic properties, as discussed earlier, TiO_2 can be used to kill bacteria under UV irradiation. For instance, *Lactobacillus acidophilus*, *Saccharomyces cerevisiae*, and *Escherichia coli* can be completely sterilized when incubated with platinum-loaded TiO_2 . TiO_2 photocatalysis is known to generate various active oxygen species, such as hydroxyl radicals and peroxide, and superoxide radical anions under UV irradiation. These properties can be used to develop disinfection materials and self-disinfecting thin films particularly attractive in places such as hospitals or for emergency medicine in disaster zones. Dye-sensitized TiO_2 films prepared with CuPc as sensitizers have shown bactericidal activities. For example, such films can kill *E. coli* DH5 α bacteria under visible light irradiation ($\lambda > 420$ nm) and the bactericidal activity is related to the adsorption amount of the dye on film (Yu et al. 2003).

Dyes can also be attached to polymers soluble in water or/and in polar solvents, or to the insoluble polymer supports for recovery from the reaction medium for further reuse. CuPc can be easily functionalized for preparation of polymer hybrid thin films (Choe et al. 2004). For example, CuPc was linked to an amino group of Amberlite IRA-93 and is strongly fluorescent in the solid state and in N,N-dimethylformamide (DMF) suspension. Singlet oxygen quantum yields were determined in suspension by monitoring the photooxidation of diphenylisobenzofuran. Fluorescence and singlet oxygen production are environmentally depended on dye aggregation (Bourdelaude et al. 1997). The degree of aggregation plays an important role in the photochemical mechanisms of photooxidation. Singlet oxygen production in these systems is expected to be different for monomers (Abramczyk et al. 2004).

Currently, photodynamic antimicrobial treatment is gaining more interest. Although photosensitizing agents and light have been used for medical purposes for a very long time, only little information is available about the exact mechanism of protein disulfide isomerase (PDI) for bacteria. Some studies have been carried on gram-negative bacteria involved in chronic infections such as cystic fibrosis and also one of the common causes of hospital-acquired infections. Recent examples are studies of the phototoxic effects of the (acridyl)bis(arginyl)porphyrin on the sensitivity of *Pseudomonas aeruginosa* (Steenkeste et al. 2010). The photodynamic inactivation efficiency of *E. coli* was investigated in bacteria treated with 5,10,15-tris[4-(3-N,N,N-trimethylammoniumpropoxy)phenyl]-20-(4-trifluoromethylphenyl)porphyrin iodide. Here, photosensitization activity of the porphyrin such as damage of plasmid and genomic DNA was compared with other porphyrin-based active tetracationic sensitizers (Camino et al. 2008).

35.1 Introduction

The synthesis of metal nanomaterials has received considerable attention in the past few decades owing to the enhancement of chemical, catalytic, and optical properties of the metal upon approaching dimensions on the order of the Bohr radius.¹ Several photochemical routes have been established for the synthesis of colloidal nanoparticles, where selection of reducing agent, stabilizing agents, and irradiation conditions all play a role in particle yield. This chapter will review different photochemical methodologies for particle generation as well as highlight their applications.

One major application of metal nanoparticles is their use as a sensor through exploitation of their enhanced optical properties, and this enhancement is characteristic of noble metals. Noble metal nanoparticles in particular possess strong collective oscillations of surface electrons in the conduction band, whose resonating frequency absorbs strongly in the visible spectrum. These characteristic special features are referred to as a metal's surface plasmon resonance band (SPB).² The frequency of oscillations is a function of the metal, particle size, shape, and interparticle distance, as well as the temperature, dielectric constant,

FIGURE 35.1 UV-Vis absorbance of gold nanoparticles of variable diameter displaying their SPBs, along with their corresponding SEM image in the inset.

and viscosity of the medium. As particle size increases or as interparticle distance decreases, the resonance energy decreases and results in a redshift of absorbance maximum (Figure 35.1).

Gustav Mie investigated the photophysics of metal colloids in depth, where the sizes of spherical particles could be deduced from the position of a translational dipole.³ Additionally, oblong, prismatic, or elongated particles could be characterized by a longitudinal plasmon dipole where the position of the resonance dipole corresponds to oscillations of electrons along the major axis and depends on their aspect ratio.

35.2 Particle Growth

As the optical, electric, and catalytic properties are principally dependent on particle size and shape, great focus has been executed to determine mechanisms for particle growth and to establish optimal methods for the synthesis of small and monodisperse colloidal metal particles. Nanoparticles can be formed by a top-down approach via laser ablation⁴ or other destructive high-energy techniques, as well as the more common bottom-up wet chemical approach via self-assembly. In the latter case, metal ions are reduced to their atomic state at which nucleation of clusters can ensue.^{2,5} Nucleation occurs when a thermodynamically unstable saturated solution possesses a positive free energy change, where this change represents the driving force for the formation of a new volume and free energy relating to its surface. Above a critical radius, the free energy of this volume diminishes, allowing atoms to stabilize through agglomeration. Nucleation can continue via collisions and lead to particle growth until thermodynamic stability is attained by adsorption of ligands or solvent molecules. Slower nucleation can also ensue in an autocatalytic growth mechanism, in which metal ions are reduced on the surface of growing clusters. Both mechanisms are outlined in Scheme 35.1.

Small particles grow quickly due to their high surface energy, which decreases with growth until a narrowed and homogeneous population of particles is produced. Herein, nucleation and growth are well separated; and small, monodisperse, crystalline particles are prepared.⁶ Particle growth also occurs via molecular addition where nuclei deposit on the surfaces of growing clusters followed by coalescence.² Size broadening, also referred to as Oswald ripening, can occur where larger particles

SCHEME 35.1 Nucleation pathways toward nanoparticle growth.

SCHEME 35.2 Particle growth pathways. (Redrawn from a web source: <http://www.icmm.csic.es/gsc/sol.htm>.)

continue to grow while smaller ones dissolve and the critical nuclei radius increases thus resulting in polydisperse or ultimately larger particles (Scheme 35.2).^{2,5}

As surface energy decreases with particle growth, remaining metal ions are reduced to generate new nuclei, resulting in an overlap of nucleation and growth processes at the same time. This results in the formation of polydisperse and polycrystalline, multi-twinned particles with a tendency to coalesce. Control of particle growth can be attained with surface stabilization; achieved through ligand attachment of self-assembled monolayers, polymer, dendrimer, surfactant, oligonucleotides, amino acids, and other small biomolecules, films, glass, or other solid supports.^{7,8} Essentially, the more the stabilizer present during the synthetic steps, the smaller the resulting particle.

35.3 Photochemical Preparation of Nanoparticles

Photochemical methods to generating nanoparticles offer several advantages over traditional thermal methods. These include cleaner synthesis with fewer byproducts, lower temperatures, often less overall energy to drive the reaction, as well as spatiotemporal control over reduction rates and sites. Additionally, nanomaterials can benefit from reduction in a variety of different media, including aqueous and organic environments, polymers, micelles, films, semiconductor surfaces, and biological systems.

There are several ways to reduce metal ions to atomic metals, and many ways to achieve this goal using photochemistry. From a wet chemical perspective, nanoparticles can be synthesized from a metal salt and a reducing agent. Several photochemical pathways exist for reduction of a metal from an excited state.

SCHEME 35.3 Photochemical pathways for reductions of metal salts. Photoinduced CR, SR, and PI reduction.

In some cases, the light-driven chemistry can be the result of excitation and reduction of a chromophore at the metal salt complex itself, as illustrated in the complex reduction (CR) pathway of Scheme 35.3. This was the case for the formation of copper nanoparticles (CuNP) from the 254 nm photolysis of $\text{Cu}(\text{acac})_2$ in ethanol or polyvinylpyrrolidone (PVP),⁹ or the formation of gold nanoparticle (AuNP) from photolysis of (*p*-tosyl) CH_2NCAuCl or $\text{Au}(\text{CO})\text{Cl}$, where the latter reduction was attributed to π -acceptance ability of the ligands toward photochemical reactivity.¹⁰ In another approach, a photochemical polythiol process was devised by Warren et al. by using the strong reduction potentials of metal thiolates complexes to form bismuth, copper, lead, and antimony nanoparticles upon photolysis.¹¹ Nanoparticles can also be prepared via a sensitized reduction (SR) approach, where an excited state of one reagent transfers energy to an acceptor molecule (which then acts as a reducing agent), through proposed energy transfer for electron transfer mechanisms. Highlights of this approach will be addressed later in this chapter.

Additionally, nanoparticles can be formed from the photolysis of photoinitiators (PIs), outlined in the PI pathway in Scheme 35.3. This chapter deals largely with this case, where we present a series of strategies and methods for photochemical synthesis of metal nanoparticles mediated by reductive free radicals derived from PIs. PIs are molecules that tend to have high absorbance in the 250–450 nm range, whose excited states form reactive intermediates such as free radicals. PIs can be described in two categories: those formed by intramolecular bond cleavage (PI_1) through a unimolecular reaction, and those undergoing intermolecular hydrogen abstraction (PI_2) following bimolecular kinetics. Beyond well-established examples, there are numerous literature reports where metal reduction can be traced back to radical-mediated processes. This is something that we illustrate in some of our examples; however, no attempt has been made to be exhaustive and without a doubt, other such examples could be identified in the literature.

In designing a photochemical method using radical-mediated PIs, one must select a reducing intermediate based on energetics and thus reduction potential, stability, excited state lifetime, reactivity, and solubility. Additionally, the photochemistry required to create these reactive species is also worth considering. Utilizing chromophores with large extinction coefficients at the wavelength of absorption, while avoiding any screening by other absorbers such as metal salts or stabilizers, is paramount to efficient nanoparticle production. PI-mediated particle synthesis can be separated into two strategies based on reducing radical generation; a photorelease mechanism via homolytic cleavage (PI_1) as well as a hydrogen abstraction mechanism (PI_2), as described in the following sections.

35.4 Part I: PI_1 —Photoinduced Nanoparticle Synthesis via Unimolecular Cleavage

Photochemical generation of metal nanoparticles can occur through intramolecular bond cleavage to photorelease a reducing agent, normally a free radical. The concentration of reducing agent can be finely tuned along with the rate of its delivery for optimal spatial-temporal control of nanoparticle synthesis. This photochemical control illustrates a major advantage over traditional thermal methods, since the

SCHEME 35.4 PI_1 pathway. Intramolecular bond cleavage.

rate of reduction can separate nucleation and growth phenomena throughout nanoparticle growth and thus facilitate the preparation of small and monodisperse nanomaterials.

Significant work with photoreleasing reducing agents has succeeded with a series of benzoin, whose photodissociation is described in Scheme 35.4. Norrish-I α -cleavage generates a benzoyl radical and a ketyl radical, or an α -amino alkyl radical in the case of I-907.¹² The quantum yield for Norrish Type I photodissociation for various α -hydroxy ketones is approximately 0.3 with a excited triplet state lifetime below 100 ns.¹³ The short triplet lifetime is a key requirement for successful nanoparticle synthesis, for the excited-state species can escape both quenching from metal salts and oxygen on this timescale.

35.4.1 Nanoparticle Synthesis Mediated by Photorelease of Ketyl Radicals

Initial investigations into applications of PI_1 type photoinitiators toward nanoparticle synthesis relied on unimolecular bond cleavage to yield ketyl radicals. These were reported by Itakura et al. using BN, where UVB photolysis generated the benzoyl and the phenyl hydroxymethyl radical in deaerated ethanol solutions in the presence of metal salts with PVP as a stabilizer to yield uniform nanoparticles within 30 min.¹⁴ Silver nanoparticles (AgNP) were prepared as well from BN with $AgClO_4$ and PVP, where an increase in the ratio of BN:Ag⁺ from 1:1 to 10:1 resulted in a decrease in particle size from 17 to 7 nm. They attributed the decrease in size to the stabilization by electron injection by radicals and strong surface repulsion forces. In the same report, CuNP were prepared from $Cu(ClO_4)_2$ at a 5:1 PI: Cu²⁺ concentration ratio to afford 3 nm CuNP. The ketyl radical reduces the cupric state to Cu(I) by a one-electron reduction, where further reduction can take place with another ketyl radical or slow disproportionation of the cuprous species. AuNP were also prepared in the study by a parallel fashion with BN, yet an increase in the ketone resulted in an increase in gold particle size as well as size distribution. The authors proposed the difference with gold occurring at the initial stage of nucleation with chlorine ions, where additional radicals would lead to additional growth. The mechanism for AuNP formation follows a similar series of reduction and disproportionation events outlined in Scheme 35.5, as the unstable Au(II) oxidation state disproportionates instantaneously followed by slow subsequent disproportionation of Au(I) or further reduction in the presence of another radical.

SCHEME 35.5 Reduction steps to gold nanoparticles.

Interestingly, in the absence of BN, significant formation of AuNP occurred as a result of the photochemical (reducing) properties of PVP, whereas minimal growth occurred for silver and negligible reduction occurred with copper. The mechanism for photoreduction from PVP remains unclear but has been observed in numerous cases. Bimetallic reductions were also pursued in this study for the combination of Ag/Cu alloys, as well as Ag/Au composites. Further investigations were performed by Esumi et al. to determine nanoparticle properties from BN photoreduction using dendrimers for stabilization.¹⁵ Poly(amidoamine) (PAMAM) and poly(propyleneimine) (PPI) dendrimers of G3–G5 generations were used in the preparation of gold and Ag/Au composites. They found that a greater dendrimer concentration from a larger generation could decrease the size of AuNP down to 9.1 nm for PAMAM G5, and 6.2 nm for PPI G4. The absence of BN neglected to form nanomaterials, yet an increase in BN continued to result in an increase in particle size. The PPI dendrimer nanocomposites formed as a result of BN photolysis remained to be alloy in composition at various PPI:metal molar ratios and different dendrimer generations.

Further work on BN came from Kotenani et al. who identified the α -hydroxybenzyl radical as the reducing agent over that of the benzoyl radical through transient studies in the preparation of AgNP in PVP.¹⁶ No AgNP were prepared upon 355 nm laser flash photolysis (LFP) of benzil in the absence of a hydrogen donor. Additional work was carried out by Marin et al. using BN as a PI for the synthesis of AuNP upon continuous wave (CW) 365 nm photolysis in deaerated aqueous solutions stabilized with various surfactants.¹⁷ While different surfactants were evaluated for optimal particle yield, it was found that a positively charged surfactant such as cetyl trimethyl ammonium chloride (CTAC) offered better stability as evidenced by a narrow and blueshifted SPB in comparison with negatively charged surfactants such as sodium dodecyl sulfate (SDS) at equivalent concentrations above the critical micelle concentrations. In addition to reduction from BN photolysis, they investigated the formation of AuNP in the nanosecond timescale and measured electron transfer rates via LFP studies of α -phenyl benzoin (PBN). Excitation of the chromophore at 355 nm resulted in α -cleavage from the lowest lying excited triplet state to yield the benzoyl radical as well as the benzophenone ketyl radical (BPK). The quenching of BPK monitored at 540 nm in deaerated acetonitrile/dimethyl sulfoxide in the presence of increasing amounts of AuCl_4^- led to a rate constant for electron transfer of $k_{\text{ET}} = 9.9 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$. When identical studies were performed with AuCl, a rate constant of $k_{\text{ET}} = 2.5 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ was obtained.¹⁷ The highly favorable processes occurred at a slower rate likely due to solvation differences between the two salts over differences in redox potentials. Despite different environments and monitoring species at different wavelengths, these values agree with previous investigations, where $k_{\text{ET}} = 7.2 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ was obtained from quenching of the α -hydroxy benzyl radical of BN by AgClO_4 monitored at 310 nm in deaerated ethanol.¹⁶ In addition to transient studies performed by Marin et al.,¹⁷ steady-state growth of AuNP from reduction via PBN with different salts was investigated. Under CW UVA photolysis, it was observed that the reduction commenced sooner for AuCl with the absence of an induction period, compared to the Au^{3+} salt. Interestingly, both methods produced AuNP in 25 min yet the rate of reduction was greater for Au^{3+} than for Au^+ after the induction period. Furthermore, average AuNP sizes were 7.8 and 17.1 nm prepared from AuCl and AuCl_4^- , respectively, highlighting the relationship between shorter nucleation periods and smaller nanoparticles. When PBN was present in a stoichiometric excess of Au^+ , the same minimal induction period of less than a minute was observed but with a parallel growth rate similar to reduction with AuCl_4^- . Thus, the appearance of the SPB using Au(III) can only commence once a critical concentration of Au(I) is attained.

Table 35.1 summarizes a number of examples where unimolecular PIs have been used for the synthesis of metal nanoparticles. The table is not exhaustive and emphasizes examples from our own laboratory.

Another successful photoreleasing reducing agent has been 1-[4-(2-hydroxyethoxy)phenyl]-2-hydroxy-2-methyl-1-propane-1-one, or under the name of Irgacure-2959TM (I-2959) as a commercial PI from Ciba Specialty Chemicals (Figures 35.3 and 35.4). The lowest lying triplet state of the α -hydroxy ketone has a short lifetime of 11 ns, and the molecule dissociates to yield a benzoyl radical and the 2-hydroxy-2-propyl radical.¹³

AuNP synthesis has been thoroughly studied using benzoin I-2959, BN and PBN as PIs in deaerated CTAC solutions, and a comparative growth experiment at equimolar 1.0 mM BN revealed the formation

of similar SPB within minutes with I-2959 yielding AuNP faster than BN and PBN. In a micellar solution, the trend is likely attributed to the transients with a greater dipole moment being located closer to the micellar Stern layer and therefore more readily accessible for reduction of aqueous species.¹⁷

The hydroxyethoxyl functional group of I-2959 facilitates water solubility, and the rapid photocleavage allows for ideal photoreduction in an aqueous environment. McGilvray et al. determined favorable growth conditions for AuNP in aqueous, ambient conditions by optimizing a number of factors through photochemical control.^{17,18} Such variables included reagent concentrations, irradiation intensities, and

FIGURE 35.4 Normalized growth of I-2959-generated AuNP over time under different O₂ environments; the lines are simply visual aids.

irradiation time. Synthesizing stable nanoparticles involves working in an excess of stabilizer relative to the concentration of metal salt, and an optimal ratio of 3:1 PI: Au³⁺ (i.e., reflecting the stoichiometry) has been quite effective with I-2959.^{18,26} At lower I-2959 concentrations, slow growth was observed with the yield of larger, unstable anisotropic gold prisms and micron-sized plates similar to those in Figure 35.5A. With more I-2959, reduction occurs rapidly to yield small AuNP, but in the absence of substantial stabilizer, AuNP agglomerated and typically precipitated within a few hours. These findings define a comfortable window at which nanoparticle synthesis can occur at just the right rate and concentration. The presence of oxygen in ambient aqueous solutions was found to be beneficial as this liberated the need for any additional stabilizer.^{17,18} Oxygen is known to quench the excited triplet state of many ketones and react with free radicals.^{12,27}

The growth of AuNP over time is presented in Figure 35.4. Working with an excess of I-2959 allowed for a portion of the photocleaved radicals to be sacrificially consumed by oxidative addition. Ketyl radicals reacted quickly at near diffusion control rates to reduce the aurous salt; building up a threshold concentration of Au⁰ during nucleation represented by an induction period prior to the appearance of an SPB. Nanoparticles formed within 5 min after which growth was arrested by photogenerated stabilizers. Particularly, benzoyl radicals underwent oxidation to yield 4-hydroxyethoxy benzoic acid (4-HEBA), as confirmed by GCMS.¹⁷ The photoproduct serves as a stabilizer of surface Au⁺ charges through physisorption of the carboxylate moiety in a similar function as trisodium citrate and accounts for the negative charge of the electronic double layer on the particle surface detected by zeta potential measurements.

At higher oxygen concentration, a longer induction period and a slower rate of growth were observed. Larger, prismatic particles were obtained owing to the overlap of nucleation and growth phenomena. Alternatively, in the absence of oxygen and any additional stabilizer, AuNP grew rapidly with a short induction period, yet coalesced into larger aggregates.

Conditions to yield small, monodisperse AuNP have also been optimized by controlling irradiation intensity and the wavelength of the light source.^{17,18} Higher irradiance under ambient conditions allowed for fast nucleation from a high concentration of ketyl radicals under CW UVA to yield 8–10 nm particles as depicted in Figure 35.5D. Irradiation with UVB or UVC light where the PI absorbs strongly resulted in much greater α -cleavage. Nanoparticle synthesis was more rapid, yet the higher concentration of acid produced led to NP aggregation. The homogeneity of the irradiation source also affected the yield of nanoparticles, such that the more uniform the irradiation from the light source, the more uniform the nucleation for monodisperse particles.

Silver nanoparticles have also been formed using I-2959. Maretti et al. have succeeded in generating AgNP using PIs to reduce the monovalent salts along with a strategic selection of stabilizers to minimize

FIGURE 35.5 TEM images of gold nanoparticles prepared with I-2959 under different irradiation conditions. (A) Vis light (3% UVA), (B) 7 W/m² UVA, (C) 40 W/m² UVA, and (D) 40 W/m² UVA.

the facile oxidation of silver nanoparticles.²¹ Particles grown under aqueous conditions in the absence of stabilizers agglomerated quickly as indicated by the broadening and redshifting of the SPB. Silver nanoparticles have also been synthesized with I-2959 in aqueous, deaerated sodium citrate solution at room temperature and the carboxylate groups of the citrate functioned to stabilize the spherical particles with an average size of ~3 nm.²² Alternatively, when AgNP were prepared from an organic silver salt AgCF₃COO in an organic medium such as toluene or tetrahydrofuran and stabilized in the presence of various amines, the resulting spherical nanoparticles were found to be approximately 3.4 nm and showed fluorescence due to Ag₂ (vide infra).^{21,26}

CuNP have also been prepared using I-2959 as a benzoin PI.²⁴ The synthesis of stable CuNP has been possible by photolysis in a deaerated, aqueous environment to prevent oxidation and agglomeration. Optimal conditions for synthesis of small, stable CuNP were established by studying different copper precursor salts. CuSO₄, Cu(NO₃)₂, and CuCl₂ were observed to give varying results, whereby growth of CuNP from CuCl₂ occurred significantly faster to generate a greater yield relative to the other precursors. CuNP from CuSO₄ produced monodisperse, 7 nm particles, whereas reduction of Cu(NO₃)₂ was sluggish to generate a smaller yield of larger particles. CuCl₂ generated a mixture of small 5 nm particles along with larger aggregates and prisms around 100 nm. The reduction with CuCl₂ was further investigated, where the rapid, autocatalytic growth was attributed to chlorine ligands (Figures 35.6 and 35.7).²⁴

Moreover, a variety of particle morphologies were produced upon varying the surfactant and the surfactant counter anion. It was established that CuNP synthesis with Cl⁻ counterion surfactants CTAC, TMACI or TPAC or TBAC generated plasmon absorbances of varying widths and maxima with a single plasmon, while the identical Br⁻ counterion surfactant synthesis generally led to the appearance of a secondary SPB characteristic of anisotropic particle formation. Furthermore, by analyzing the effects of the different surfactants on stabilization, it was found that the more hindered the interaction of the nitrogen of the ammonium salt with the metallic surface, the greater the polydispersity and greater deviation from spherical morphology. These studies indicate that while the anion is likely to govern the nucleation rate, particularly for catalysis by Cl⁻, the adsorption of organic stabilizer on specific facets of the copper nanocrystal can determine the final shape.

The PI I-2959 has also been used to generate bimetallic nanoparticles, particularly, silver/gold systems.^{23,28,29} Bimetallic nanoparticles can possess increased catalytic activity relative to monometallic

FIGURE 35.6 Absorbance changes at the plasmon band maximum as a function of irradiation time for deaerated aqueous solutions containing 0.66 mM CuSO_4 (▲), CuCl_2 (■), or $\text{Cu(NO}_3)_2$ (●) and 1.3 mM I-2959.

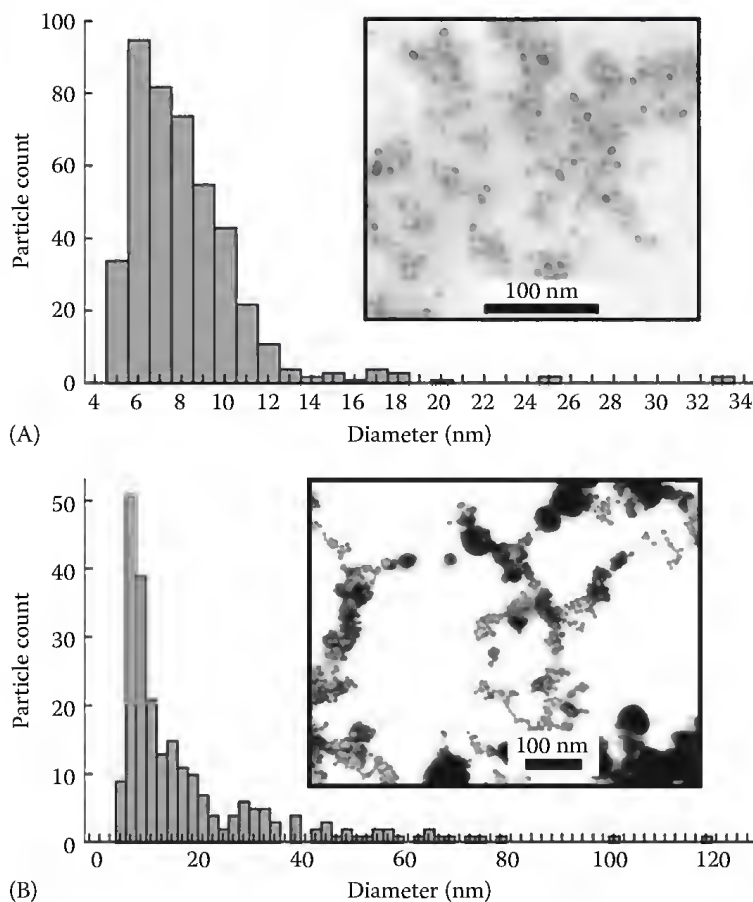

FIGURE 35.7 Size distribution histograms and SEM images (inset) for CuNP obtained from CuSO_4 (A) and CuCl_2 (B). (Adapted from Pacioni, N.L. et al., *Photochem. Photobiol. Sci.*, 9, 766, 2009.)

particles, and both gold/silver alloys and core/shell AgNP/AuNP have been prepared. Alloy nanoparticles were prepared with the HAuCl_4 , AgNO_3 , I-2959, and SDS micelles during UVA photolysis. When the ratio of starting material salts was varied to observe changes in alloy composition, clear changes in the SPB of the resulting colloids were observed. As the ratio of Au:Ag was increased, a single, broad SPB characteristic of alloys redshifted from 400 nm toward the absorbance of gold at 520 nm, as depicted in

FIGURE 35.8 UV-vis absorption spectra of Au-Ag alloy nanoparticles with increasing gold molar fraction X_{Au} shown in the numbers. In all cases the total cation concentration was 0.2 mM. (Adapted from Gonzalez, C.M., and Scaiano, J.C., *J. Phys. Chem. C*, 113, 11861, 2009.)

Figure 35.8. Stable Ag/Au alloy NPs were prepared at a 20:80 composition with an average size of 7.4 nm spherical particles. High-resolution transmission electron microscopy (TEM) further revealed lattice defects indicative of stacking faults. Time-resolved steady-state kinetic studies indicated that the gold salt was reduced first following generation of the characteristic SPB, followed by a reduction of AgNO_3 and concomitant blueshifting of the translational plasmon band.²³

Further, bilayer Ag/Au core/shell NPs were constructed by simple deviations in the order of addition or reagents throughout the synthesis. In this case, HAuCl_4 was first combined with CTAC, followed by the addition of I-2959, finalized by the addition of AgNO_3 following immediate irradiation. The temporal isolation of AuCl_4^- from Ag^+ and I-2959 by the micellar interface facilitated the initial sole reduction of AuNP followed by the formation of a silver shell. One of the primary characteristics of identifying bilayer nanoparticles is the presence of two maxima with the SPB for Au blueshifted relative to its characteristic monometallic plasmon.²⁹ In **Figure 35.9**, the peak representing the Ag SPB

FIGURE 35.9 UV-Vis spectra of self-assembled Au-Ag core-shell nanoparticles with varying gold:silver ratio for a 0.2 mM solution (total metal ions) containing CTAC and I-2959 irradiated for 6–8 min. The inset shows the core-shell structure as seen in a TEM image: the size bar is 5 nm. (Adapted from Gonzalez, C.M. and Scaiano, J.C., *J. Phys. Chem. C*, 113, 11861, 2009.)

remained at a similar wavelength. In contrast, when separate solutions of prepared AuNP and AgNP were combined, their absorption maxima remained at their characteristic wavelengths.²³

35.4.2 Nanoparticle Synthesis Mediated by Photorelease of α -Aminoalkyl Radicals

Along the lines of photorelease from triplet ketones, another PI I-907, or 2-methyl-1-[4-(methylthio)phenyl]-2-(morpholinyl)phenyl-1-butanone, undergoes α -cleavage under UVA photolysis to generate a benzoyl radical and an α -aminoalkyl radical with strong reducing properties.³⁰ CuNP were also prepared by in deaerated acetonitrile from copper acetate ($\text{Cu}(\text{OAc})_2$) using CTAC as stabilizer to afford 30 nm CuNP after 60 min irradiation.²⁴ CuNP were also prepared with thiophene or cyclohexylamine as stabilizer with reduction complete in half of the time. Trioctylphosphine oxide (TOPO) was also tested for stabilization, yet the resulting particles seemed larger and more polydisperse, judging from the broader SPB.

35.4.3 Two-Color, Two-Laser AuNP Synthesis

Sakamoto et al. devised a method for the generation of AuNP in polymer films by a two-color, two-laser method²⁵ that has been proposed to involve H atoms. In a poly(methylmethacrylate) (PMMA) or poly(vinyl acetate) (PVAc) matrix, carbazole was illuminated by 368.8 nm laser to generate the lowest lying singlet state, which decays to the lowest lying triplet upon intersystem crossing. Alternatively, when 368.8 and 514.5 nm lasers photolyze the sample simultaneously, carbazole is excited to a higher singlet state where N–H bond cleavage to generate the carbazyl radical and the hydrogen radical was suggested. Surprisingly, the presence of oxygen did not play a role in quenching the reaction. The resulting hydrogen radical possesses strong reducing properties and generates AuNP only at the fine intersection of the two laser beams, allowing for precise localization of nanoparticle generation. TEM analysis revealed the formation of spherical AuNP of approximately 19 nm. The two-laser technique also allowed for writing and patterning, with linewidths as thin as 4–5 μm .

The application of type 1 PIs has stretched beyond the accustomed generation of polymers and plastics, and into new domains for nanomaterials synthesis. UV absorption, short triplet lifetimes, and n,π^* reactivity allow for easy generation of reducing species for colloidal nanoparticle synthesis.

35.5 Part II: Photosensitized Generation of Metal Nanoparticles via Ketone Photoreduction

Photoinduced hydrogen atom abstraction by ketones is one of the most important reactions in organic photochemistry,^{12,31} where the excited triplet ketone will abstract hydrogen from a donor to yield two radicals or a biradical. Aryl ketones are a common photochemical sensitizer owing to their low-lying n,π^* state and thus high reactivity for hydrogen abstraction (Scheme 35.6).¹²

The rate of hydrogen abstraction is dependent on the electronic configuration of the ketone, where ketones with n,π^* character have been reported to be more than 100 times faster than carbonyls with π,π^* character.^{12,32} Additionally, the rate of reactivity also depends on the donor, where primary and

SCHEME 35.6 Schematic structures of BP, XAN, and 1-axaxanthone (AZX).

SCHEME 35.7 PI_2 pathway via intermolecular hydrogen atom transfer.

secondary alcohols, ethers, and alkyl benzenes induce faster reactivity with n,π^* character over π,π^* dominant ketones, yet phenolic hydrogen donors induce faster hydrogen transfer with π,π^* carbonyls.³³ Hydrogen abstraction results in the formation of two radicals, which can undergo photoaddition, dimerization, further hydrogen abstraction, or chemical reduction in the case of ketyl radicals in the presence of many metal salts. Ketyl radicals can reduce metal ions to metal atoms in the same manner as described in Section 35.4. Scheme 35.7 illustrates the process for M^+ , where only one electron is needed.

There has been abundant research into generating ketyl radical species via hydrogen abstraction from triplet ketones.^{17,31,34–37} The lifetime of the reducing radical or its precursor can dictate the efficiency of the reaction. Notably, it has been widely observed that metal salts can quench the excited-state triplets of many carbonyls with rates approaching diffusion control (*vide infra*). With this hindrance in mind, one way to maximize photochemical nanoparticle generation has been to prepare the materials in the presence of stabilizers such as polymers, dendrimers, or micelles, as they can compartmentalize the excited-state triplet species and enhance radical-pair generation via hydrogen abstraction,³⁸ yet the supramolecular structures also function to minimize quenching. As a proof of concept, nanoparticle synthesis in the absence of micelles using benzophenone (BP) in acetonitrile remains a challenge as a low yield of metal nanoparticle aggregates was obtained for experiments with silver or gold. A review of commonly used sensitizers for nanoparticle synthesis will be presented.

35.5.1 Acetone

Many reports exist for the photochemical generation of nanoparticles and nanorods using acetone.^{36,39–44} In many cases, particle formation requires 254 nm light and irradiation times on the order of several hours. Significant progress has been put forth by Dong et al. in the use of acetone to produce colloidal AuNP using a variety of different hydrogen donors, stabilizers, and photon energies.^{43,44} Solar irradiation of an Au(III)–sodium citrate solution produced 9–12 nm particles. Nanoparticles of approximately 7.5 nm in diameter were prepared by photolysis of an Au(III)–sodium dodecyl sulfonate–acetone system, yet substitution with sodium dodecylbenzene sulfonate yielded smaller, 6.7 nm particles with a narrower size distribution. Further, 3–5 nm particles have been prepared by 300 nm photolysis and subsequently used as seeds for further photochemical growth of 10–66 nm particles in an Au(III)–poly(ethylene glycol) (PEG)–acetone solution. Bimetallic Au/Ag core/shell particles were also synthesized utilizing the photochemical seeding technique where 3 nm AuNP seeds were added to a PEG–acetone– AgNO_3 solution. Finally, gold nanorods were prepared from an Au(III)–dimethylformamide–CTAC–acetone system to yield monodisperse rods with high aspect ratios greater than 10:1. Other syntheses of nanorods from acetone have been reported, many of which require the addition of AgNO_3 for directed growth.^{40–42} Interestingly, none of the reports mentioned here addressed deaeration during synthesis. With triplet lifetimes around 1–4 μs in aqueous systems, significant quenching by oxygen or other metal species were likely contributors to the required long irradiation times. Working with aryl or biaryl ketones, on the other hand, employs chromophores with absorption shifted to lower energies in the UV region, and thus shorter necessary irradiation times as well as shorter triplet lifetimes. An example of such a chromophore is BP.

35.5.2 Benzophenone

BP has been a widely used sensitizer for the generation of colloidal nanoparticles.^{34,45–48} In one example, Eustis et al. prepared colloidal AgNP from photolysis of BP with 265 nm 100 fs pulses and CW light in the presence of AgNO₃ and cetyl trimethyl ammonium bromide (CTAB) as a stabilizer.⁴⁶ They investigated the growth mechanism and observed a competition between formation and ablation at irradiation times over 2 h, as well as aggregation once BP had been consumed. They also established BP as the limiting reagent in their system. Increasing the laser power or the irradiation time resulted in sharper SPB peaks as ablation processes dominate at the higher intensities and photodecomposition could displace the capping material and lead to aggregation. In another report, Esumi et al. prepared AgNP by tethering BP to the surface of SiO₂ nanoparticles in the presence of isopropyl alcohol.⁴⁸ Positioning the reducing agent on an inert support minimized the formation of light absorbing transients produced from primary photochemical reactions of isopropyl alcohol and BP and thus minimized the degree of post irradiation particle degradation allotted to ketone transient recombination.³⁹ CuNP were prepared by Kapoor et al. using CuSO₄, BP, and PVP as a stabilizer in the presence of CW 253.7 nm light.⁴⁹ LFP studies of this system revealed that the BP triplet transferred its energy to PVP without hydrogen abstraction. As the BP ketyl radical was not detected in the 470–600 nm region, this implied that the excited PVP was responsible for the reduction. Photolysis of PVP in the presence of CuSO₄ alone, however, did not yield nanoparticles. This preparation yielded polydisperse particles as small as 15 ± 4 nm. In later studies, the author succeeded in preparing 10–40 nm CuNP from BP with gelatin as a hydrogen donor.⁵⁰ AgNP have also been prepared using BP from AgClO₄ in 2-propanol/acetonitrile and SDS as a stabilizer.⁵¹ The rate constants for BP triplet quenching were measured as $4.3 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$, and $4.3 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ for quenching of the BPK by Ag⁺.

While micelles can segregate photochemical reactions from quenching events, their cage-like function can also enhance geminal recombination of radical pairs and thus decrease micellar escape of reducing radicals to yield nanoparticles.⁵² This challenge can be overcome by working in the presence of a magnetic field. Since geminal recombination of these reactive triplet transients requires a spin-flip, lifting the degeneracy of the triplet states in the magnetic field significantly reduces probability for recombination and hence promotes micellar exit, which is not affected by magnetic fields, and subsequent nanoparticle synthesis. With this knowledge in mind, Scaiano et al. prepared AgNP via 320 nm photolysis of BP with AgNO₃ via hydrogen abstraction from 1,4-cyclohexadiene (1,4-CHD) in 0.1 M SDS, where 1,4-CHD was strategically used as a strong hydrogen donor (Figure 35.10).³⁴ The yield of

FIGURE 35.10 Formation of silver nanoparticles during UV irradiation in the absence (●) and presence (■) of a 50 mT magnetic field (BP 0.005 M, SDS 0.1 M, Ag⁺ = 0.01 M, and 0.04 M 1,4-CHD). The inset shows AgNP photographs in the presence and absence of an applied magnetic field. (Adapted from Scaiano, J.C. et al., *J. Phys. Chem. B*, 110, 12856, 2006.)

FIGURE 35.11 Growth of AuNP over time incorporating BP (●) or BP and 1,4-CHD (■) in CTAC. The TEM image in the inset illustrates the particles obtained in the absence of 1,4-CHD. (Adapted from Marin, M.L. et al., *J. Am. Chem. Soc.*, 130, 16572, 2008.)

nanoparticles was seen to increase up to 67% upon application of a magnetic field and saturated at around 100 mT. An increase in the size of spherical particles from 4 to 8 nm was also observed, along with an increase in the rate of their formation by 30%.

BP has also been used as a sensitizer for the generation of AuNP. BP was photolyzed in an aqueous system in the presence of CTAC and HAuCl_4 to yield 7 nm particles with good monodispersity (Figure 35.11).¹⁷

Under these conditions, the surfactant behaves as a mild hydrogen donor, whereby the methylene hydrogens have been known to be abstracted at rates approaching $3 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$.³⁴ Varying the R groups of the ketyl radical will modify the energy levels required for carbonyl excitation and consequently determine the reactivity of the excited state. To illustrate the diversity in chromophore selection, xanthone (XAN) was also tested for nanoparticle synthesis.

35.5.3 Xanthenes

In aqueous media, xanthenes is known to have a low-lying $^3\pi, \pi^*$ state and thus has poor reactivity toward hydrogen abstraction.^{37,53} AuNP were generated from XAN slowly and with very low yield as indicated by the redshifted and low-lying SPB absorbance for the produced colloid. Alternatively, when a pyridine ring is substituted into the framework, the excited triplet state of 1-azaxanthone has a low-lying $^3n, \pi^*$ state and is higher in energy than that of BP.³⁷ Owing to this, the generation of AuNP from the 1-azaxanthone system provides the fastest generation (<1 min vs. ~10 min for BP) as well as blueshifted SPB of 511 nm, and smallest particle size in comparative studies. A TEM image of AuNP prepared from AZX in CTAC is provided in Figure 35.12.

These structural differences highlight the ability to control the size and efficiency of nanoparticle generation by selection of a ketyl radical precursor with high hydrogen abstraction reactivity. In the presence of 1,4-CHD, even XAN reaches high SPB absorbances. As a strategy, those ketones with low-lying $^3n, \pi^*$ states perform best.¹⁷ Note that the ketone plays a catalytic role, since it is reformed following electron transfer to the metal ion. A summary of bimolecular reactions is shown in Table 35.2; as in the case of Table 35.1, it emphasizes work from our laboratory (Scheme 35.8).

Control experiments were also conducted in the presence of the diene yet the absence of a ketone, which revealed the formation of AuNP after some 20 min with a higher absorption intensity and greater

FIGURE 35.12 TEM image of AuNP prepared from 0.33 mM HAuCl_4 and 1.0 mM 1-azaxanthone in deaerated 17 mM CTAC following 30 minutes UVA photolysis. Scale bar represents 20 nm.

redshift. This would suggest that the formation of the cyclohexadienyl radical could also play a role in the reduction of metal salts. As many of these ketone triplets or their ketyl radicals can be quenched by molecular oxygen, these studies were performed with deaerated samples. Nevertheless, when hydrogen abstraction synthesis was performed under air, a similar relative reactivity among the three chromophores was still observed with longer induction periods.

35.5.4 Polymers

Various polymers have been utilized in metal nanoparticle synthesis with the function of macromolecular stabilization of small particles, where careful selection of polymer, its molecular weight, and additives offer control over particle size and shape in solution and in thin films. Interestingly, various polymers can also partake in photochemical reduction owing to the presence of a ketone and undergo hydrogen atom transfer between sensitizer and donor to form the reducing ketyl radical. AgNP were produced in the presence of PVP under 254 nm photolysis, where Huang et al. acknowledged that a higher %wt PVP resulted in both a greater yield and smaller nanoparticles.⁶³ Platinum and AuNP have also been produced in deaerated aqueous/ethanol polymer solutions containing PVP.^{55,56} Average particle sizes were reported to be 2–2.5 nm for platinum nanoparticle (PtNP) and 10.6 nm for AuNP, where the growth mechanisms were investigated using extended x-ray absorption fine structure (EXAFS). Nanoparticles have also been prepared in poly(vinyl alcohol) (PVA) solutions where the polymer performs as a hydrogen donor for BP, where the ketyl radical of BP in the D_1 excited state is generated by two-photon LFP to generate AuNP in films,⁴⁷ or by hydrogen abstraction with a known sensitizer such as BP for the formation of Au/Cu bimetallic nanoparticles.⁵⁴ An interesting report by Korchev et al. revealed their development of Cu, Ag, and AuNP in polymer films utilizing a sulfonated poly(ether ether ketone) (SPEEK)/PVA system.⁵⁷ Herein, the BP moiety of the SPEEK polymer abstracted hydrogen from PVA to yield two ketyl radicals and subsequently reduce metal salts in the presence of 350 nm light. PVA has been known to initiate a thermal reduction of metal salts over long time periods (days) as well as a slower photochemical reduction in the absence of sensitizer,

yet kinetics of systems incorporating SPEEK/PVA were considerably faster. AgNP of 6 nm diameter were generated from AgClO_4 in as little as 30 s, and it was observed that lower concentrations ($18 \mu\text{M}$) of the metal salt formed AgNP at faster rates than at higher concentrations ($90 \mu\text{M}$). At higher salt concentrations, more protons are produced as photoproducts, which can quench the SPEEK ketyl radical and thus inhibit reduction. CuNP were prepared from CuSO_4 under identical deaerated conditions to yield a broader sized distribution of 5–40 nm particles. The authors attributed the primary reduction of Cu(II) to Cu(I) to the ketyl radical with the formation of a CuOH complex absorbing at 460 nm, where no further reduction ensued if illumination was stopped. Additionally, when CuSO_4 was injected into a pre-irradiated solution of SPEEK/PVA in the dark, only a peak at 460 nm was produced. They interpret the final reduction as occurring via disproportionation of the cupric ion in acidic media to form Cu(0) leading to nucleation and growth, adding that the reduction of Cu^+ to Cu(0) is further catalyzed in the presence of CuNP. AuNP were also prepared in an identical system, and investigated the kinetics of the induction period prior to SPB generation, and attributed it to the initial reduction and disproportionation to AuCl_2^- with an absorbance at 246 nm but screened by the competitive absorption of SPEEK. Au^+ eventually yields Au(0) and nucleate to form nanoparticles.

Another approach to the photochemical generation of nanoparticles using polymers has been through the 254 nm photolysis of methoxy polyethylene glycol in water to generate the highly reactive primary alcohol radical to form silver, gold, or Au/Ag bimetallic particles.^{58,60}

35.5.5 Nanoparticle Generation from Inorganic Free Radicals

AuNP have also been prepared by an alternative photochemical method free from inorganic free radicals and thus reducing contaminants (Scheme 35.9). In a recent publication, the photochemistry of HAuCl_4 has been utilized to generate spherical and anisotropic gold nanomaterials.⁶² Upon absorption

SCHEME 35.9 Proposed mechanism for AuNP generation from H_2O_2 .

FIGURE 35.13 UV-vis absorbance of AuNP generated from UVA photolysis of HAuCl_4 and H_2O_2 , and corresponding SEM image of AuNP prepared under aerated conditions.

of UV light, the excited state of the salt, AuCl_4^{*-} , dissociates homolytically under aqueous conditions to generate AuCl_3^- and liberate Cl^\bullet .

The chlorine atom, in turn, is a powerful hydrogen abstractor and reacts with hydrogen peroxide to yield HCl and the hydroperoxyl radical, HOO^\bullet under aerated or deaerated conditions. This free radical can operate as a one-electron reducing agent to form AuNP. Representative data are shown in [Figure 35.13](#).

Under deaerated conditions, nanoparticle formation occurs quickly to yield a strong SPB absorbance. An air or argon atmosphere yields similar absorbance spectra. If, however, an aqueous stabilizer is added to the synthesis such as 4-HEBA, platelet formation is significantly suppressed.

35.5.6 Direct Photoreduction by Excited-State Species

One approach for photochemical preparation of AgNP utilized the reduction potential of excited-state species of pyrene or L-crown-pyrene created from 350 nm laser excitation of methanolic solutions to reduce AgClO_4 .⁶⁵ With fluorescence lifetimes of 296 and 51 ns for pyrene and L-crown-pyrene, respectively, the addition of AgClO_4 resulted in singlet quenching with rate constants of $4.7 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ and $3.7 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$, respectively. The reduction path from the pyrene moiety was attributed to electron transfer from the excited singlet state owing to a large $\Delta E_{\text{ST}} = 28.9 \text{ kcal mol}^{-1}$ and energetically favorable emf values. The generation of colloidal silver was evident from SPB at 405 and 425 nm for pyrene and L-crown-pyrene, respectively. The absorption intensity for L-crown-pyrene was redshifted and more than twice as large as that for pyrene at equimolar pyrene moiety concentrations, indicating larger particles and a greater particle yield due to enhanced Ag^0 stabilization in the crown ether cavity. In the absence of additional stabilizer, the colloids were found to decompose overnight. Other reports by Gratzel et al. have identified similar Ag^0 -chromophore-azo-crown ether complexes from photosensitized reduction of a cyanine dye in the presence of lipids, vesicles, and micelles, and attributed the stability of the reduced species to the segregating function of the stabilizer.⁶⁶

In a report from Sudeep et al., thionene was photolyzed with visible light to generate transients capable of forming AgNP in the 2–20 nm range.⁶⁷ Steady-state photolysis with a 530 nm cutoff filter or using a 532 nm laser source generated triplet thionene. Triplet thionene could either react with a donor through electron transfer or undergo self-quenching with the ground-state species to yield semithionene. LFP studies indicated little triplet quenching upon addition of AgNO_3 , and that the reductive semithionene was proven to be generated from self-quenching at micromolar concentrations, followed by electron transfer to form the

reduced semithionene. The electron transfer process is solvent dependent, where Ag^+ is effectively reduced in 1:1 toluene:ethanol, yet no AgNP evolved when the photolysis was performed in aqueous media.

Another photochemical synthesis of metal nanoparticles was developed from singlet oxygen-mediated photooxidation of amphiphilic dendrimers to generate reductive radicals upon photocleavage.⁶⁸ Oligo (*p*-phenylenevinylene) core branches and oligo(ethylene oxide) terminal chains were oxidized at the olefin center to generate the oxygen biradical, which photodegraded to yield the reductive α -hydroxymethyl radical as well as the aryl aldehyde product; 20 nm AuNP was prepared from the radical-induced reduction and was stabilized by the dendrimer or photodegraded dendrimer fragments.

35.6 Applications

35.6.1 Fluorescent Nanoparticles

In a recent publication, Maretti et al. reported the ability to construct fluorescent silver clusters following Ag^+ photoreduction with I-2959.²¹ AgNP were prepared from UVA photolysis of I-2959 and silver trifluoroacetate in the presence of cyclohexylamine or hexadecylamine as stabilizing agents in toluene or tetrahydrofuran. Small Ag_2 silver clusters were stabilized on the surface of the larger 3 nm AgNP and displayed strong fluorescence centered at 550 nm (Figure 35.14). The silver clusters show absorption and emission properties that did not overlap with the small SPB for AgNP at 390 nm. The emission has molecular-type properties with a characteristic mirror-image resemblance between absorption and emission, relatively long fluorescence lifetimes, simple monoexponential decay, and static quenching by nitroxides. These silver fluorescent nanoparticles (AgFNP) are stable for months, prepared under deaerated, yet stored under ambient conditions and lighting. AgFNP could be transferred to other solvents such as tetrahydrofuran (THF) with preservation of the fluorescent properties. AgFNP synthesized in THF displayed a narrower size distribution. The fluorescence was attributed to the Ag_2 silver clusters on the surface of the larger AgNP. Control experiments have been performed to rule out fluorescence from I-2959 photoproducts, residual amines complexing with silver salts, or from starting materials. The fluorescence quantum yield of the Ag_2 clusters was measured to be 0.11–0.15 depending on the solvent and the stabilizing amine. Fluorescence lifetimes were also measured for the AgFNP, and their decays (>98%) were found to be monoexponential with a lifetime of 2.6 ± 0.1 ns. These values agreed well with reported lifetimes of Ag_2 clusters in encapsulated or inert gas phase environments. The trifluoroacetate anion was critical to the synthesis of fluorescent AgNP, and ^{19}F NMR studies confirmed the presence of surface

FIGURE 35.14 Spectroscopy of fluorescent AgNP; fluorescence of Ag clusters on AgNP surface and schematic representation of the aggregates responsible for the fluorescence emission.

trifluoroacetate. The stability of the particle fluorescence was also found to depend on the ammonium ion, where larger ions are paramount to the particle and cluster stability.

TEM studies on AgFNP showed a particle size to be 3.4 ± 0.7 nm when prepared in THF and transferred to toluene for TEM analysis. Fluorescence microscopy studies were performed to localize the fluorescence in an environment most similar to solution conditions, optimized in a thin polystyrene film containing hexadecylamine AgFNP, where it was verified that emission arose from discrete particles and that Ag₂ fluorescent clusters must reside on the AgNP.

The clusters exhibit simple monoexponential decay characteristic more of smaller molecules than the complex, multiexponential decay of metal particles such as quantum dots. Other reports have also detected fluorescence of NP in the 2–3 nm range and attributed it to Ag₂ clusters.⁶⁹ These clusters still possess their emissive properties upon aggregation, yet the sharpness of their absorption and emission profiles are compromised. The generation of AgFNP in organic media has numerous possible applications for polymer, lithographic, and conductive material applications.

35.6.2 Photochemical Control over Particle Morphology

In a separate report, Stamplecoskie et al. have recently devised a method for synthesizing AgNP with tailored morphology.²² Aqueous AgNP were prepared from equimolar I-2959 and AgNO₃ with UVA irradiation in the presence of excess sodium citrate as a stabilizer to afford spherical nanoparticles 3.3 ± 0.4 nm in diameter. When colloidal solutions were subsequently exposed to light-emitting diodes (LEDs) with intense irradiation, anisotropic nanoparticles with different geometries were realized, depending on the irradiation wavelength. Essentially, excitation of the local plasmon reduced the intensity of the translation SPB of silver seeds at 395 nm and induces the growth of another SPB at a wavelength of lower energy than the excitation wavelength. Upon illumination with a 405 nm LED, the SPB of the AgNP solution shifted from 395 to 416 nm with a corresponding increase in size of spherical particles from 3 to 25 nm for as long as 2 h of irradiation (Scheme 35.10). This illustrated a strategic method for tuning the size of spherical AgNP photochemically and emerges as one of the simplest and cleanest methods for producing monodisperse nanoparticles, while other photochemical methods necessitate the presence of citrate, L-arginine, and PVP with long irradiation times for resultant polydisperse particles and variable morphology.

The architecture of AgNP could also be tuned by excitation at different wavelengths. Irradiation at 455 nm light, for instance, generated larger dodecahedra nanoparticles via the light-induced agglomeration of multi-twinned seeds to form lower energy surfaces. Analysis of the changes in absorption spectroscopy revealed a decrease in the dipole transient SPB at 395 nm and growth of a new peak at 495 nm and a broad shoulder appearing around 650 nm. Further, irradiation between 505 and 627 nm led to the generation of nanoprisms where the aspect ratio increased with irradiation wavelength. The appearance of truncated triangular or hexagonal prisms also appeared to be less prominent with lower irradiation energy. A similar decrease in the intensity of the translational SPB was followed by the appearance of a longitudinal SPB at a wavelength of lower energy relative to the excitation source. When 720 nm LEDs are used, the translational surface plasmon is excited, resulting in a variety of nanorods of different aspect

SCHEME 35.10 Generation of AgNP with differing morphology from LED-seeded growth. (From Stamplecoskie, K.G. and Scaiano, J.C., *J. Am. Chem. Soc.*, 132, 1825, 2010.)

ratios. The mechanism has been theorized to be dependent on the excitation of surface electrons where the corresponding electromagnetic field is generated, which induces agglomeration followed by growth along the direction of the excited dipole. Generally, the resulting absorption is redshifted relative to the LED source, and the morphologies tend to be a single species of anisotropic species when one sharp SPB peak emerges, or a mixture of shapes when translational and longitudinal SPBs are apparent with significant scattering. In terms of time required to prepare the different morphologies, synthesis can be complete in as little as 2 h for dodecahedra, yet 7 h or more for conversion to plates. Since nanoparticle growth and agglomeration are dependent on excitation of the SPB, it is reasonable that nanoparticle synthesis utilizing an LED source with longer wavelengths requires longer irradiation times since the absorbance intensity is significantly lower. To verify the aggregation/coalescence mechanism for this photochemical approach, it was observed that different morphologies were only successfully prepared using a CW light source, and that no change in the spherical seed AgNP occurred when a pulsed lamp such as a YAG-pumped OPO at 410 nm with a 10 ns laser pulse was used.

A secondary approach to photochemical control over particle morphology has been applied to AuNP adapting a photochemical seeding technique. Several reports have been recently presented on the optimization monodispersity of nanoparticle size by way of seeding.^{6–8,70,71} This method physically and temporally separates the nucleation and growth stages of nanoparticle formation by placing preformed nanoparticles (or seeds) in the presence of additional metal salt and a mild reducing agent. In the case of AuNP, mild reducing agents such as ascorbic acid or hydroxylamine hydrochloride are too weak to reduce the aurous salt, yet strong enough to induce surface-catalyzed reduction for the metal salt physisorbed to the nanoparticle. One challenge in this approach is to limit the degree of growth of new nanoparticles formed, otherwise known as secondary nucleation, where nanoparticle surfaces can catalyze the reduction of gold salts to atoms, yet the atoms nucleate independently to generate new small nanoparticles. Work by Gearheart et al. advanced seeded growth of spherical particles as well as extending growth into nanorods with the use of CTAB, acetone, and AgNO₃ and careful control of growth solution and seed concentrations.⁷⁰ While seeding of the photochemically generated nanoparticles can be executed thermally using mild reducing agents, we have recently been able to carry out photochemical seeding (Figure 35.15). While ketyl radicals have a high reduction potential, minimizing the concentration and performing subsequent seeding has allowed for optimal growth conditions. A similar approach has been developed using H₂O₂ as a mild reducing agent. With this photochemical subsequent seed-mediated growth method, gold nanoparticles were synthesized using the I-2959 method¹⁸, and employed as seeds for addition to a growth solution HAuCl₄ and photochemical reducing agent and irradiated through CW UVA photolysis. The resulting enlarged seeds were used again as seeds for

FIGURE 35.15 Sequential photoinduced seeding of AuNP using H₂O₂ and H₂AuCl₄.

further subsequent photochemical seeding. Spherical seeds with great monodispersity were produced up to ~120 nm. Upon further successive seeding, anisotropic particles and platelets took shape, presumably owing to the lower surface energies of larger particles. Control experiments in the absence of seeds resulted in slow growth of platelets and large prisms of micrometer length, thus confirming that controlled growth of spheres is a result of catalytic growth at the particle surface. Controlled photochemical seeded growth was also carried out using H_2O_2 as a reducing agent in the growth solution with I-2959 generated AuNP. In these experiments, the concentration of H_2O_2 was also kept approximately equimolar with the aurous salt concentration. Greater yields of nanoparticles were formed using H_2O_2 . While these larger (>20 nm) nanoparticles offer little use for catalytic reaction, many applications can harness into the strong surface plasmon absorption from larger particles, in such cases as imaging and drug delivery.

35.6.3 Functionalization of Metal Nanoparticles for Biological Applications

Recent studies by Narain et al. have revealed bioconjugated Streptavidin to AuNP with a photochemical approach.^{19,20} Here, AuNP were prepared via photolysis of I-2959 in the presence of HAuCl_4 , methoxy-poly(ethylene glycol) thiol (MPEG-SH), poly(*N*-isopropylacrylamide) (PNIPAAm), and a specific glycopolymer containing biotin under 350 nm light. Exposure to streptavidin resulted in a bathochromic shift in the SPB solution, indicative of selective binding of the functionalized AuNP. Subsequently, the authors also succeeded in stabilizing AuNP with bovine serum albumin as well as PEG-SH, where these biocompatible shells can allow stabilization and further functionalization for drug delivery applications.

35.6.4 Photo-Patterning of Metal Nanoparticles

Photochemical synthesis of nanomaterials has also been extended into lithographic deposition with spatiotemporal control over feature size and shape. Notable efforts have been put forth by Sakamoto et al. in the generation of various metal features patterned in polymer matrices.^{25,47} In particular, two-photon production of AuNP in PMMA and PVAc films has yielded 3D patterns such as grids and writing of Chinese characters with feature sizes in the nanoscale. Seeding growth has also been employed in the growth of preassembled nanostructures.⁷

35.7 Conclusions

Photochemical synthesis of metal nanoparticles offers some of the advantages that are common to photochemistry, such as relatively mild conditions along with spatial and temporal control. The reaction intermediates responsible are frequently (even if not always) reducing free radicals, such as ketyl and α -aminoalkyl radicals; a key to utilizing these efficiently involves avoiding precursor quenching, usually of an excited triplet state.^{17,26} Standard approaches to achieve this include (a) selection of short-lived excited state (a few nanoseconds) to minimize quenching by precursor metal ions and oxygen; (b) "segregation," such as the use of micelles, polymers, and dendrimers to minimize exposure of excited states to metal ions; (c) addition of good hydrogen donors that compete favorably with metal ion quenching; and (d) presence of stabilizing agents, some photogenerated as in the case of I-2959, to enhance the stability and monodispersity of the yielded particles. Furthermore, photochemistry of the metal salt itself can also be critical to nanoparticle synthesis, particularly where absorption by the metal complex can generate an excited-state complex capable of reduction itself such as the case for $\text{Cu}(\text{acac})$ or enhancement of reactivity due to cleavage of Cl atoms for HAuCl_4 .

Photochemical approaches can also be used to control shape and size, either by seeding growth methods or by LED exposure.²² The absence of multiple step syntheses or a complex pot of stabilizing agents and additives offers several advantages to these clean photochemical modification techniques. Other possible strategies may involve taking advantage of intense plasmon fields in the vicinity of the particle, an emerging field in nanoparticle research.⁷²

Glossary

AgNP	Silver nanoparticle
AuNP	Gold nanoparticle
AZX	1-Axaxanthone
BN	Benzoin
BP	Benzophenone
BPK	Benzophenone ketyl radical
BSA	Bovine serum albumin
1,4-CHD	1,4-Cyclohexadiene
CTAB	Cetyl trimethyl ammonium bromide
CTAC	Cetyl trimethyl ammonium chloride
CuNP	Copper nanoparticle
CW	Continuous wave
ΔE_{ST}	Singlet-triplet energy gap
EXAFS	Extended x-ray absorption fine structure
4-HEBA	4-Hydroxyethoxy benzoic acid
I-2959	1-[4-(2-Hydroxyethoxy)phenyl]-2-hydroxy-2-methyl-1-propane-1-one, or Irgacure-2959
I-907	2-Metyl-1-[4 = (methylthio)phenyl]-2-(morpholinyl)phenyl-1-butanone, or Irgacure-907
LED	Light-emitting diode
LFP	Laser flash photolysis
MPEG-SH	Methoxy-poly(ethylene glycol) thiol
PBN	α -Phenyl benzoin
PEG	Poly(ethylene glycol)
PMMA	Poly(methylmethacrylate)
PNIPAAm	Poly(<i>N</i> -isopropylacrylamide)
PtNP	Platinum nanoparticle
PVA	Poly(vinyl alcohol)
PVAc	Ply(vinyl acetate)
SDS	Sodium dodecyl sulfate
SPB	Surface plasmon resonance band
SPEEK	Sulfonated poly(ether ether ketone)
TBAC	tetrabutylammonium chloride
TDAB	tetradecylammonium bromide
THF	tetrahydrofuran
TMACl	tetramethylammonium chloride
TPAC	tetrapropylammonium chloride
XAN	Xanthone

36.1 Introduction

The global annual energy consumption is predicted to rise from 13.5 TW/year (2001) to 27 TW/year by 2050 and triple by the end of the century.^{1,2} This massive increase in demand is driven by both the predicted rapid economic growth in the developing world and an overall increase in the global population. Currently, the vast majority of energy is obtained through the combustion of fossil fuels with nuclear, hydroelectric, biomass, and renewable energy (solar, wind, wave, and tide), contributing a combined total of less than 15% of the required demand.³ The limited fossil fuel reserves, coupled to acute environmental concerns related to their utilization, is the driving force behind the development of renewable and clean energy resource. Solar energy represents the most abundant energy source on the planet, with 100,000 TW/year of energy reaching the earth's surface.³ The ability to capture this energy efficiently and store it in the form of a chemical fuel, allowing for its later use in dark periods, is a key goal for researchers. Development of this technology would offer access to a clean renewable source of fuels and would remove our dependence on fossil fuels.

The light-driven production of hydrogen and oxygen from water utilizing a photocatalytic material has been widely investigated due to its ability to provide a chemical fuel, H_2 , from widely available, low-cost resources (sunlight and water). The water-splitting photocatalytic material can be considered to be a mimic of the light reaction center in natural photosynthesis (Figure 36.1). In natural photosynthesis, the oxidation of water by PSII leads to the formation of O_2 and production of reducing equivalents, which are further used in the Calvin cycle in the reduction of CO_2 . Here, our artificial systems are also designed to oxidize the water, in a light-driven process, to produce O_2 ; however, in this case, the goal is also to drive the reduction of protons to produce H_2 (Equation 36.1).

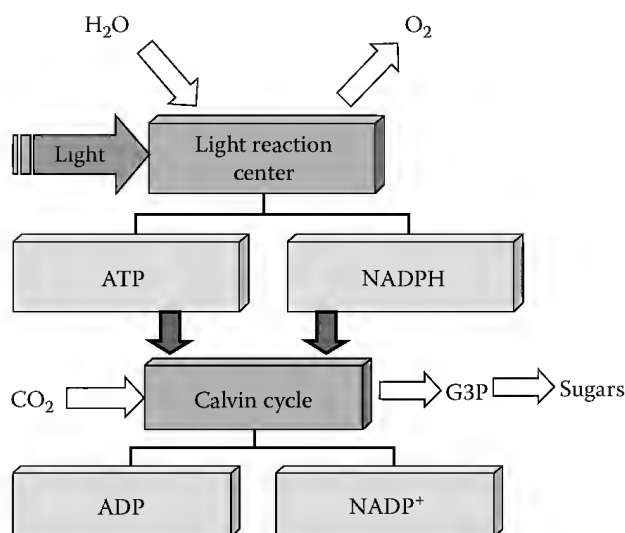

FIGURE 36.1 Schematic diagram of natural photosynthesis.

The use of hydrogen, either directly in combustion or in a fuel cell, leads to the release of energy and the formation of water, making this benign cycle a potentially carbon free way to power our lives using solar energy. The photocatalytic splitting of water over semiconductor materials was first demonstrated over 30 years ago by Fujishima and Honda.⁴ Their work utilizing a robust, cheap inorganic semiconductor, TiO_2 , as a photoanode illustrated the great potential of this technology. However, TiO_2 is only responsive to UV light, which consists of only a very small portion of the solar spectrum (ca. 4%), leading to a very low-energy conversion efficiency. Since this pioneering report, extensive studies have been carried out with the aim of developing materials that can efficiently absorb solar radiation and utilize the energy in the water-splitting reaction. It has been estimated that a minimum 10% solar energy to hydrogen fuel conversion efficiency is required for the commercialization of this technology.⁵ While several materials have been found to be active toward visible light, to date no single material has been able to deliver the required efficiency over a sustained period at an acceptable cost.

In this review focusing on water splitting over inorganic semiconductor photocatalysts, we first describe the principles in water splitting over inorganic photocatalysts and then we consider several categories of representative materials. Next, some important factors influencing water-splitting efficiency will be listed. Finally, we consider mechanistic work that is being carried out to guide the design of future materials. This is a very widely studied and fast moving field. A number of excellent review articles have been published in recent years.^{6–11} Therefore, due to the limited space available, we have concentrated on looking at a limited number of materials, and we have not considered in detail the use of photocatalytic materials as photoanodes in the photoassisted electrolysis of water.

36.2 Fundamentals of Water Splitting on Semiconductor Photocatalysts

If an incident photon has an energy that is in excess of the semiconductors bands gap, the region extending from the top of the filled valence band (VB) to the bottom of the vacant conduction band (CB), then absorption of the photon and formation of an electron, hole pair can occur, [Figure 36.2](#). If these charge carriers are able to reach the material's surface, then the VB holes and CB electrons can act as oxidizing and reducing species, respectively.

FIGURE 36.2 Idealized energetic diagram of a semiconductor photocatalyst for photochemical water splitting. VB refers to the valence band and CB the conduction band.

For hydrogen production to occur during water splitting, the electrons in the VB are required to have a potential that is more negative than the redox potential of H^+/H_2 (0 V vs. standard hydrogen electrode (SHE)). While for water oxidation and oxygen production to occur, a hole potential that is more positive than the redox potential of $\text{O}_2/\text{H}_2\text{O}$ (+1.23 vs. SHE) is needed. On this basis, a minimum theoretical band gap energy of 1.23 eV is required. In reality, the minimum practical energy required to drive water splitting is much higher due to energy losses associated with the overpotentials required for hydrogen and oxygen production and driving force for charge carrier transportation. It has been commonly predicted that a practical minimum band gap energy of 1.6 eV (775 nm) is required. Therefore, development of a photocatalyst with activity from the UV through to visible wavelengths (~ 750 nm) with a VB and CB that straddle the water-splitting potentials is a key goal in obtaining optimum solar to hydrogen fuel efficiency. The band levels of some simple semiconductors have been measured and are shown in Figure 36.3.⁶

These energetic requirements make knowledge of the band gap and position an essential condition when considering semiconductor materials for photocatalytic water splitting. Band gaps of materials are commonly measured by UV–visible absorption spectroscopy. The position of the CB edge is measured using several photoelectrochemical and spectroscopic measurements. On the other hand, the CB edge of an oxide can also be obtained by calculation. This is based upon the Mulliken electronegativities of the constituent atoms. It has been found to be a relatively simple and useful technique.^{12–14} The Mulliken electronegativities of atoms are based upon physical measurements and are often described as

FIGURE 36.3 Band positions of selected semiconductor materials. (Reproduced from Kudo, A. and Miseki, Y., *Chem. Soc. Rev.*, 38, 253, 2009. With permission.)

the absolute electronegativity, in a sense being electrochemical potential of the electron in the neutral atom. The CB position of a semiconductor at the point of zero charge can be expressed empirically by Equation 36.2:

$$E_{\text{CB}} = X - 0.5E_{\text{g}} \quad (36.2)$$

where

E_{CB} is the CB edge potential relative to vacuum

X is the electronegativity of the semiconductor, which is the geometric mean of the Mulliken electronegativity of the constituent atoms

E_{g} is the band gap energy of the semiconductor

The process of water splitting by semiconductor photocatalysts is often considered as encompassing three steps: (1) charge carrier (electron/hole) generation following absorption of a photon of suitable energy, (2) charge carrier separation and transportation, and (3) chemical reaction between surface species and the charge carriers. Photocatalytic water splitting is therefore a complicated combination of photophysical and photochemical processes. There have been numerous examples within the literature of semiconductor materials that are able to evolve both hydrogen or oxygen from water in the presence of a suitable charge carrier scavenger (e.g., to observe H_2 production a hole scavenger is employed), but that are unable to produce both oxygen and hydrogen simultaneously through photochemical water splitting. This demonstrates that although the correct positioning and energy of the band gap is a prerequisite, it is not the sole factor in determining water-splitting activity. Other factors such as kinetic competition, through charge carrier recombination, which may occur at a greater rate than the required surface reductive and oxidative chemistry, can be the dominant factor in determining materials reactivity toward the water-splitting reaction and following an overview of UV and visible active materials, kinetic studies will be examined in Section 36.4.

36.3 Material Development

To date, there are approximately 200 different materials that have been developed for either overall water splitting (hydrogen and oxygen production) or for hydrogen or oxygen production alone (utilizing the relevant scavengers) under UV and visible light irradiation. These materials can be grouped into three main categories, transition metal oxide photocatalysts, main group metal oxide photocatalyst, and others including sulfides and nitrides. In the following sections, we have attempted to provide an overview of key materials that are either active under UV or visible irradiation in each of these categories. Where a material is described as having water-splitting activity, it refers to the production of H_2 and O_2 in a 2:1 ratio from water. If it is described as being active for H_2 or O_2 production, then chemical scavengers will have been employed to scavenge either holes or electrons. Hole scavengers commonly include methanol (MeOH), Na_2S , and Na_2SO_3 ; and these are used to selectively produce hydrogen. Electron scavengers commonly include Ag^+ , $\text{S}_2\text{O}_8^{2-}$, and $\text{Ce}(\text{SO}_4)_2$; and these are used to selectively produce oxygen. Reported H_2 and O_2 production rates can be misleading as indicators of material activity as these will depend heavily on conditions such as light source and reactor design. Where possible, we have attempted to report quantum yield for a particular wavelength of light [$\text{QY} = (\text{number of reacted charge carriers/incident photons}) \times 100$].

36.3.1 UV Active Semiconductors

36.3.1.1 Transition Metal Oxides

It is over three decades since Fujishima and Honda first demonstrated photoassisted electrolysis of water for O_2 production on a TiO_2 anode under an external bias in a three electrode system, where a Pt counter electrode was used to generate H_2 .⁴ This stimulated extensive research interest in solar hydrogen

generation over metal oxide semiconductors. A key advantage of a number of the metal oxides, such as TiO_2 , is their high stability under a range of conditions; unfortunately, this is often associated with a large band gap leading to photocatalytic activity under UV light only. UV-active metal oxides normally have a VB composed of filled O 2p orbitals and CB, which is composed of empty d orbitals for transition metal oxides or s, p orbitals for main group metal oxides. In the following section, a number of UV-driven transition metal oxide photocatalysts are reviewed.

TiO_2 has continued to be widely studied as a UV-active water-splitting material. Various studies have been carried out since that have confirmed the initially reported activity of TiO_2 and these have identified O_2 and H_2 as the products formed during water splitting.^{5,15} In place of an externally applied electrical bias, a pH difference between two compartments of a cell can be used to promote electron transportation from a TiO_2 photoanode to a Pt cathode.¹⁶ Subsequent studies on powdered TiO_2 catalysts have examined the photoactivity of TiO_2 in the absence of any applied bias, and it has been reported that TiO_2 can split preabsorbed water vapor.¹⁷ Grätzel et al.¹⁸ reported that UV irradiation of colloidal TiO_2 loaded with both Pt and RuO_2 lead to the formation of both H_2 and O_2 , though O_2 was believed to be bound to the catalyst surface preventing its observation for an initial period. Mills and Porter¹⁹ also investigated the addition of a Pt catalyst to the TiO_2 surface and reported that H_2 production but no O_2 production was observed, presumably due to photoabsorption of the O_2 produced. In 1985, Yamaguti and Sato²⁰ found loaded both Rh and NaOH onto TiO_2 and reported a greatly enhanced activity for photochemical splitting of water vapor (QY = 29%). Since these initial reports, there have been a range of other transition metal oxides developed that are active under UV illumination and Table 36.1 shows a brief summary of their activities.

From Table 36.1, it can be seen that the oxides of groups IV (Ti, Zr), V (Nb, Ta), and VI (Mo, W) have been heavily researched for their photocatalytic ability. From group IV, particular attention has been paid to SrTiO_3 except TiO_2 , a perovskite structured material. In the presence of a NiO cocatalyst, SrTiO_3 has been reported to be active for both O_2 and H_2 production under UV illumination (H_2 : 40 $\mu\text{mol/h}$, O_2 : 19 $\mu\text{mol/h}$).^{22–27} In these studies, the NiO cocatalyst was prepared by H_2 reduction and subsequent O_2 oxidation of NiO to form a Ni/NiO double layer structure. RhO_x has also been reported to be an active cocatalyst for water splitting on SrTiO_3 .⁷¹

Other important titanates that have been studied include, $\text{La}_2\text{Ti}_2\text{O}_7$, a layered structure consisting of four TiO_6 unit slabs separated by La^{3+} ions layers. $\text{La}_2\text{Ti}_2\text{O}_7$ has demonstrated stoichiometric oxygen and hydrogen production from photocatalytic water splitting with a high QY (up to 12%) when used with a NiO cocatalyst.²⁸ The doping of $\text{La}_2\text{Ti}_2\text{O}_7/\text{NiO}$ with BaO and the addition of NaOH to the catalyst suspension leads to an even greater enhancement in the water-splitting ability and a QY of ~50% (UV region), the second highest QY for a UV-water-splitting photocatalyst in the absence of scavengers, has been reported.⁷² The closely related layered perovskite materials, $\text{M}_2\text{La}_2\text{Ti}_3\text{O}_{10}$ (M = alkaline metal) also have reported high activities for water splitting following UV excitation.^{30,31}

ZrO_2 with a rutile structure has a very large band gap of 5.0–5.7 eV.^{70,73} Unlike most binary metal oxides, it has been shown to be active for water splitting without a cocatalyst under UV irradiation. The rate of water splitting can be optimized by the addition of alkali carbonates to the water and NaHCO_3 treatment has been found to give the highest efficiency.⁷⁰ In contrast to a number of other metal oxides, the addition of cocatalysts such as Pt, Cu, Au, or RuO_2 to the ZrO_2 surface actually leads to a decrease in photocatalytic water splitting, suggesting a large energetic barrier between the cocatalyst and semiconductor material as a result of the large band gap and position of the CB and VB.

In group V, a number of tantalates and niobates have shown high levels of activity for photocatalytic water splitting, these include MTaO_3 (M = alkaline metal),^{38–40} MTa_2O_6 ,⁴² $\text{M}_2\text{Ta}_2\text{O}_7$,^{43–46} and $\text{M}_2\text{Nb}_2\text{O}_7$ (M = earth alkaline metal).^{44–46,48} While these materials are suitable for both H_2 and O_2 production, their large band gap limits their potential use as a practical solar hydrogen material. Most of these materials are characterized by a perovskite-type structure (ABO_3), which allows for the preparation of a wide range of derivative photocatalysts by means of incorporating suitable metals into A and/or B sites. NaTaO_3 when loaded with a NiO cocatalyst exhibits a particularly high QY (20% at 270 nm)

TABLE 36.1 UV Active Transition Metal Oxide Photocatalysts

Photocatalyst	Experimental Conditions	Cocatalyst	H ₂ Evolution (μmol/h)	O ₂ Evolution (μmol/h)	QY (%)	References

Where available, QY should be used as a measure of material activity for photochemical water splitting. An O₂ evolution rate of "Stoich" refers to a reported stoichiometric production of H₂:O₂ but with no directly reported rate of O₂ evolution. Pt cocatalyst was used for hydrogen evolution with the relevant electron donors and NiO or RuO₂ cocatalysts for complete water splitting. It is same in the following tables unless stated otherwise.

for water splitting.^{39,40} Doping of this material ($\text{NaTaO}_3/\text{NiO}$) with 2 mol% La was believed to cause reduction in the particle size of the catalyst, enhancing the materials surface area. The increase in photocatalyst surface area along with a nanostructuring effect, that was believed to spatially separate the sites of water oxidation and hydrogen evolution, was attributed to be the cause of a massive increase in the QY for water splitting. The QY of 56% is the current record for the UV-driven photocatalytic splitting of water in the absence of any scavengers.^{41,42}

An interesting layered material is $\text{M}_4\text{Nb}_6\text{O}_{17}$ (M = alkaline metal), which is active for water splitting under UV irradiation.^{38,54,55} It has been suggested that H_2 production occurs on one interlayer while O_2 production occurs in the other interlayer. This is a key advantage of this material as it facilitates H_2 and O_2 separation, preventing recombination, which is a key issue with photochemical water splitting using a photocatalyst suspension.⁷² These materials have shown activity for water splitting even in the absence of a cocatalyst. It has been reported that an enhanced activity for H_2 production can be achieved by ion exchange of protons with a suitable hole scavenger.⁷⁴

$\text{BaNi}_{1/3}\text{M}_{2/3}\text{O}_3$ (M = Nb, Ta) and $\text{BaZn}_{1/3}\text{M}_{2/3}\text{O}_3$ (M = Nb, Ta)⁵² are derivatives of tantalates and niobates with a ABO_3 perovskite structure. These compounds show the same lattice parameters due to the same ionic radius of Nb^{5+} and Ta^{5+} . Raman spectra and photocatalytic measurement were used to correlate material activity with the phonon modes inside these materials. Some phonon modes in the bending branch of the Raman spectra of the Ta-containing photocatalysts show an obvious redshift in their frequency, compared with those of Nb-containing photocatalysts. The Ta-containing materials have a lower activity for H_2 production compared to the Nb-containing materials even though the latter samples have a smaller surface area and larger band gap. The authors suggested that these phonon modes play an important role in the control of migration of the charge carriers inside the photocatalyst and this dominates photocatalytic activity. The ability of these ABO_3 perovskites to accommodate a range of different transition metal dopants has led to a high level of interest into these materials with the aim of tuning dopants to not just enhance UV-light-driven efficiency but also extend activity into the visible region.

Tungstates and molybdates have also displayed UV-driven photocatalytic activity. It has been demonstrated that these materials require an appropriate sacrificial electron or hole scavenger to observed the generation of O_2 or H_2 , respectively. For example, AgInW_2O_8 has been reported to be active for H_2 production in an aqueous MeOH solution and O_2 production in silver nitrate solution under UV illumination.⁶² However, in the absence of chemical scavengers, H_2 is produced without O_2 evolution on NiO-loaded AgInW_2O_8 under UV light. This result would suggest that O_2 formation is occurring but that it is absorbed on the photocatalyst surface, which greatly limits the materials efficiency.⁶²

36.3.1.2 Main Group Metal Oxides

Metal oxides containing the elements of groups XIII and XIV, such as In, Sn, Sb, Ga, and Ge, have been reported to be active for water splitting when loaded with a suitable cocatalyst (e.g., RuO_2) under UV light (Table 36.2). MIn_2O_4 (M = Ca, Sr, and Ba),^{79,80} containing distorted InO_6 octahedra, shows H_2 and O_2 production from pure water when a cocatalyst (RuO_2) is added to the material through an impregnation method. Among these structures, CaIn_2O_4 has the highest demonstrated activity for water splitting under UV light. Materials of the type MSnO_3 (M = Ca, Sr, and Ba) have also demonstrated O_2 and H_2 production from pure water when a RuO_2 cocatalyst is deposited on the semiconductor surface.⁷⁵⁻⁷⁷ RuO_2 loaded SrSnO_3 shows the highest level of activity for photochemical water splitting among these tin oxides, which has been attributed to the suitable positioning of the conduction and VB edges and to the high mobility of the photogenerated charge carriers caused by the proper distortion of SnO_6 connection in SrSnO_3 . The influence of SrSnO_3 morphology on H_2 and O_2 production yields in the presence of sacrificial charge carrier scavengers was investigated further. A nanorod morphology that was obtained by hydrothermal synthesis was found to be the most active with a 10-fold increase in photocatalytic activity when compared to standard particles prepared by high-temperature solid-state reaction with a similar surface area and optical density.⁷⁷ $\text{M}_2\text{Sb}_2\text{O}_7$ (M = Ca, Sr) containing corner-shared octahedral

Where available, QY should be used as a measure of material activity for photochemical water splitting.

SbO₆ units are known to be active photocatalysts for the overall splitting of water when loaded with RuO₂ and these materials have displayed near-stoichiometric H₂ and O₂ yields.⁸¹ Ga₂O₃ has also shown some activity for water splitting under UV illumination when loaded with a NiO cocatalyst,⁸² and this can be greatly enhanced through doping with 1% Zn, which leads to an eightfold increase in water-splitting activity.⁸³

36.3.1.3 Other Compounds

A number of sulfides and nitrides have reported photocatalytic water-splitting ability under UV illumination in which the VB is primarily composed of S 3p or N 2p orbitals, Table 36.3. ZnS has a band gap of 3.66 eV limiting its activity to UV light, despite this it has been extensively investigated for photocatalytic hydrogen production.^{85–87} Yanagida et al. first reported the evolution of hydrogen over ZnS under illumination of a 125 W Hg lamp in the presence of tetrahydrofuran or an alcohol hole scavenger. To confirm that photocatalytic hydrogen evolution was occurring from water experiments in the presence of D₂O were carried out leading to the evolution of D₂.⁸⁷ Reber and Meier,⁸⁶ systematically investigated the photochemistry of ZnS examining a range of factors including electron donors, pH, and temperature, which lead to a record QY of 90% following 313 nm excitation of ZnS coated with Pt in a solution of Na₂S, H₃PO₃, and NaOH.^{85,86} CuInS₂ and CuIn₅S₈ have also shown activity for UV-driven hydrogen production from water in the presence of a sulfite electron donor.⁸⁸ However, in

Where available, QY should be used as a measure of material activity for photochemical water splitting.

common with all of the sulfide materials reported here photochemical corrosion has proved to be a major obstacle, with sulfide oxidation to sulfates and sulfur occurring in the absence of suitable sacrificial electron donors.

Domen et al. recently developed a new family of UV-active nitride photocatalysts.^{90–95} The VB of these photocatalysts is composed primarily of N 2p orbitals, instead of O 2p orbitals as in metal oxides, resulting in a narrowing of the band gap. When loaded with a RuO₂ cocatalyst Ge₃N₄ is an active photocatalysts for water splitting under UV irradiation. Ge₃N₄ is also the first reported nonoxide photocatalyst for the complete splitting of water in the absence of a chemical scavenger, and a QY of 9% at 300 nm has been reported.^{90–93} GaN, the widely used material in blue light emitting diodes (LEDs), also displays water-splitting activity under UV illumination when modified with an Rh_{2–x}Cr_xO₃ cocatalyst.⁹⁴

36.3.2 Visible Light–Driven Photocatalysts

In the following section, a review of materials suitable for visible light–driven photocatalytic water splitting is carried out. In order to achieve visible light absorption, a number of groups have examined using of anion- or cation-doped materials. In these materials, a dopant level is introduced into the band gap, for example, between the VB (mainly O 2p) and the CB (transition metal 3d) of a metal oxide. The function of the dopant is to lead to the formation of either a new VB (anion doping, such as N, C, and P) or CB (cation doping, such as Cr and Ni).

36.3.2.1 Metal Oxides

WO₃ has been widely studied for its known ability to act as a photocatalyst for water oxidation under visible light irradiation in the presence of an electron acceptor, such as Ag⁺. However, the position of the CB of WO₃ makes H₂ production energetically unfavorable (Figure 36.2).⁹⁶ Numerous groups have attempted to modify tungsten oxide to enable both H₂ and O₂ evolution. Theoretical calculations predicted that a series of tungsten oxide–based photocatalysts including AgInW₂O₈, AgBiW₂O₈, Ag₂WO₄ would have a raised CB compared to WO₃ allowing for both H₂ and O₂ production. Experimental photocatalytic water studies have since confirmed these theoretical studies with these materials demonstrating activity for both O₂ and H₂ production (Table 36.4).^{13,62,63}

There has been considerable interest in the modification of SrTiO₃. This material has shown activity for water splitting under UV light and research has concentrated on extending the absorption profile of this material into the visible region with the hope of producing a cheap, robust visible-light active-water-splitting photocatalyst. Cr–Sb codoped SrTiO₃ with a Pt cocatalyst has been used to produce H₂ under visible light irradiation in a solution containing methanol as an electron donor.⁹⁷ Doping of SrTiO₃ with solely Cr has also been shown to enhance H₂ evolution under visible irradiation, provided that the Cr occupies Sr sites in the SrTiO₃ structure, if Cr replaces Ti sites, then it retards photocatalytic ability, demonstrating that the site of doping is a crucial factor influencing material performance.⁹⁹ Rh-doped SrTiO₃ has also been studied and under visible irradiation photocatalytic H₂ production has been reported when a Pt cocatalyst and a methanol hole scavenger are used.¹⁰¹ In these studies, doping of SrTiO₃ with Rh and Cr has not led to effective visible light water oxidation catalysts with reported O₂ production rates being very limited even in the presence of sacrificial electron donors such as Ag⁺. Solid solutions of AgNbO₃–SrTiO₃ have been shown to photocatalytically split water to produce oxygen under visible light in the presence of an electron scavenger, though this material does not appear to have any H₂ evolution activity.¹⁰²

Kudo et al. have reported that monoclinic BiVO₄ is a very active water oxidation photocatalyst under visible irradiation with a QY for O₂ production of 9% at 450 nm.^{117–119} The photocatalytic activity of BiVO₄ has been found to be strongly influenced by the material preparation route, with precipitation method producing more active photocatalyst than the other reaction syntheses regardless of the low surface area of the catalyst.¹¹⁹ The lower efficiency of the materials prepared by high-temperature solid synthetic routes has been proposed to be due to an increase in the defect concentration in this material

Where available, QY should be used as a measure of material activity for photochemical water splitting.

FIGURE 36.4 Water splitting on Ni-doped InTaO_4 under visible light irradiation. (Reproduced from Zou, Z.G. et al., *Nature*, 414, 625, 2001. With permission.)

as a result of the high temperatures employed. Ye et al.¹²⁰ have investigated the effect of doping BiVO_4 with Mo, which led to the reporting of a very high QY for O_2 production (31%) at 420 nm.

The group of Ye has also investigated many photocatalysts containing Cr or V including $\text{In}_6\text{NiTi}_6\text{O}_{22}$, $\text{In}_3\text{CrTi}_2\text{O}_{10}$, and $\text{In}_{12}\text{NiCr}_2\text{Ti}_{10}\text{O}_{42}$.¹⁰³ These materials all have a similar monoclinic crystal system and the same space group $P2_1/a$, which allowed the authors to clarify the effects of transition metal cations (Ni and/or Cr) with partially filled 3d orbitals on the photocatalytic properties of the system. Even though the band gap energies of the three systems are very similar, they showed significantly different photocatalytic H_2 evolution rates. The much higher activity of $\text{In}_{12}\text{NiCr}_2\text{Ti}_{10}\text{O}_{42}$ for H_2 evolution was attributed to continuous CB and VB, formed by the hybridization of split Ni 3d and Cr 3d orbitals with Ti 3d and O 2p orbitals, which would be expected to be beneficial for charge carrier transportation, suggesting the importance of charge carrier mobility in these systems.

All of the materials described earlier have reported activity for H_2 and/or O_2 production under visible light, only in the presence of an appropriate sacrificial reagents. To date, the only metal oxide (other than solid solution) with reported visible light activity for water splitting in the absence of scavenger species is Ni-doped InTaO_4 , which was reported by Zou et al.¹²⁴ When an RuO_2 or NiO cocatalyst is employed on the Ni-doped InTaO_4 , H_2 and O_2 are produced with a ratio of 2:1 from pure water under visible irradiation with a QY of 0.66% at 402 nm (Figure 36.4). The photoactivity of undoped NiO-InTaO_4 has been investigated and found to be less active. It is suggested that Ni^{2+} ions displace In^{3+} causing a contraction of the lattice and that the partially filled Ni d orbitals reduce the band gap of the material leading to visible light absorption (<480 nm).

36.3.2.2 Metal Sulfides and Nitrides

Both sulfides and nitrides have great potential as visible light photocatalysts for the production of solar H_2 and the representative materials are listed in Table 36.5. Among them, sulphides application has been limited due to photocorrosion that hampers the materials stability. In an attempt to improve resistance to photocorrosion, electron donors such as S^{2-} and SO_3^{2-} are often added into the water solution. Among the sulfides, CdS is the most extensively investigated material due to its narrow band gap and ideal bands positions for both O_2 and H_2 evolution (CB at -0.87 V and VB 1.5 V vs. SHE) (Figure 36.3).^{89,125,126}

Where available, QY should be used as a measure of material activity for photochemical water splitting.

Both Mills et al.¹⁹ and Darwent^{147,148} investigated CdS for water splitting using Ethylenediaminetetraacetic acid (EDTA) as an electron donor. Under visible light irradiation, Pt coating of CdS was found to improve H₂ evolution rates from aqueous EDTA by a factor of 10. A very high activity for H₂ evolution was reported on Pt–CdS in NaSO₃ aqueous solution (QY = 35%, 430 nm). Very recently, Li et al. improved the activity of CdS for H₂ production in Na₂S and Na₂SO₃ solution by co-functionizing CdS with Pt and PdS leading to a QY of 93% at 420 nm.¹⁴⁶ Grätzel et al. have also reported that co-functionized CdS with Pt and RuO₂ is an effective water-splitting photocatalyst under visible irradiation and, furthermore, that the RuO₂ on the CdS surface mediates photocorrosion.¹⁴⁹ A number

FIGURE 36.5 Water splitting on solid solution of GaN–ZnO under visible light irradiation. (Reproduced from Maeda, K. et al., *Nature*, 440, 295, 2006. With permission.)

of different strategies have been employed to overcome the photocorrosion of CdS including encapsulation of CdS nanoparticles,^{150,151} forming composites of CdS with materials such as TiO₂^{152,153} and ZnS,¹²⁶ and doping of CdS by noble metals and transition metals^{154,155}; however, photocorrosion still remains a significant problem with CdS photocatalysts.

Domen et al. have developed a family of nitrides/oxy-nitrides visible light-driven photocatalyst.^{127–132} The oxy-nitrides can be prepared by nitriding metal oxides using ammonia. TaON has a band gap of 2.5 eV and has been found to be active for O₂ evolution (QY = 34%, 420–500 nm) in the presence of a sacrificial electron acceptor (AgNO₃(aq)) and separately for H₂ production when used with a Pt cocatalyst in an La₂O₃ buffered methanol/water solution.¹²⁹ Tantalum nitride (Ta₃N₅) also has reported activity for both H₂ and O₂ evolution in the presence of sacrificial electron/hole scavengers, though the QY for O₂ production (10%, 420 nm) is significantly lower than that of TaON.^{127,128} It should be noted that the nitrides/oxy-nitrides reported earlier need an La-containing material such as La₂O₃ or La(NO₃)₃ to be added to the aqueous solution to buffer the pH for to maintain continuous O₂ production.

Solid solutions of nitride-oxide mixes such as GaN–ZnO and ZnGeN₂–ZnO have been found to be active photocatalysts under visible light irradiation.^{133–136} Ga_{0.88}N_{0.88}·Zn_{0.12}O_{0.12} coated with a cocatalyst is able to photocatalytically split water with a high QY under visible illumination (QY = 5.9%, 420 nm), [Figure 36.5](#).^{133–135} In order to obtain this record high QY, it is essential that a Rh_{2–x}Cr_xO₃ cocatalyst with a particle size of 10–30 nm is deposited on the Ga_{0.88}N_{0.88}·Zn_{0.12}O_{0.12} surface and that the pH is adjusted to 4.5 with H₂SO₄. In the absence of the cocatalyst, negligible water-splitting activity is observed. It has been proposed that the Rh_{2–x}Cr_xO₃ sites promote H₂ production and inhibit potential O₂ photoreduction.

36.3.2.3 Other Materials

In the previous sections, we have reviewed a large number of materials that are active for only H₂ or O₂ production, but very few that are able to photocatalytically split water to produce H₂ and O₂ simultaneously. Recently, Z-scheme systems have been employed to combine two semiconductor materials, one for H₂ production, one for oxygen production together to make a complete system for water splitting, [Figure 36.6](#). The Z-scheme methodology has been applied to several different material combinations including Pt/SrTiO₃–Pt/WO₃ and Pt/SrTiO₃–BiVO₄.^{156,157} Of particular interest is the Z-scheme of Pt/TaON–Pt/WO₃ with an iodine couple electron mediator, which has obtained a QY of 0.4% under 420 nm irradiation and maintains this even after 100 h of use.¹⁵⁸

A recent exciting report has demonstrated photocatalytic hydrogen production under visible illumination using carbon nitride, a metal free catalyst. While the reported activity for hydrogen production

FIGURE 36.6 Z-scheme diagram employing two photocatalysts. (Reproduced from Kudo, A. and Miseki, Y., *Chem. Soc. Rev.*, 38, 253, 2009.)

in the presence of an electron scavenger was very low, this research is very promising due to its utilization of a polymeric organic semiconductor that is both thermally and chemically stable under water-splitting conditions, which is based on cheap and commonly available materials.¹⁵⁹ The authors did achieve an enhancement in hydrogen evolution by the use of a Pt cocatalyst and O_2 evolution was also observed when a RuO_2 cocatalyst was employed on the carbon nitride in a solution containing an appropriate sacrificial reagent; however, the QY reported for H_2 production remained relatively low ($\sim 0.1\%$, 420–460 nm).

36.3.3 Key Factors in Determining Photocatalyst Activity

36.3.3.1 Photocatalyst Surface Area

It might be expected that an increase in the catalyst surface area would be advantageous due to an increased number of active surface reaction sites. While this phenomenon is commonly observed in thermal heterogeneous catalysis, the influence of surface area on water-splitting photocatalysis is less well understood. In the photocatalysis systems discussed earlier, the surface catalysis is only one of the three steps outlined in Section 36.2, and the photocatalyst particle size can have a significant effect on the initial charge carrier separation and on the rate of electron–hole recombination. For example, in studies on $NaNbO_3$ samples prepared by different methods an increase in the surface area from $1.7\text{ m}^2/\text{g}$ (solid-state reaction) to $38\text{ m}^2/\text{g}$ (polymerized complex method) enhanced the O_2 evolution rates threefold from 42 to $137\text{ }\mu\text{mol/h}$ and the H_2 evolution rate sixfold from 1100 to $7200\text{ }\mu\text{mol/h}$.¹⁶⁰ This in contrast is not the case for the activity of $BiVO_4$ for O_2 production. Kudo et al. reported that crystalline $BiVO_4$ samples (49–490 nm) prepared either through precipitation and hydrothermal approaches had similar optical absorptions at wavelengths less than 520 nm, yet the smaller particles displayed much lower activities for O_2 evolution.¹¹⁹ In another report, hydrothermally synthesized $La_2Ti_2O_7$ with a large surface area of $54\text{ m}^2/\text{g}$ exhibited a high activity for H_2 production ($72\text{ }\mu\text{mol/h}$), while material prepared by solid-state reaction with a surface area of $1\text{ m}^2/\text{g}$ showed a very low level of photocatalytic activity ($<1\text{ }\mu\text{mol/h}$).¹⁶¹

36.3.3.2 Choice of Cocatalyst

The choice of cocatalyst has been shown to be very important in determining the activity of a system for photochemical water splitting with materials such as NiO , RuO_2 , Pt, and $Rh_{2-x}Cr_xO_3$ being employed. Numerous examples of the role of cocatalysts are listed earlier. From Table 36.1, it can be seen that NiO has been very widely employed to realize stoichiometric hydrogen and oxygen production from water.²² The role of cocatalysts is particularly evident on the two most active materials for the photocatalytic splitting of water under visible light. With the NiO/Ni shell/core structure being key in the activity of $In_{0.9}Ni_{0.1}TaO_4$,¹²⁴ while $Ga_{0.88}N_{0.88}\cdot Zn_{0.12}O_{0.12}$ does not show any activity for water splitting in the absence

of $\text{Rh}_{2-x}\text{Cr}_x\text{O}_3$.¹³⁴ Currently, the exact mechanisms of enhancement of activity of most cocatalysts are not known, which complicates the choice of the appropriate material.

36.3.3.3 Other Factors

The morphology and crystal structure of the photocatalyst are also very important factors influencing the performance of photocatalysts for water splitting. Ye et al. found that SrSnO_3 prepared by two different methods, by solid reaction or hydrothermal routes, show significantly different levels of activity.^{75,76} SrSnO_3 synthesized by a solid-state reaction consisted of sphere-like particles while hydrothermal synthesis produced nanorod-structured materials. It was found that both materials had a similar surface area and optical absorption but the nanorod morphology lead to a greater than 10-fold increase in photocatalytic ability for H_2 and O_2 production from water. In Section 36.3.1.1, the effect of La doping of NaTaO_3 was reviewed where the presence of the dopant led to a nanostructuring effect that was proposed to be a key factor in a large enhancement in photocatalytic activity.^{41,42} LiTaO_3 and KTaO_3 have also been investigated for water splitting, here the effect of alkali metal ion on material structure and activity has been investigated. These materials have similar perovskite-like structure and are composed of corner-shared TaO_6 octahedra; it was found that as the bond angle of Ta-O-Ta approaches 180° upon changing the alkali metal from LiTaO_3 to KTaO_3 . This was reported to enhance electron-hole migration through the crystal ($\text{LiTaO}_3 < \text{NaTaO}_3 < \text{KTaO}_3$), which had an effect on the materials photocatalytic activity.³⁸⁻⁴⁰

36.4 Mechanism of Photocatalytic Water Splitting

It has been estimated that a 10% solar energy to hydrogen fuel conversion efficiency is required to make solar hydrogen production from water economically viable.⁵ Currently, there are no reported economically feasible materials that are able to deliver this required efficiency for prolonged periods of use. Fundamental mechanistic research can greatly aid the design of new materials with enhanced photocatalytic activities. Despite this, there have been only a limited number of studies that have addressed the fundamental mechanisms occurring during photocatalytic water splitting.

36.4.1 Transient Spectroscopy of Charge Carriers

In addition to extending the absorption profile of photocatalysts to harvest a greater portion of the solar spectrum, a key goal is to enhance the utilization of the charge carriers formed. Measuring charge recombination processes and the rate of charge carrier reactions to produce photoproducts in candidate photocatalysts is therefore a powerful tool to aid the evaluation of potential materials. Transient absorption spectroscopy (TAS) has been used to monitor the charge carriers following initial UV laser excitation of TiO_2 colloids and nanocrystalline (nc-) TiO_2 films. Following UV excitation initial trapping of the photoholes and photoelectrons has been reported to occur within 200 fs, with further electron relaxation occurring within 500 ps.¹⁶² Several groups have identified the transient absorption spectra of the trapped photoelectrons and holes in nc- TiO_2 , with the hole having an absorption maximum of $\sim 450\text{ nm}$, while photoelectrons have been reported an absorption that increases with wavelength, with trapped electrons having a maxima from $\sim 800\text{ nm}$ upward.¹⁶³⁻¹⁶⁵

Following initial electron-hole trapping, recombination has been reported to occur at a range of different rates, with up to 90% of charge carriers recombining within 10 ns in one report using a high UV laser intensity.¹⁶⁶ Several TAS studies have since demonstrated that the rate of recombination is strongly dependent upon the UV excitation intensity, and under light intensities that are more comparable to solar radiation intensities, power law type decays that have significant electron-hole concentrations beyond the microsecond timescales have been observed.^{162,165,167} This fast (sub-ms) electron-hole recombination has been found to be the key factor in determining the lack of water-splitting activity of nc- TiO_2 in the absence of a cocatalyst or chemical scavenger.¹⁶⁵ Experiments in the presence of Ag^+ prevent electron-hole recombination allowing for the rate of hole reaction with water to produce O_2 ,

FIGURE 36.7 Kinetics of holes (traces a and b) and electrons (traces c and d) in TiO_2 film with Ag^+ (traces a and d) and Pt (traces b and c) as the electron scavengers after band gap excitation with laser wavelength of 335 nm. (Reproduced from Tang, J.W. et al., *J. Am. Chem. Soc.*, 130, 13885, 2008. With permission.)

to be observed [trace (d) Figure 36.7].¹⁶⁵ This reaction has found to be very slow with an averaged hole lifetime of ~ 0.2 s at neutral pHs. The observed rate of decay of the holes on nc- TiO_2 is composed of several components as water oxidation is a multihole process. The yield of QY oxygen versus number of photons absorbed per TiO_2 particle has been examined, and it has been observed that the yield peaks at ~ 4 photons per TiO_2 particle suggesting that the production of one oxygen molecule requires four holes in artificial water-splitting systems, which although is an expected requirement for water oxidation this was the first experimental observation of four hole chemistry in artificial water-splitting systems.¹⁶⁵ Based on a range of TAS studies,^{165,166,168} a summary diagram has been produced to illustrate key reaction timescales during nc- TiO_2 water splitting, Figure 36.8.

Transient measurements have also been used to study several other materials closely related to nc- TiO_2 . The electron dynamics of TiO_2 codoped with both Sb and Cr have been examined. These materials show visible light activity for oxygen evolution in the presence of Ag^+ . It was observed experimentally that the oxygen yield was optimized when the TiO_2 was doped with a Cr:Sb ratio of between 1 and 2, which was found to be due to an increased electron lifetime at this Cr:Sb ratio, leading to a decrease in electron-hole recombination.¹⁶⁹ The electron-hole dynamics on a range of materials including TiO_2 hybrids and doped TiO_2 samples has been examined by the group of Majima et al.,¹⁷⁰ although these studies primarily concentrate on the oxidation of organic materials they do provide important insights into electron-hole dynamics that are directly applicable to the study of water splitting.

The effect of La doping on electron lifetimes in NaTaO_3 has also been examined.¹⁷¹ In previous sections, the large increase in photocatalytic water-splitting activity of NaTaO_3 upon La has been discussed in relation to changes in the catalysts nanomorphology. Transient measurements have also revealed

FIGURE 36.8 Timescales of processes occurring on nc- TiO_2 following UV excitation. (Reproduced from Tang, J.W. et al., *J. Am. Chem. Soc.*, 130, 13885, 2008. With permission.)

FIGURE 36.9 Proposed mechanisms of water photooxidation on TiO₂ materials at pH < 12. (a) Nucleophilic attack mechanism of Nakato et al.¹⁷⁹ and (b) Ti-OH oxidation pathway.¹⁷⁷ (Adapted from Wilson, R.H., *J. Electrochem. Soc.*, 127, 228, 1980.)

that the La doping greatly reduces electron-hole recombination. In the absence of an La dopant, electron decay occurs within 1 ms when the sample is under a vacuum, while addition of 2% La leads to an electron signal at times beyond 1 s. Addition of a NiO cocatalyst lead to electron transfer from NaTaO₃ to NiO within 1 μs and further studies in the presence of water vapor provided evidence for H₂ formation on the milliseconds timescale. Interesting TAS experiments have also been carried out on several materials including Fe₂O₃¹⁷² and a TiO₂/dye/IrO₂ hybrid that are for use in photoelectrochemical cells,¹⁷³ though in this review materials that require the application of an electrical bias are not being considered.

36.4.2 Reaction Pathway

Several groups have examined the surface mechanism of photocatalytic water splitting on TiO₂. Experiments have employed a range of techniques including using electrochemical methods,¹⁷⁴ electron paramagnetic resonance (EPR) spectroscopy,^{175,176} photoluminescence,^{177,178} and Fourier transform infrared spectroscopy (FTIR) spectroscopy.¹⁷⁹ Nakato et al. have used attenuated total reflectance (ATR), FTIR spectroscopy, and photoluminescence measurements at range of pHs. At pH < 12, they have reported that initial nucleophilic attack of a water molecule to a surface-trapped hole at oxygen bridging sites leads to the formation of TiOOH and TiOOTi, which have been reported to be primary intermediates of the oxygen photoevolution reaction, [Figure 36.9a](#).^{178–180} This is in contrast with a previously proposed mechanism where the initial step in water oxidation on TiO₂ at pH < 12 is the oxidation of a surface Ti-OH group leading to the formation of OH radicals that could then couple to form H₂O₂, which is readily decomposed in a further two hole oxidation to form O₂, [Figure 36.9b](#).^{174,177,181}

36.5 Conclusions

It has been over 30 years since the initial reports of photoassisted electrochemical water splitting on TiO₂. Since then progress has been made toward the development of materials and systems that are able to photocatalytically evolve both O₂ and H₂ under solar illumination, without the need for an additional electrical bias. Despite this to date, no material has reached the required 10% solar to hydrogen fuel conversion efficiency to make this an economical process. The current “state-of-the-art” materials for the complete photocatalytic splitting of water (both O₂ and H₂ evolution) include, under (a) UV light include NiO-modified La/NaTaO₃ (QY = 56%, 270 nm), and NiO-Ba/La₂Ti₂SiO₇ (QY = 50%, 0.01 M NaOH, wavelength unknown) and (b) under visible light; Rh_{2–x}Cr_xO₃/Ga_{0.88}N_{0.88}Zn_{0.12}O_{0.12} (QY = 5.9%, 420 nm,

H₂SO₄ solution), NiO-In_{0.9}Ni_{0.1}TaO₄ (QY = 0.66%, 400 nm), and the Z-scheme system of Pt/SrTiO₃:Cr, Ta-Pt/WO₃ (QY = 1%, 420 nm, IO₃⁻/I⁻ electrolyte). While CdS is a very effective photocatalyst for H₂ production in the presence of a suitable electron donor, problems persist with its stability due to photo-corrosion of the catalysts that has greater limited its application in photocatalytic water splitting.

Several key factors have been identified in the research reported, such as the choice of cocatalyst, nanomorphology, etc. Although these are known to be important in enhancing material efficiency the exact mechanisms occurring during photocatalysis are often not well understood, highlighting the need for fundamental mechanistic research to enhance our understanding of the factors controlling photocatalyst activity.

Acknowledgments

We are grateful to Prof. James Durrant, Prof. David Klug in Chemistry, Imperial College London and Prof. Jinhua Ye, National Institute for Materials Science, Japan for their useful suggestions on water-splitting research.

37.1 Introduction

Scientific studies using titanium dioxide photocatalysis to purify water began almost four decades ago and since then research effort has diversified into several different approaches. One of the newest methods is combining titanium dioxide and an adsorbent material to create integrated photocatalytic adsorbents (IPCAs). This chapter surveys and critically reviews studies involving IPCAs synthesized using titanium dioxide and activated carbon (AC). A brief introduction and history of photocatalysis is included and the technical, environmental, and economic advantages of IPCAs are outlined.

The approaches used to create IPCAs are categorized according to AC type and the differing preparation methods are summarized. Various mathematical kinetic models developed for the IPCA systems are described. The research needs for photocatalytic water treatment are also explored and it is concluded that demonstration of the effectiveness of IPCAs in treating actual water and wastewater samples in pilot plant scale reactors is the next stage required in the development of this technology.

37.1.1 Photocatalysts

In recent times, considerable attention has been focused on the safety and efficiency of water treatment technology [1,2]. The reasons for this include increasing concerns about hazardous organic pollutants (HOPs) such as endocrine-disrupting chemicals (EDCs), active pharmaceutical ingredients (APIs), and pesticides found in drinking water and the surrounding environment [3–7]. In addition, conventional water treatment processes such as ozonization and chlorination create disinfection by-products (DBP) such as bromate and trihalomethanes, respectively, which are potentially toxic [1,8–10]. In order to avoid such problems, attention is now being focused on advanced oxidative processes (AOP) including photodegradation. Photodegradation is defined by the International Union of Pure and Applied Chemistry (IUPAC) as “the photochemical transformation of a molecule into lower molecular weight fragments, usually in an oxidation process” [11]. This process is usually too slow and inefficient to be useful in water treatment and requires the addition of a photocatalyst. These catalysts are activated by light and the resulting photocatalytic reactions are defined by IUPAC as “catalytic reaction involving light absorption by a catalyst or by a substrate” [11]. Several types of photocatalysts are available, but most scientific effort has been concentrated on titanium dioxide due to its high photocatalytic activity, chemical stability, nontoxic nature, and relatively low price [12].

When titanium oxides are irradiated with light that exceeds their band gap energy, electrons are promoted from the valence band to the conduction band. The resulting electrons are highly reactive and have a very large reduction potential. The promotion of these electrons creates electron “holes” in the valence band and these have a highly reactive oxidation potential [13]. These “electron–hole pairs” are responsible for the photocatalytic properties of titanium oxides and can degrade organic pollutants on the catalysts surface either directly or indirectly in a water solution by creating hydroxide and superoxide radicals [14].

The original research on the photocatalytic properties of TiO_2 focused on solar energy conversion using an electrochemical photocell with TiO_2 and platinum electrodes [12]. Under illumination with near-UV light, photoelectrolysis occurred resulting in the splitting of water into hydrogen and oxygen. The hydrogen yield from this experiment was too low to be of practical use although there are continuing developments in this field [15]. In the late 1970s, the ability of TiO_2 to oxidize organic matter was applied to cyanide degradation and this led to a substantial increase in research interest in the environmental applications of photocatalysts [16]. This research focused on air purification especially the photodegradation of volatile organic carbons (VOCs) and nitrogen oxides (NO_x), water pollutants, and microorganisms [14]. Photocatalysts have since been commercialized in several consumer and industrial products, especially self cleaning surfaces—due to the photocatalytic properties of TiO_2 —and air cleaning equipment/surfaces [13].

The first study of IPCAs to degrade water pollutants was conducted in 1996 [17] and the number of published studies using IPCAs has grown steadily since then (Figure 37.1). The term IPCA was coined much later in 2005 [18]. Photocatalysts have not yet been commercially deployed in large-scale water treatment, although research and development is ongoing [19] worldwide.

37.1.2 Activated Carbon

AC is “a porous carbon material, a char which has been subjected to reaction with gases, sometimes with the addition of chemicals, e.g., ZnCl_2 , before, during or after carbonization in order to increase its adsorptive properties.” [20]. In this review, AC is categorized based on its physical form as the diverse physical

FIGURE 37.1 Number of surveyed AC/TiO₂ IPCA (degrading water pollutants) studies published per year 1996–2009.

and chemical properties of AC such as iodine number, N₂ adsorption, density, mesopore, and micropore volume are not detailed in the majority of articles cited. The most popular forms of AC are powdered activated carbon (PAC) and granular activated carbon (GAC). Other forms such as extruded activated carbon (EAC) and activated carbon cloths (ACC)/activated carbon filters (ACF) are also available but are not widely used in water treatment. GAC is most commonly used in water treatment due to its relatively large size, which makes it easy to handle and form filter beds, unlike PAC, which due to its small grain size becomes easily suspended in solution and thus must be filtered or coagulated out of the solution.

The porosity of AC is the most important factor affecting its adsorption ability. More porous carbons have higher adsorption capacity, which is usually described using Brunauer, Emmett, and Teller (BET) surface area. Generally, 1 g of AC will have a surface area of between 500 and 2000 m², which is determined by N₂ gas adsorption or a simple liquid adsorption, calculated using Langmuir isotherm for monolayer adsorption or BET isotherm for multilayer adsorption [21]. The porosity of AC can be further classified into micropores (widths smaller than 2 nm), mesopores (widths between 2 and 50 nm), and macropores (widths larger than 50 nm) [21]. Mesopores are often expressed as a methylene blue (MB) number as it is assumed that a large molecule such as MB cannot penetrate the micropores. Micropores are usually expressed as iodine number as the iodine atom can penetrate into the micropores. By comparing the iodine and MB numbers of an AC, it is possible to determine the relative microporosity to mesoporosity ratio. The point of zero charge of an AC is the pH at which the AC has no charge. At a pH below this, the carbon is positively charged and above this it is negatively charged. This property will greatly influence the adsorption of HOPs onto the carbon surface and is an important consideration when selecting an AC for creating IPCAs as changes in pH will greatly influence adsorption [22] and the photodegradation rate [23,24].

37.2 Integrated Photocatalytic Adsorbents

The chemical inertness of titanium oxides is both an advantage and disadvantage: the inertness prevents toxicity and ensures longevity of the catalyst, but it severely limits the adsorption potential of the catalyst, which is negligible in most cases [24–26], although this varies with substrate and pH [23]. This is significant as the electron–hole pairs are only effective if the target chemical is near or on the catalyst surface as the absence of a suitable electron acceptor (e.g., a pollutant) will cause a dramatic decrease in photocatalytic reactions due to charge–carrier recombination [14]. Hydroxide and superoxide radicals recombine easily and therefore are only effective near the catalyst surface.

FIGURE 37.2 (a) Unmodified AC. (b) AC modified with TiO₂.

By combining the adsorption potential of ACs (Figure 37.2a) with the photocatalytic properties of titanium dioxide, it is possible to create an IPCA (Figure 37.2b) with improved photocatalytic potential. IPCAs may consist of either AC coated with TiO₂ or TiO₂ coated with a carbonaceous material that has been heat treated to form an AC. Several studies (Tables 37.1 and 37.2) have reported synergistic effects between mixtures as opposed to composites of TiO₂ and AC [27–33]. Other adsorbent types have been used to create IPCAs including zeolites [18,34–39], alumina silicates [40–45], and carbon nanotubes (CNTs) [46–53].

Composites of TiO₂ and CNTs are unusual as they can be considered doped TiO₂ as well as an IPCA. The CNT acts as an adsorbent providing all the associated benefits (adsorption capacity, substrate concentration) as AC [47]. The conductive properties of CNTs allow electrons that have been promoted to the valence band by the photocatalysis process to be transferred away from the TiO₂ surface. This reduces electron–hole pair recombination, and by prolonging the electron holes on the TiO₂ surface increases the likelihood of a photodegradation reaction and therefore a corresponding increase in the photodegradation rate [47,52]. CNTs are also claimed to increase the adsorption spectrum of TiO₂ in the visible spectrum allowing photodegradation using visible light [49]. The progress and challenges of CNT IPCAs have been reviewed elsewhere [132].

37.2.1 Photocatalyst Choice

TiO₂ occurs in several phases or polymorphs which are different arrangements of the TiO₂ molecules crystal structure, the three polymorphic forms of notes are anatase, rutile, and brookite [133–135]. Rutile is the most thermodynamically stable phase, whereas anatase and brookite are metastable and are readily transformed to rutile when heated. The phase change from anatase to rutile has been reported to occur in different temperature ranges from 600°C to 1100°C, depending on the preparation conditions, particle size, and the presence of impurities [135,136]. The most photoactive form of TiO₂ is the anatase phase and it has been widely studied due to its technological importance in various applications. The rutile phase has lower photoactivity although it has a high refractive index that is useful for optical devices [137]. The basic difference between anatase and rutile is the symmetry about oxygen atoms as well as differences in the polarization of the oxygen ions [77,138,139].

Pure anatase TiO₂ is the most popular photocatalyst for preparing IPCAs (Tables 37.1 and 37.2). Anatase TiO₂ can be prepared using a sol-gel method with low calcination temperatures or can be bought commercially in powdered form. After pure anatase, IPCAs composed of a mixture of anatase and rutile TiO₂ are the most numerous. Studies that use high calcination temperature for preparing

TABLE 37.1 IPCA Wet Preparation Methods

Preparation Method	Adsorbent	Photocatalyst	Substrate (Initial Concentration)	Irradiation Source	References
Sol-gel method used to prepare TiO ₂ and magnetic particles solution. Impregnated using refluxing and ultrasonification	Magnetic AC: (PAC containing magnetic magnetite particles)	Anatase TiO ₂	X-3B (50 mg L ⁻¹)	250 mL breaker irradiated with UV; 200 W UV, Visible; halogen 500 W lamp	[54]
As given previously	Magnetic AC (PAC)	Anatase TiO ₂	Phenol (100 mg L ⁻¹)	Cylindrical stainless steel photoreactor with a 20 W UV lamp (365 nm) covered by a quartz glass sleeve	[55]
Preparation methods as given previously with the exception that some of the samples were calcinated at 350°C or 450°C in a N ₂ atmosphere for 2 h	Magnetic AC (PAC)	Anatase TiO ₂	Phenol (100 mg L ⁻¹)	Photoreactor consisting of a glass beaker covered in silver paper with an 8 W UV lamp (365 nm)	[56]
Separate sol-gel methods were used to prepare TiO ₂ and magnetic ferrite particles. The ferrite and TiO ₂ particles were then applied to the AC using ultrasonification	Magnetic ferrite AC (PAC)	Anatase and rutile (P25 as reference)	MO (20 mg L ⁻¹)	500 mL cylindrical glass reactor with a UV lamp (365 nm) and circulating water jacket. Aeration of 0.6 L min ⁻¹ was used	[57]
Sol-gel method was used to prepare a TiO ₂ solution. Impregnation used ultrasonification and dip coating onto glass plates	PAC coated on a glass plate	Anatase TiO ₂ (P25 as reference)	4-Chlorophenol (100 mg L ⁻¹)	Cylindrical silica reactor with 200 W UV lamp (365 nm, 9 mW cm ⁻²)	[58]
TiO ₂ was synthesized using a sol-gel method and a "dip coating method" and sonification for impregnation	GAC	Anatase TiO ₂	Phenol (10 mg L ⁻¹)	Electrodeless discharge lamp (EDL) excited by microwave irradiation (254–579 nm, output not stated)	[59]
As given previously	PAC	Anatase TiO ₂	Rhodamine B (RhB) (30 mg L ⁻¹)	50 mL solution irradiated in a microwave with a microwave-electrodeless discharge mercury lamp (MW-EDML) output not stated	[60]
TiO ₂ prepared using a sol-gel method. Impregnation using heating and stirring, followed by calcination	GAC	Anatase TiO ₂ (P25 as reference)	MO (50 mg L ⁻¹)	500 mL cylindrical glass reactor inside equipped with an UV lamp (365 nm, output not stated) with aeration	[61]
Sol-gel method used to prepare TiO ₂ . Impregnation using ultrasonification followed by heat treatment	GAC	Anatase and rutile TiO ₂	MO (5 × 10 ⁻³ mol L ⁻¹ and 3, 6, 7, 12, 15 × 10 ⁻³ mol L ⁻¹)	280 mL photoreactor with 10–40 W UV lamp (135 mW cm ⁻² , λ: 320–400 nm, peak: 365 nm) and aeration (56 mL min ⁻¹)	[62]
Sol-gel method was used to prepare TiO ₂ . Impregnation using ultrasonification followed by calcination	GAC	Anatase/rutile TiO ₂ , % ratios 1:0 and 35:65	MB (20 mg L ⁻¹)	As given previously	[63]

(continued)

TABLE 37.1 (continued) IPCA Wet Preparation Methods

Preparation Method	Adsorbent	Photocatalyst	Substrate (Initial Concentration)	Irradiation Source	References
Sol-gel method was used to prepare TiO ₂ . Impregnation using stirring followed by calcination	GAC	Anatase and rutile TiO ₂	MO (1×10^{-3} mol L ⁻³)	Pyrex reaction cell equipped with an air-aerated stopcock, 40 W UV lamp, fixed in the middle of the quartz cell	[64]
As given previously	GAC	Anatase to rutile TiO ₂ in the ratio of 2.3	Rhodamine B (RhB) (1, 2.5, 5, 8, and 10 mmol L ⁻¹)	UV light intensity in 250 mL Pyrex photoreactor: 0, 15, 25, 40, and 60 mW cm ⁻² with aeration (56 mL s ⁻¹)	[65]
As given previously	GAC	Anatase and/or rutile phase	<i>Escherichia coli</i> (<i>E. coli</i> , NCIMB 8277)	IPCA was suspended in sterilized water using ultrasonication and stirred. Irradiation using a black light fluorescent lamp	[66]
Sol-gel method using a rotary evaporator was used to prepare the IPCA	GAC	TiO ₂ (phase not stated)	Microcystin-LR (cyanobacteria endotoxin) (50 mg L ⁻¹)	Cylindrical continuous flow fluidized bed reactor with a 4 W black light lamp (370 nm, 0.6 mW cm ⁻²)	[67]
As given previously	GAC	Anatase TiO ₂	Microcystin-LR (200 mg L ⁻¹)	1 L glass cylinder with a water jacket for cooling. Irradiation was provided by a 4 W black light lamp (370 nm, 0.6 mW cm ⁻²)	[68]
Commercial TiO ₂ was loaded onto an ACF using an epoxy resin followed by calcination	ACF	P25 (30 nm)	Paper mill effluent	350 mL cylindrical photoreactor with water-cooling jacket, 500 W high-pressure Hg lamp (365 nm), and aeration	[69]
As given previously	ACF	Degussa P25 (30 nm)	b-Cyclodextrin ((C ₂ H ₁₀ O ₆) _n) (200 mg L ⁻¹)	As given previously	[70]
As given previously	ACF	P25 (30 nm)	MB (85 mg L ⁻¹)	As given previously	[71]
Sol-gel method was used to prepare a TiO ₂ solution and ultrasonification was used for impregnation	PAC	Anatase TiO ₂	Phenol (100 mg L ⁻¹)	500 mL photoreactor with 20 W UV lamp (peak 365 nm)	[72]
Sol-gel method was used to prepare TiO ₂ solution. Impregnation involved mixing followed by heat treatment	PAC, powdered silica, mordenite	TiO ₂ (phase not stated most likely anatase)	Propyzamide (7.8 mg L ⁻¹)	Pyrex reaction cell with a 400 W Xe lamp and UV cutoff filter ($\lambda > 300$ nm, 135 mW cm ⁻²)	[17]
As given previously	PAC	TiO ₂ (phase not stated most likely anatase)	Dichloromethane, trichloromethane, tetrachloromethane (1.0 mmol dm ⁻³)	Reaction cell with 10 W fluorescent black lamp (300–430 nm, peak of 352 nm, 1.8 mW cm ⁻²)	[73]

Sol-gel method used to apply TiO ₂ to the surface of Poly(Vinyl Butyral) (PVB) followed by heat treatment	PVB carbonized to form an AC	Anatase and rutile TiO ₂ in the ratio of 1–0.3	Phenol (0.05 g L ⁻¹)	Degradation experiments were carried out under illumination from six UV lamps with 20 W power	[74]
Carbon precursor applied to P25. The composite was then dehydrated and carbonized at 600°C	Cellulose/TiO ₂ microsphere composites	P25 (20 nm)	Acetaldehyde (2000 mg L ⁻¹)	Cell containing 3 cm ³ reactant illuminated with two 4 W black lights λ : 300–400 nm)	[75]
As given previously	ACF	Anatase and rutile TiO ₂	MB (concentration not stated)	Not stated (looks at reuse of an IPCA)	[76]
Sol-gel method used to prepare TiO ₂ . Impregnated onto the AC cloth by dip coating followed by calcination	ACC	Anatase and rutile TiO ₂	MB (2.94 \times 10 ⁻⁴ mol L ⁻¹)	“UV irradiation”	[77]
Sol-gel method was used to prepare the pure TiO ₂ and impregnate the AC. The solutions were then dried and calcinated at different temperatures	PAC	Anatase and rutile TiO ₂ (P25 as reference)	Chromotrope 2R (10–80 mg L ⁻¹)	Low-pressure Hg-vapor lamp (λ max: 253.7 nm, 3 W radiant flux)	[78]
Coating of commercial TiO ₂ with a carbon-based precursor. The mixture was then carbonized at 700°C	Carbon-coated TiO ₂	Anatase TiO ₂ (traces of rutile)	MB (2.94 \times 10 ⁻⁴ mol L ⁻¹) and heavy oil	10 W m ⁻² UV irradiation from a “black light” for MB and 16.4 W m ⁻² UV irradiation for the heavy oil	[79]
The IPCAs were prepared by several methods, mechanofusion using a theta composer, and boiling impregnation (boiling dry a solution of TiO ₂ and AC)	PACs and GACs prepared by different activation methods	P25	MB, Procion red MX-B5 (reactive red 2)	4 W low-pressure Hg UV lamp (approx 0.37 mW cm ⁻² for batch studies and 2 mW cm ⁻² for column studies)	[22]
TiO ₂ solution	ACF	Anatase TiO ₂	MO and acid fuchsin (120 mg L ⁻¹)	250 mL cylindrical photoreactor and water-cooled quartz jacket with 500 W high-pressure Hg lamp (365 nm, 12.5 mW cm ⁻²) and aeration	[80]
The WO ₃ -TiO ₂ photocatalyst was prepared by a sol-gel method. Impregnation involved stirring and calcination	GAC	WO ₃ -TiO ₂ (anatase TiO ₂)	Congo Red (10–50 mg L ⁻¹ with H ₂ O ₂ addition)	2.5 L “fluidized bed photoreactor” with 500 W high-pressure Hg-vapor lamp and aeration (0.2 m ³ h ⁻¹)	[81]
P25 was added to an epoxy resin solution and drip coated onto an ACF and then calcinated	ACF	P25	MB (85 mg L ⁻¹)	350 mL cylindrical photoreactor with a water-cooled quartz jacket and 500 W high-pressure Hg lamp (365 nm)	[82]
Various quantities of commercial TiO ₂ and AC were mixed in an aqueous solution and stirred for 1 h before filtration	AC (form not stated)	P25	Phenol, salicylic acid, 4-aminophenol, or <i>p</i> -nitrophenol (100 mg L ⁻¹)	250 mL photoreactor(s) with air sparging (100 mL min ⁻¹) and irradiated with a “UV lamp.” Natural sunlight was also used (no further information given)	[83,84]

(continued)

TABLE 37.1 (continued) IPCA Wet Preparation Methods

Preparation Method	Adsorbent	Photocatalyst	Substrate (Initial Concentration)	Irradiation Source	References
Sol-gel methods were used to prepare a TiO ₂ solution and impregnation used stirring, followed by calcination	PAC	Anatase and Rutile TiO ₂ (depending on calcination temperature)	Phenol (50 mg L ⁻¹)	Six UV lamps were used to irradiate the solution from the top	[85]
Sol-gel method was used to prepare the IPCA. Impregnation involved stirring and was followed by calcination	PAC	Anatase TiO ₂ (P25 as reference)	Phenol, MO, and Cr(VI)	Cylindrical quartz photoreactor (with water-cooling jacket) with an 8 W UV lamp (365 nm) position	[86]
Commercial TiO ₂ powder was carbon coated by mixing with polyvinyl alcohol in different mass ratios. The resulting IPCA was then calcinated	Carbon-coated anatase powders	Anatase TiO ₂	MB (3.2×10^{-5} mol dm ⁻³)	PMR with direct-contact membrane distillation and Hg UV lamp (355 nm, 146.1 W m ⁻² at irradiation plate)	[87]
The Fe was added to the ACF by dip coating. The Fe-ACF was then added to a solution of TiO ₂ precursor and stirred followed by vaporization and calcination at 700°C	Fe-ACF	Mixture of anatase and rutile TiO ₂	MB (1.0×10^{-5} mol L ⁻¹)	UV lamp above the solution (20 W, 365 nm)	[88]
LPD used to apply TiO ₂ to the ACF. The ACF was then dried and annealed at high temperature	ACF	Anatase TiO ₂	AOII (200 mg L ⁻¹)	Photoreactor consisting of quartz reactor irradiated by a 15 W germicidal lamp (90% output at 253.7 nm). The IPCA was used as the photoanode, Pt wire used as the counter electrode	[89]
A sol-gel method was used to prepare carbon-coated TiO ₂ . The resulting solution was dried, pulverized, and calcinated	Carbon-coated TiO ₂	Anatase and rutile TiO ₂	MB (1.6×10^{-5} M)	UV light bulb (0.5 mW cm ⁻² , 364 nm) and visible light from an incandescent light bulb (13.6 mW cm ⁻²). LEDs used to provide lighting for NO degradation	[90]
Electrophoretic deposition was used to apply a suspension of P25 and AC to a conductive glass plate electrode. The electrodes were then placed in an oven and heated in air at 450°C for 30 min	PAC	P25	Orange-II (OG-II) (50 mg L ⁻¹)	Glass reactor with direct illumination by a low-pressure mercury vapor UV lamp (75 mW cm ⁻² , λ : 365 nm)	[91]
Commercial TiO ₂ was carbon coated by exposing it to ethanol vapors for 1 h in temperature ranging from 150°C to 400°C	Carbon-coated TiO ₂	Tytanpol A11 (Police, Poland) and P25 (Degussa, Germany)	Phenol (100 mg L ⁻¹)	Artificial solar light was provided by using a 100 W lamp (354 W m ⁻² visible, 0.09 W m ⁻¹ UV) and UV light was provided by six, 20 W UV lamps (100 W m ⁻² visible, 154 W m ⁻² UV)	[92]

A sol-gel method was used to prepare TiO ₂ /ACF composite. The gel was then dried and then calcinated	ACF	Anatase and rutile TiO ₂	Toluene (20 mg L ⁻¹)	Solution was irradiated with a 500 W high-pressure mercury lamp (380 nm)	[93]
A sol-gel method was used to prepare F-doped TiO ₂ . Impregnation used ultrasonification	PAC	F-doped anatase TiO ₂ (brookite traces)	Phenol (25 mg L ⁻¹)	Silica photoreactor with 250 W halogen lamp with a light filter cutting the light <400 nm (11.3 mW cm ⁻²)	[94]
Commercial TiO ₂ was impregnated on the ACF by stirring and then sonification. The resulting IPCA was then calcinated	ACF	Anatase TiO ₂	MB (100 mg L ⁻¹)	Lamp fitted along reaction cell and the ACF was fixed horizontally along the reaction cell (no information on power output or lamp type)	[95]
Commercial TiO ₂ was impregnated onto the PAC using sonification. N-doped IPCA was prepared by adding saturated urea to the TiO ₂ suspension and then following the procedure outlined earlier	PAC	Anatase TiO ₂	Soman, VX, and Yperite (concentration not stated)	Photoreactor consisting of a closed quartz tube flushed with air (50 cm ³ min ⁻¹), 125 W high-pressure black-bulb lamp (λ : 365 nm, 3.0 W UVA, λ : 315–400 nm)	[96]
Commercial TiO ₂ powder was coated with poly(vinyl alcohol) and then carbonized. The powder was then adhered onto organic adhesive tape or a film using an organic binder	Carbon-coated TiO ₂	Anatase TiO ₂ (ST-01)	MB (2.94×10^{-5} mol L ⁻¹)	3 \times 20 W UV light bulbs were placed 200 mm from the IPCA tape or film	[97]
Commercial TiO ₂ was applied to the GAC using ultrasonification. Commercial TiO ₂ was added to a chitosan solution and cast into beads by a “phase-inversion technique”	GAC	Anatase TiO ₂	<i>Salmonella choleraesuis</i> subsp. ATCC 14028 (10 ⁸ cfu mL ⁻¹)	1 L batch photoreactor with 20 W high-pressure mercury lamp (320–400 nm)	[98]
Sol-gel method was used to prepare the entire IPCA followed by heat treatment at 200°C in air	GAC	Anatase TiO ₂ , rutile and brookite traces	Color (organics absorption at 254 nm)	Adsorption was carried out separately. UV regeneration using six 18 W UVA or UVC lamps and/or ultrasonic bath	[99]
Sol-gel method used to prepare TiO ₂ solution. Varying amounts of GAC were added to this solution, which underwent hydrothermal treatment at 180°C for 8 h. Calcination at 600°C for 2 h was the final step in IPCA calcination	GAC	Anatase TiO ₂	MO (50 mg L ⁻¹)	500 mL cylindrical glass reactor using a central UV lamp (365 nm, 300 W) containing a 250 mL solution	[100]

(continued)

TABLE 37.1 (continued) IPCA Wet Preparation Methods

Preparation Method	Adsorbent	Photocatalyst	Substrate (Initial Concentration)	Irradiation Source	References
Sol-gel processes were used to prepare separate solutions of ZnFe_2O_4 and TiO_2 . The latter solution was added dropwise to the ZnFe_2O_4 . GAC was then added to the combined solution and shaken for 12 h and dried. The samples were then calcined at 500°C for 2 h	GAC	Anatase TiO_2 doped with ZnFe_2O_4	Acid dye—brillred-RH (not stated)	“Recycle fluidized bed reactor” with 150 W visible light source	[101]
CdS P25 was prepared by a sol-gel and a precipitation method. These catalysts were applied to ACFs using an adhesive and dip coating	ACFs	CdS doped P25	MB (50 mg L^{-1})	75 mm \times 50 mm pieces of the IPCA were put into 100 mL flasks and exposed to natural sunlight for 5 h	[102]
Sol-gel method used to prepare the doped TiO_2 . This solution was added dropwise to the ACF. Followed by calcination at 600°C–800°C in N_2	ACF	Fe(III) and Ho(III) doped TiO_2	MO (120 mg L^{-1})	250 mL cylindrical vessel with a water-cooled quartz jacket with a 500 W high-pressure Hg (365 nm). Aeration was used	[103]
Sol-gel method used to prepare Fe(0)-doped TiO_2 . ACF was dip coated using this solution and calcined at 200°C for 2 h	ACF	Fe(0) TiO_2 (phase not stated)	2,4-Dichlorophenol (10–100 mg L^{-1})	Cylindrical quartz tube 30 cm \times 3 cm (height \times diameter) with a 20 W germicidal low-pressure Hg lamp (λ : 254 nm, 92 W cm^{-2} at 365 nm)	[104]
The IPCAs were obtained by mixing P25 and AC at different proportions in water and stirred for 3 h followed by filtering and drying	PAC	P25	Pentafluorobenzoic acid (100–600 mg L^{-1})	Heber immersion type photoreactor with either a 16 W low-pressure Hg lamp (λ : 253.7 nm, photon flux: 2.54×10^{-5} Einstein $\text{L}^{-1} \text{s}^{-1}$) or 8 W medium pressure Hg lamp (λ : 365 nm, photon flux: 2.08×10^{-6} Einstein $\text{L}^{-1} \text{s}^{-1}$). Aeration 8.1 mL s^{-1}	[105]
A commercial solution of amorphous TiO_2 was applied to either a plain PET film or a PET film with GAC adhered to it using a silicon binder. The GAC film was sprayed with the TiO_2 and dried a total of five times	GAC	Anatase TiO_2	2,4-Dinitrophenol (1–250 mg L^{-1})	Batch-recirculation flow system with 6 W black light blue fluorescent lamp (λ : 300–400 nm)	[106]
As given previously	As given previously	As given previously	2,4-Dinitrophenol (5–80 mmol m^{-3})	As given previously	[107]

Sol-gel method used to prepare a TiO ₂ solution. The ACF was impregnated with TiO ₂ by immersing it in this solution for 1 h followed by calcination at 500°C in an Ar atmosphere	ACF	Anatase TiO ₂	Phenol, MO (80 and 120 mg L ⁻¹ , respectively)	Quartz reactor with Hg UV lamp (300 W, 365 nm)	[108]
P25 was added to an acetone and epoxy solution and stirred vigorously. Prewashed GAC was added to this solution. The suspension was filtered, washed, and dried. Followed by calcination at 500°C for 2 h in an N ₂ atmosphere. These processes were repeated once to yield the final IPCA	GAC	P25	Rhodamine B (5 × 10 ⁻³ mol L ⁻¹)	Photodegradation experiments used a Pyrex reaction cell aerated at 0.6 L min ⁻¹ . A UV lamp was fixed in the middle of the quartz cell (light intensity varied between 50 and 200 W)	[109]
Catalyst I: TiO ₂ deposited on cellulose fibers. Catalyst II: A composite of a layer of cellulose fibers with deposited TiO ₂ , a layer of carbon fibers and a layer of cellulose fibers. Both catalysts were rinsed for 12 h by deionized water	Commercial photocatalyst fibers from Ahlstrom (France)	Commercial TiO ₂ (type not stated)	Basic red 46 (10 and 25 mg L ⁻¹)	Polytetrafluoroethylene (PTFE)-coated flat plate photoreactor inclined at 30° with two 15 W UV lamps (emission λ: 365 nm) or two visible light lamps. Natural sunlight was also used (180–190 W m ⁻²)	[110]
Sol-gel method used to prepare TiO ₂ . ACF was then added to this solution and stirred vigorously for 1 h. IPCA was then dried and calcined at 900°C for 2 h in an N ₂ atmosphere	ACF	TiO ₂ (type not stated)	MO (80 mg L ⁻¹)	200 mL pulsed discharge reactor with aeration (oxygen flow rate of 96 L h ⁻¹). UV light generated by the pulse discharges irradiated a suspended ACF IPCA	[111]
Sol-gel method was used to prepared Fe-doped TiO ₂ using Fe(NO ₃) ₃ and tetrabutyl orthotitanate. Ultrasonic impregnation was used to apply the doped TiO ₂ to the AC. The dried IPCA was calcined at 250°C in air and then 500°C in N ₂	GAC	Fe-TiO ₂ (anatase and rutile TiO ₂)	Wastewater (from a “dye factory,” municipal wastewater was also used)	Continuous flow 6.3 L stainless steel cylindrical photoreactor with two UV lamps mounted in the center. Aeration (56 mL s ⁻¹) was used	[112]
Boiling impregnation was used to apply commercial TiO ₂ to the adsorbent. These were then heat treated at 550°C	GAC, glass beads, zeolite, brick, quartz	P25	Propoxur (4.78 × 10 ⁻⁴ M)	1 L double-jacked vessel with a quartz cover. UV irradiation was provided by three 10 W low-pressure Hg lamps (peak λ: 254 nm) above the reactor	[113]
V-doped titania (VTO) was prepared using a sol-gel method. Ultrasonic impregnation was used to apply the VTO to PAC. This IPCA was then applied using dip coating to a glass plate	PAC	VTO	X-3B (50 mg L ⁻¹)	Cylindrical silica batch photoreactor system with 250 W halogen lamp (light filter cutting off < 400 nm) and vertical aeration with IPCA placed on the bottom of the reactor	[114]

(continued)

TABLE 37.1 (continued) IPCA Wet Preparation Methods

Preparation Method	Adsorbent	Photocatalyst	Substrate (Initial Concentration)	Irradiation Source	References
Solution of P25 was applied to the AC and carbon foam by mixing in a rotary evaporator followed by drying. Carbon form prepared by acid modification of coal tar pitch followed by heat treatment at 600°C in N ₂ and then stream activation at 800°C for 1 h	"Carbon foams" & GAC	P25	Phenol (100 mg L ⁻¹)	400 mL photoreactor with 125 W high-pressure Hg lamp vertically suspended in a cylindrical quartz cooling jacket	[115]
A sol-gel method was used to prepare N-doped TiO ₂ . PAC was then added to this solution and stirred followed by filtration to remove the IPCA, which was calcined at 400°C in N ₂	PAC	Anatase TiO ₂ with traces of brookite	Bisphenol—A (36 mg L ⁻¹)	250 mL solar simulator equipped with a 150 W Xe arc lamp (light intensity: 1000 W m ⁻² , UV/Vis intensity approx 6.5%/40%). Additional light filters used to control certain wavelengths	[116]
Chitosan/ACF composite films were prepared by adding the ACF to a chitosan and pore-forming agent solution. A separate sol-gel TiO ₂ solution was prepared and applied to the chitosan/ACF using dip coating	Chitosan/ACF	TiO ₂ (phase not stated)	2,4-Dichlorophenol (1–50 mg L ⁻¹)	On-site regeneration: irradiation with 20 W UV light (λ : 254 nm). Off-site regeneration: IPCA was dipped in distilled water in a shallow tank reactor under the same light source. Fenton reagent was also investigated for regeneration	[117]
Prepared by a one-step carbonization (at 450°C under vacuum) of a self-assembled matrix consisting of titanium tetra-isopropoxide and a triblock copolymer	Form not stated	C-doped Anatase TiO ₂	MB (10 mg L ⁻¹)	25 mL quartz photochemical reactor with 150 W Xe lamp (180 mW cm ⁻²) with UV-cut off filter (<400 nm)	[118]
Ultrasonication used to apply P25 to GAC followed by oven drying, filtering, and washing	GAC	P25	Indomethacin (0.1–1.5 mmol L ⁻¹)	1 L photoreactor and water-cooled immersion well with 125 W medium pressure Hg lamp	[119]

TABLE 37.2 IPCA Dry Preparation Methods

Preparation Method	Adsorbent	Photocatalyst	Substrate	Irradiation Source	References
AP-MOCVD (atmospheric pressure-metal organic chemical vapor deposition) used to prepare the IPCA	PAC	Anatase TiO ₂	MO (100 mg L ⁻¹)	1.5 L cylindrical glass photoreactor, with a central UV lamp (356 nm, 1.2 mW cm ⁻²)	[120]
MOCVD was used to apply TiO ₂ to a commercial AC to create an IPCA	PAC	Anatase TiO ₂	MO (100 mg L ⁻¹)	1.5 L cylindrical glass photoreactor, with a UV lamp (356 nm, 1.2 mW cm ⁻²) in the center	[121]
As given previously	PAC	Anatase TiO ₂	MO (100 mg L ⁻¹)	1 L cylindrical glass photoreactor with a 300 W high-pressure mercury lamp (356 nm). Aeration was used (1.2 m ³ h ⁻¹)	[122]
MOCVD—using tetrabutyl orthotitanate and N ₂ —was used to apply TiO ₂ onto pretreated PAC	PAC	Anatase TiO ₂	MO (100 mg L ⁻¹)	1.5 L photoreactor with UV lamp (365 nm, 1.2 W cm ⁻²)	[123]
TiCl ₄ was deposited onto ACFs using MAD, a form of CVD to create an IPCA	ACF	Anatase/rutile TiO ₂	MB (2.498 mmol L ⁻¹)	Pyrex reaction cell (80 mm diameter × 95 mm height) with 24 W low-pressure mercury lamp (254 nm)	[124]
As given previously	ACF	Anatase TiO ₂	MB (10–16 × 10 ⁻⁴ mol L ⁻¹)	Two pieces of the IPCA were placed on a reaction cell described above and aeration was used (90 mL min ⁻¹)	[125]
TiO ₂ was applied to AC using CVD. Ag was applied to the TiO ₂ -AC composite using the same method	PAC	Anatase TiO ₂ doped with Ag	MO (200 mg L ⁻¹)	1 L cylindrical photoreactor with UV lamp (356 nm, 1.2 mW cm ⁻²)	[126]

IPCA's create mixed-phase photocatalysts comprising a mixture of rutile and anatase, for instance, 30%:70% rutile:anatase [77,124]. These mixtures are an inevitable consequence of using a calcination step to prepare IPCAs as the anatase phase is converted to the rutile phase by high temperatures. These studies usually investigate a range of temperatures (e.g., 700°C–900°C) to create different IPCAs in order to determine which temperature produces the most photoactive IPCA [77]. Higher calcination temperatures cause more anatase to be converted to the rutile phase. However, increasing calcination temperature will also cause the TiO₂ particles to become larger and it has been suggested [77] that the larger TiO₂ particles will not block the pores of the AC thus increasing the adsorption capacity of the IPCA. It has been noted that certain adsorbents (ACFs) [124] can protect the anatase phase thus allowing the use of high calcination temperatures without causing a phase change.

The next most popular is P25, a photocatalyst manufactured commercially by the Evonik Industries (formerly the Degussa Corporation) and sold under the trade mark AEROXIDE® P25. P25 is a mixture of anatase and rutile in the range of 70%–90% anatase and is manufactured by flame synthesis. P25 has an average particle diameter of 35–40 nm (anatase), 85–95 nm (rutile) as determined by x-ray diffraction (XRD) and transmission electron microscopy (TEM) analysis and a specific surface area of 44–50 m² g⁻¹ [140]. There is disagreement in the literature about the precise composition of P25, it has been cited as 92% anatase, 8% rutile [42], 75% anatase, 25% rutile [48], and 80% anatase, 20% rutile [53]. The anatase and rutile phases exist separately in powdered form and while the anatase phase is more photoactive, the mixture of the two phases is synergetic and allows P25 to have better activity than anatase and rutile separately [141]. The wide availability of P25 means that it is used both as photocatalyst in IPCAs but also as a reference photocatalyst to compare IPCA performance [142]. Five authors in the surveyed literature [17,67,73,111,117] did not state the TiO₂ phase that they were using.

37.2.2 Doping/TiO₂ Modification

Doping has been used to improve the photocatalytic performance of TiO₂. The purpose of doping is to apply a transition metal (V, Cr, Mo, Fe), lanthanide metal (La, Eu, Nd, Ce), or nonmetal atom (C, N, O) to the TiO₂ either to alter its band gap [143], serve as an electron scavenger [112] (thus preventing recombination of the electron-hole pairs) or to act as an adsorbent [144] in its own right. Chemical vapor deposition (CVD) has been used to add Ag to an IPCA in order to overcome its lower photocatalytic performance compared to TiO₂ slurry [126]. Six IPCAs using different Ti:Ag ratios and deposition times were prepared and compared to an IPCA using P25 as the photocatalyst. The performance of the doped IPCAs increased with the Ti:Ag ratio and deposition time and with the exception of the IPCA with the highest deposition time and Ti:Ag ratio, all of the doped IPCAs had higher photodegradation ability for methyl orange (MO) than the P25 IPCA. Doping has also been attempted with the adsorbent used in the IPCA albeit with limited success. A laboratory-prepared ACF doped with Fe by immersion in ferric nitrate solutions was then added to a tetrabutyl orthotitanate solution in order to apply TiO₂ to the IPCA [88]. However, the resulting IPCAs possessed similar photodegradation ability as the undoped TiO₂ ACF.

ZnFe₂O₄ has been applied to TiO₂, which was then coated onto GAC [101]. The absorption spectrum of this IPCA increased significantly in visible wavelengths (400–800 nm) and the reaction rate constant in ideal photodegradation conditions was increased by 79% for degrading brilliant-RH compared to the unmodified GAC. However, due to the lack of an undoped TiO₂ control, it is unclear if this photocatalyst has any advantages over unmodified TiO₂. P25 modified with CdS was prepared using separate sol-gel and precipitation methods [102]. The modified P25 was applied to an ACF and used to degrade MB with sunlight as the irradiation source. The apparent reaction rate constants of the doped IPCA prepared using the precipitation methods and sol-gel methods were 70% and 21% higher, respectively, than the unmodified P25 IPCA. Another approach used co-doping of anatase TiO₂ with Fe(III) and Ho(III) followed by application to an ACF [103]. It was noted that the doping could “restrain the forming of crack[s] in TiO₂ films” on the surface of the ACF, although the mechanism remains unknown. Fe(0) was applied to TiO₂ and then impregnated onto an ACF [104]. The doped IPCA degraded approximately 20% more 2,4-dichlorophenol than the IPCA using unmodified P25. The improved photodegradation performance was attributed to the superior dechlorination ability of Fe(0) combined with the synergistic properties of the TiO₂ ACF IPCA.

Another study [112] utilized a Fe-doped TiO₂ to prepare an ACF IPCA that was used to degrade dye wastewater. COD removal was approximately 50% higher than the unmodified TiO₂, while color removal was comparable. The improvement in performance was attributed to trapping of photogenerated electrons in the conduction band of Fe³⁺, which decreased electron-hole pair recombination in the TiO₂, although no direct evidence of this was provided. V-doped TiO₂ has been used to degrade X-3B (Reactive Brilliant Red dye) under visible light [114]. The doped IPCA, V-doped TiO₂, and P25 degraded 89%, 60%, and 7% of the X-3B, respectively. The diffuse reflection spectra of the V-doped TiO₂ showed enhanced adsorption of visible light (380–800 nm) compared to the unmodified TiO₂ causing its enhanced performance. The V-doped TiO₂ also displayed enhanced hydrophilicity, which was attributed to photogenerated holes diffusing to the surface and reacting with the surface oxygen lattice leading to the dissociative adsorption of water at those defective sites.

TiO₂ has been doped with C and then surrounded by AC [118]. Anatase TiO₂ grains were prepared in a copolymer that was then heat treated to form an AC. The anatase grains become doped with C during the carbonization process and develop enhanced visible light adsorption. Under visible light illumination, MB was effectively degraded in less than 1 h.

The choice of substrate for degradation is an important consideration in measuring doping performance. At visible wavelengths, photoadsorption of visible light by MB can induce a reaction in TiO₂ that causes photodegradation of the MB [145]. This is a separate effect to conventional doping

allowing the TiO_2 to photodegrade under visible light and has led to the recommendation that “transparent substrates” be used for determining photocatalytic activity of visible light photocatalysis in the 540–680 nm range [145].

37.2.3 Activated Carbon Type

IPCA can be made with a wide variety of ACs and these carbons exist in a multitude of physical forms. PAC is the adsorbent most widely used in the literature for synthesis of IPCAs (Tables 37.1 and 37.2), followed by GAC and ACFs. The other major group of adsorbents is carbon-coated TiO_2 that appears to be in the form of PACs. Some studies used AC and other adsorbents in order to provide a comparison between adsorbents [17,113,128]. Other studies used specialist adsorbents such as proprietary photocatalyst fibers [110] and carbon foams [115] for preparing IPCA.

AC provides a synergistic effect by creating a common interface between both the AC and the TiO_2 particle phases [29]. The synergism results due to enhanced adsorption of the target pollutant onto the AC phase followed closely by a transfer through an interphase to the TiO_2 phase, giving a complete photodegradation process.

The abundance of literature describing the use of PAC is most likely due to its ease of use and preparation compared to GAC and EAC especially given that the latter is prepared by compressing PAC and a binder. IPCAs have also been prepared using AC created in the laboratory from a diverse set of precursors including wood [29,30], coconut shell [67,68], Jordanian olive stone [129], pyrolyzed sewage sludge [27], and coal tar pitch [115]. In theory, any natural organic material can be converted to AC, although economic considerations limit the number of viable feedstocks for commercial production [146]. The flexibility of source materials for AC production will allow IPCAs to be prepared from a multitude of raw materials and industrial wastes permitting sustainable production.

37.3 Methods of Preparation

IPCA preparation methods can be broadly divided into “dry” and “wet” methods. Dry methods use a physical and/or gaseous/vapor process, whereas wet processes use an aqueous phase in applying the TiO_2 to the adsorbent. Wet processes including sol-gel, boiling impregnation, liquid phase deposition (LPD), and electrophoretic deposition constitute the majority of methods used to prepare IPCAs (Tables 37.1 and 37.2). However, there is an increasing number of papers on dry methods for preparing IPCAs and further developments in combining dry powders such as PAC and powdered TiO_2 , which may be used to create IPCAs [147,148]. Proponents of dry methods cite as advantages the absence of waste streams and avoidance of several of the preparation steps needed for sol-gel methods such as saturation, aging, and drying [126,149]. In spite of these claimed advantages, wet methods are much more common in the literature. Wet methods are generally more accessible because complex, specialist, and proprietary equipment is not a prerequisite for their use [101].

37.3.1 Wet

Wet methods comprise more than three-quarters of the methods surveyed in the literature and nearly 90% of wet methods involve sol-gel processes with only two studies using a non sol-gel wet method. Other wet methods such as spray pyrolysis that is used to prepare metal oxide thin films [143] would be suitable for photocatalytic applications, however, there are to date no studies reporting their use for IPCA preparation.

37.3.1.1 Sol-Gel

Sol-gel methods are used to prepare either the virgin TiO_2 or the complete IPCA. Although these methods are generally categorized as sol-gel, there is considerable variation relating to precursor and adsorbent choice and the method of impregnation.

While the majority of IPCAs are prepared by applying TiO_2 to AC, a smaller subset of IPCA preparation methods apply either the TiO_2 to a carbonaceous material or vice versa, which is then converted to AC. For instance, hydroxypropyl cellulose has been applied to commercial TiO_2 powder (ST-01) and then activated at 700°C in N_2 and the resulting IPCA was used to decolorize MB [79]. The IPCA with the highest carbon content was the least effective at decolorizing MB when the IPCA was not presaturated before illumination. However, when the IPCAs were presaturated, the reverse was true.

Tetrabutyl orthotitanate was used to precipitate TiO_2 onto the surface of poly(vinyl butyral), which was then carbonized and used to degrade phenol [74]. The best performing IPCA removed >95% of the phenol in solution after 5 h of illumination compared to greater than 12 h for P25. A one-step sol-gel method was used to prepare IPCAs consisting of P25 and cellulose microspheres, which were then carbonized [42]. The IPCA was twice as effective at degrading acetaldehyde as plain TiO_2 of the same particle size. Poly(vinyl alcohol) and commercial TiO_2 (ST-01) combined in different ratios and then carbonized and the resulting IPCAs were then immobilized onto a thin film or tape using an organic binder [97]. A plain TiO_2 control was not included to provide a benchmark to the IPCAs photocatalytic performance. Repeated photodegradation cycles demonstrated that these IPCAs could be reused for a minimum of six cycles although photocatalytic performance decreased with each cycle.

The second category of sol-gel studies used a sol-gel process to prepare the TiO_2 used in the impregnation process. Sol-gel TiO_2 prepared using tetrabutyl orthotitanate dissolved in absolute ethanol was applied using dip coating to a GAC [59]. The resulting IPCAs had twice—in terms of reaction rate constants—the photodegradation ability of P25. Another study used the same solution but containing diethanolamine dissolved in the ethanol. GAC was added to this solution and the gel-coated GAC was heat treated in air at 250°C and the temperature was then raised from 300°C to 800°C in a nitrogen atmosphere [64]. All of the resulting IPCAs had considerably higher photodegradation ability than unmodified TiO_2 slurry. Tetrabutyl orthotitanate dissolved in ethanol has been used as a precursor solution to prepare nano-sized TiO_2 particles. A mixture of water and nitric acid was added to prepare the TiO_2 solution followed by the addition of GAC. After gelation of the solution, the IPCA was heat treated in air at 200°C [99]. The resulting IPCA exhibited similar adsorption ability as the unmodified GAC, and using a separate regeneration step, its adsorption ability could be returned to almost original levels.

Low-temperature methods have been used to prepare IPCAs and these methods are reported to be superior to high-temperature preparation methods as the surface area of the TiO_2 particles is not decreased as a result of heat treatment [55,72,119]. Preparation involves a sol-gel method to prepare TiO_2 but uses ultrasonification to mix the TiO_2 and PAC solution followed by drying with a rotary evaporator. Another low-temperature preparation method stirred different proportions of commercial TiO_2 powder (P25) and AC in an aqueous solution for an hour followed by filtration and drying [83]. The resulting IPCA had improved photodegradation ability in both natural sunlight (six times higher apparent first-order rate constants) and UV light (two-thirds higher) compared to virgin TiO_2 .

37.3.1.2 Other Wet Methods

Wet chemical impregnation techniques are of interest due to their straightforward protocols, low temperature, and energy costs. Boiling impregnation was used to apply TiO_2 to GAC [22]. The method involves mixing TiO_2 and AC and repeatedly boiling dry the solution to create an IPCA. The resulting IPCA degraded 80% and 90% of MB initial concentrations of 10 and 20 mg L^{-1} , respectively, and it was regenerated twice. This method was also used to apply a solution of P25 (sonicated beforehand) to a series of inert and adsorbent supports including GAC and zeolite [113]. The coated supports were then calcined and used to degrade propoxur. The GAC-based IPCA removed almost four times more propoxur than P25. When the adsorption capacity of the IPCA was taken into account, its mineralization and oxidation performance was approximately equivalent to P25.

The LPD method is a simple and easily-controlled process for fabricating thin films coating on ACF and does not require special equipment [89]. It consists of submerging a pretreated ACF into a solution of TiO_2 precursor for several hours followed by drying and annealing for 180 min at 350°C in an N_2

atmosphere. The resulting IPCA demonstrated much higher photodegradation (49.1%) of acid orange II (AOII) compared to virgin TiO_2 (10.7%). In the same study, electro-photocatalysis was used parallel to conventional UV photocatalysis. The IPCA was used as an anode and an electric current was passed through it to decrease electron-hole recombination and this achieved a degradation rate approximately 10% greater than conventional UV photocatalysis [89].

Electrophoretic deposition—a form of electroplating—has been used to apply a suspension of commercial P25 [in a 5% (v/v) 2-propanol] and PAC to iridium glass plates [91], which function as the cathode in the process. The resulting nanocomposite electrodes prepared using a range of different synthesis suspensions were sintered (heat treated) in air. The IPCA present on the surface of the electrodes was three times more effective at decolorizing Orange-II dye (30% reduction of Orange-II compared to a 10% reduction in the TiO_2 control after 200 min of UV irradiation). The study did not use a photolysis control or total organic carbon (TOC) to monitor degradation but measured the production of H_2O_2 (a key reactive oxygen species) and determined that it was 50% higher in the IPCA compared to virgin TiO_2 .

37.3.2 Dry

Dry methods constitute less than a quarter of the methods used in the literature, with CVD and its variants comprising the majority of these methods.

37.3.2.1 Chemical Vapor Deposition

CVD involves creating a vapor using an inert carrier gas (typically N_2) and a chemical precursor(s) that is to be applied to a substrate, typically AC. CVD can be categorized according to the pressure or the physical characteristics of the vapor used for deposition. Atmospheric pressure (AP) CVD [126,128,130] and metal organic chemical vapor deposition (MOCVD) [120,121] have been used to prepare IPCAs. Although not explicitly mentioned in every study, all CVD methods appear to have been used at AP. The distinguishing feature of MOCVD is that it uses a metallic or metalloid precursor for deposition onto the substrate. Given that all CVD methods use a carrier gas containing titanium, then all CVD methods may be categorized as MOCVD. Low-pressure MOCVD [150] was used to prepare supported anatase TiO_2 on the surface of silica gel. The photocatalytic activity of the supported TiO_2 was nearly half of that of the powder photocatalyst (P25). Coated anatase thin films generated using MOCVD have been applied onto a window glass substrate, which resulted in the larger surface area for photocatalytic dissociation of benzene [151]. CVD has been used to create an EAC-based IPCA as well as IPCAs using silica gel and $\gamma\text{-Al}_2\text{O}_3$ [128]. The silica gel had the highest photodegradation ability of the IPCAs, in degrading phenol and this is attributed to its greater surface area. An initial increase in phenol concentration was attributed to the release of phenol from the EAC-based IPCA and no TiO_2 slurry was included as a control. These factors limit the usefulness of this study in comparing AC to other adsorbents.

Molecular adsorption-deposition (MAD) has been used to apply a TiO_2 precursor (TiCl_4) to ACFs [124]. The method consists of heating the ACF under vacuum followed by adsorption of TiCl_4 vapor and saturated water vapor at room temperature. The system was then heated to 90°C and evacuated, followed by calcination. As this method creates a vapor that is deposited on a substrate, it could also be considered lower pressure chemical vapor deposition (LPCVD).

37.3.2.2 Mechanofusion: Theta Composer

A dry mechanical process used a Theta Composer[®] to apply P25 to PAC [22]. The Theta Composer[®] is a proprietary elliptical rotor-type powder mixer that uses a rotating vessel and rotor to create high shear forces that bind the particles together. Resulting IPCAs exhibited MB decolorizing potential comparable to IPCAs prepared by boiling impregnation. The most important consideration for IPCAs prepared using this method was the process used to activate the AC as the ACs prepared by acid washing were ineffective compared to AC activated by steam. The increasing number of dry methods and equipment

available to prepare composite powders have been reviewed [148]. It is likely that other mechanofusion methods and equipment such as magnetic assisted impaction coating (MAIC), hybridizer, and rotating fluidized bed coater (RFBC) will be adopted for IPCA preparation in the future [147].

37.4 Substrate for Photodegradation

IPCA's have been used principally to photodegrade a variety of organic contaminants, typically hazardous substances such as phenol, chlorophenol, azo dyes, and dichloromethane (Figure 37.3).

However, only three studies in the literature surveyed involved an actual characterized wastewater sample. For wastewater from a paper mill, the best performing ACF-based IPCA's removed 15 mg L⁻¹ more COD and color removal was 50% faster as compared to P25 [69]. The IPCA showed minimal loss of photocatalysis ability after several cycles. A similar study used an Fe-doped, ACF-based IPCA [112]. The Fe-doped IPCA could reduce COD by a third more than the IPCA containing nondoped TiO₂ and was twice as effective as unmodified TiO₂. The same pattern was repeated for color removal although the differences in the color removal rate were much smaller with the Fe-doped IPCA removing almost 100% of the color compared to 80% for bare TiO₂. Regeneration using UV light allowed it to maintain a 50% removal rate for COD under pilot plant conditions. The IPCA was also used to reduce the COD of effluent from a municipal sewage plant demonstrating the longevity of the IPCA in typical operating conditions. This study is one of only two in the surveyed IPCA literature to use an IPCA on municipal wastewater; however no other information was provided on the characteristics of the wastewater other than the COD that the IPCA removed. This makes assessing the overall effectiveness of this IPCA—as a polishing treatment of municipal wastewater—impossible. An IPCA based on a GAC designed for wastewater treatment was used to remove color compounds (absorbance at 254 nm, with molecular weights of 400–10,000 Da) for a municipal sewage treatment plant [99]. The initial color removal declined from 90% to 50% after 10 adsorption cycles, and using separate regeneration steps, the color removal could be returned to approximately original levels. Because the comparison for the regeneration step was undertaken only once, there is no indication of the long-term lifespan of the IPCA.

GAC IPCA's prepared using a sol-gel method with 3%–63% TiO₂ loading have been used to sterilize microorganisms [66]. The best performing IPCA (47% TiO₂) sterilized the sample in 175 min compared to a 70% reduction in viable *E. coli* numbers in 250 min for 100% TiO₂ slurry. Another IPCA prepared by a sol-gel method was used to degrade 50 and 200 mg L⁻¹ of microcystin-LR (cyanobacteria endotoxin) [67,68].

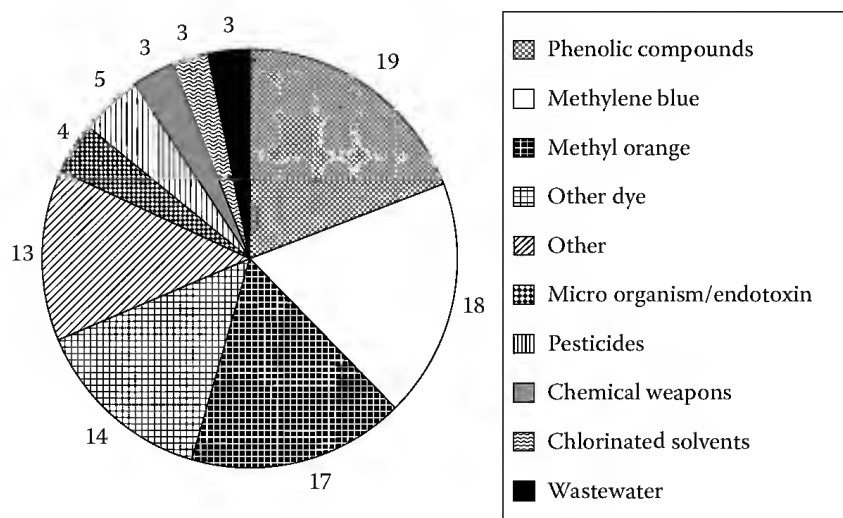

FIGURE 37.3 Number of substrates used for photodegradation in the surveyed literature (some studies use more than one).

The removal of microcystin-LR was accomplished in 15 min under UV illumination compared to a 60% reduction in 60 min without illumination. No TiO₂ slurry control was included, so it is unclear if this IPCA has enhanced photodegradation properties compared to virgin TiO₂.

A mixture of P25 and AC—prepared by pyrolysis (activation) of sewage sludge—was used to reduce ionic mercury Hg(II) to elemental mercury Hg(0) [27]. Hg(0) is less soluble in water than Hg(II) and thus has a higher affinity for AC. Under UV illumination, this system was able to remove a third more mercury than the AC on its own. Recovery from the AC of 40%–65% of the adsorbed Hg(0) was possible using separate chemical processing.

Generally, studies of dyes as target compounds use decoloration to measure degradation [22,59,64,124], while studies using HOPs measure the degradation of the target compound [34,73]. TOC and/or dissolved organic carbon (DOC) or CO₂ released during photodegradation can also be used to measure the mineralization of the compound [152]. If the target substrate is a simple compound or is well characterized, then investigation of intermediate formation yields additional information on IPCA efficiency. For instance, MO photodegradation creates phenol as an intermediate product. Comparing sol-gel with CVD IPCA, both are equally efficient in degrading MO; however, the CVD IPCA was more effective at degrading the intermediate product (phenol) and consequently the mineralization rate measured by TOC was approximately 100% higher [127].

Artificial aeration has been incorporated into some experimental designs [61,62,65,81,122,125,127,128]. Aeration may improve photodegradation by ensuring that there is sufficient O₂ that can be reduced to the superoxide radical O₂^{•−} that speeds up degradation [23]. However, it remains unclear if O₂ addition improved performance in all cases. IPCAs have also been used to degrade gaseous or volatile pollutants such as formaldehyde [153], methanol [154], ethylene [155], and BTEX (benzene, toluene, ethylbenzene, and xylenes) compounds [156]. This application of IPCAs has been commercialized for air cleaners [16] and remains the only current practical demonstration of the technology.

37.5 Mathematical Models

Heterogeneous photocatalysis is a complicated process, involving several factors and possible synergies. Photocatalysis reactions proceed at the surface of the semiconductor and are the result of several steps: production of electron–hole pairs by irradiation of TiO₂ with photons; formation of highly reactive hydroxyl radicals (OH[•]); reaction between the photogenerated hydroxyl radicals with the pollutant. In the case of immobilized catalyst, the coupling between mass transfer from the liquid phase to the catalyst surface, adsorption of the pollutant, and an “intrinsic” reaction has to be taken into account in the modeling of the photocatalytic reactor. Generally, adsorption occurs at the surface of the catalyst particles with very low microporous volume. Assuming that the surface adsorption rate for physical adsorption is rapid enough to be considered instantaneous relative to transfer across the fluid film around the particle, the flux density (N_f) of pollutant at the catalyst surface is given by

$$N_f = -K_f(C - C_e) = -K_s(q_e - q), \quad (37.1)$$

where

C is the pollutant concentration in the fluid bulk phase

C_e is its concentration at the surface of the catalyst in equilibrium with the adsorbed phase

K_f is the fluid film mass transfer coefficient

Similarly, the flux density can be expressed with a mass transfer coefficient K_s based on the solid phase with q the adsorbed-phase concentration and q_e the adsorbed-phase concentration in equilibrium with the bulk fluid phase.

According to Ollis [157,158], the “intrinsic” reaction rate may be expressed as a first-order expression of the amount of pollutant adsorbed:

$$r = kq = (\alpha I)q = (\alpha^* I_r)q, \quad (37.2)$$

with k being the rate constant (s^{-1}) depending of the production of hydroxyl radicals OH^* , which is assumed to be directly proportional to local UV irradiations, I , and the α coefficient is related to the semiconductor activity. The coefficient α^* can be defined by considering the system geometry involved and the irradiation at the external surface of the reactor, I_r .

In order to represent the dynamic behavior of any reaction system, the species balances have to be considered for both liquid and solid phases [159]. By considering the total volume of liquid present in the system (V_T), the reactor volume (V_r), and the equivalent surface of catalyst per unit of reactor (S_{cat}), the material balance equations are given by

$$\frac{dC}{dt} = -\frac{V_r}{V_T} S_{cat} K_s (q_e - q), \quad (37.3)$$

$$\frac{dq}{dt} = K_s (q_e - q) - (\alpha^* I_r)q. \quad (37.4)$$

Solution of the aforementioned (Equations 37.3 and 37.4) system of differential equations provides the concentration profiles as a function of the time. Dark adsorption experiments correspond to the special cases of an irradiation I_r equal to 0. First-order kinetics have been successfully used to model the photocatalytic degradation of various organic molecules [160–166]:

$$r = -\frac{dC}{dt} = k_{app}C, \quad (37.5)$$

where k_{app} is the apparent first-order rate constant (with the same restriction of $C = C_0$ at $t = 0$, with C_0 being the initial content in the bulk solution after adsorption and t the reaction time). The kinetic behavior in which k_{app} is affected by the initial organic content is commonly described in terms of a modified Langmuir–Hinshelwood (L–H) model. This has been successfully used in heterogeneous photocatalytic degradation to determine the relationship between the apparent first-order rate constant and the initial content of the organic substrate [167,168], and is commonly expressed as Equation 37.6:

$$r = -\frac{dC}{dt} = \frac{k_r K_s C}{1 + K_s C_0} = k_{app}C, \quad (37.6)$$

$$\frac{1}{k_{app}} = \frac{1}{k_r K_s} + \frac{C_0}{k_r}, \quad (37.7)$$

where

C_0 is the initial organic content

k_r is the reaction rate constant

K_s is the adsorption rate constant

The reaction rate is dependent on the light intensity and adsorption performance of the catalyst. In certain cases [76], the light intensity affected both constants (k_r and K_s) in the L–H model.

The Elovich rate equation is widely used to describe heterogeneous photocatalysis [169–171]. It is empirical in nature and given as follows:

$$r = \frac{dq_t}{dt} = \alpha_E \exp(-\beta_E q_t), \quad (37.8)$$

where

r (or dq_t/dt) is the photocatalytic rate (in units of $\text{mg g}^{-1} \text{min}^{-1}$)

α_E is the initial rate ($\text{mg g}^{-1} \text{min}^{-1}$) when q_t approaches zero (at irradiation time $t = 0$)

β_E is related to the extent of surface coverage for photocatalytic activity of pollutant degradation

Integrating Equation 37.8 with the condition ($q_t = 0$ at $t = 0$) and subsequently linearizing the integrated equation results in

$$q_t = \frac{1}{\beta_E} \ln(t_0) + \frac{1}{\beta_E} \ln(t + t_0), \quad (37.9)$$

where t_0 is equal to $1/\alpha_E \beta_E$. If $\alpha_E \beta_E t \gg 1$, then Equation 37.10 can further be simplified as

$$q_t = \frac{1}{\beta_E} \ln(\alpha_E \beta_E) + \frac{1}{\beta_E} \ln(t). \quad (37.10)$$

A plot of q_t versus $\ln(t)$ yields the apparent Elovich rate constants, α_E and β_E , from the intercept and the slope of the linearity equation.

37.6 Regeneration

The ability of IPCAs to be regenerated with UV light is a primary consideration if practical applications of IPCAs are to be demonstrated. Repeated adsorption/degradation tests have been conducted on a limited number of IPCAs using 3 [22,69], 4 [103,108], 5 [56,119], 6 [54,55,72,106], 7 [104], or 15 [112] regeneration/degradation cycles. Fifteen adsorption/degradation cycles using MB led to a reduction of the MB removal rate from 100% to 92% with a 7% TiO_2 loss [76]. The photodegradation ability decreased with each cycle to varying degrees. This is attributed to the blocking of micropores and the inability of the UV light to enter these pores to trigger photodegradation. Another consideration is that the presence of UV light may enhance/inhibit π – π interactions and thus adsorption of certain organic compounds (MB, procion red MX-5B) on the carbon surface and this may be responsible for some of the reported degradation of IPCAs [172].

For regenerating IPCAs, several processes have been investigated either as an alternative to or supplement to UV light. A hybrid ultrasound (from an ultrasonic bath) and UV system was used to regenerate an IPCA used to remove color compounds from treated wastewater [99]. Regeneration using UV light alone required 16 h, UV light and hydrogen peroxide required 3 h, but regeneration using UV and ultrasound required only 30 min and achieved the highest regeneration standard levels. This study did not consider the effect of ultrasound on the stability of the AC. Separate research using ultrasound to regenerate GAC [173] has shown that the percentage of particles smaller than what could be considered GAC ($<2.5 \text{ mm}$) increased from 0% to 4.6% after 1 h of sonication. While it was noted that this is smaller than the loss of GAC in thermal reactivation of approximately 10%, it is a disadvantage of ultrasonic regeneration. This is especially relevant to IPCAs as ultrasonication may not only affect particle size but also loosen the deposited TiO_2 on the IPCA surface. Another study compared the efficiency of regenerating

a coated chitosan ACF IPCA using UV light with regeneration using Fenton reagent [117]. In six subsequent adsorption/regeneration cycles, the removal rate of the UV-regenerated and Fenton-regenerated IPCAs remained above 82% and 86%, respectively, while the removal rate of the nonregenerated IPCA declined from 91% initially to 51% after six cycles. Although the Fenton reagent performed marginally better, UV regeneration was recommended in order to avoid the “very violent oxidants [Fenton reagent] that may affect the structure of [the] composite membrane.”

Ultrasonication is an alternative to UV light for creating positive electron holes in an IPCA. In ultrasonication studies, 90 g L⁻¹ of IPCA degraded 1 mol L⁻¹ of phenol in 180 min, while 1.5 g L⁻¹ IPCA degraded 0.6 mol L⁻¹ of phenol in 540 min [174]. Increasing catalyst loadings markedly increased phenol degradation rates and it was noted that this would not be possible using photocatalysis due to light penetration problems. However, the effect of ultrasonication on the stability of the IPCA was not investigated.

37.7 IPCAs and Photocatalytic Reactor Design

Conventional photocatalysis test systems typically use either a suspension of TiO₂ [24,25,175] or an immobilized layer [19,176,177] of unmodified TiO₂. In order to treat wastewaters effectively, the TiO₂ must be kept under constant illumination. This represents a major drawback when one considers the lengthy reaction times for pollutant photodegradation and mineralization. Under illumination from a 125 W Hg lamp, up to 28 h were required for complete mineralization of a 47 mg L⁻¹ solution of gemfibrozil with 0.4 g L⁻¹ of photocatalyst [178] although mineralization times for gemfibrozil in a membrane photoreactor (with 1.0 g L⁻¹ photocatalysts) can be as short as 150 min for greater than 97% mineralization [25]. In contrast, an IPCA can concentrate the pollutant in a smaller area improving efficiency by increasing substrate contact time with the photocatalyst [179], which is important when the pollutant concentration is very low. Moreover a photocatalysis system using a suspension of TiO₂ (or a PAC-based IPCA) requires that the suspension be removed from the water after the photocatalysis step is finished. In a water treatment plant, this may be done via filtration or coagulation limiting the possibility of recovery of the catalyst and increasing the cost of treatment. This problem can be overcome by using a GAC-, EAC-, or ACF-based IPCA that can be readily filtered from the water or used in a fixed or fluidized bed arrangement obviating the need for separation.

An alternative approach is the use of photocatalytic membrane reactors (PMRs), which filter out the TiO₂ after the photocatalysis step [180]. While PMRs remove the TiO₂ suspension and allow its reuse, they do not overcome the low adsorption and constant illumination problems of TiO₂ suspensions. Systems that use immobilized thin films of unmodified TiO₂ have higher photodegradation efficiencies [181]—most likely due to a reduction in the extinction coefficient—and do not have the removal problems of suspensions of TiO₂. However they are limited by their low surface to volume ratio and therefore require large capacities although the use of microstructured reactors is being investigated to overcome these problems [182,183].

Magnetic separation represents an innovative solution to liquid–catalyst separation. It involves applying TiO₂ to an inert silica or AC support that had been impregnated with magnetic magnetite particles [54,55,57,184]. The resulting composites are used in photocatalytic reactors where a magnetic field is used to both stir and recover the catalyst.

The cost of a typical detoxification system is broadly divided into nonrecurring capital costs and recurring operation and maintenance (O and M) costs. While capital costs can be reduced by designing more efficient systems, O and M costs depend on factors including the type and concentration of the pollutant, the degradation rate constants, the desired level of treatment, IPCA dose, and regeneration [185]. In terms of economies of scale for intermediate and large reactors designs, the costs of photocatalysis were comparable to those of AC systems [185]. The process economics between photocatalytic systems and AC adsorption was evaluated using a reference integrated water treatment process for the removal of polychlorobiphenyls (PCBs) [157].

IPCA generally have reaction rates higher than unmodified or virgin TiO_2 (Section 37.3) and the use of IPCAs with larger particles sizes allows the use of IPCAs in fluidized bed type reactors which are simpler and do not require active filtration thus reducing reactor costs. In the future, low-cost manufacture of IPCAs will significantly reduce the cost of photocatalytic water treatment, especially if they have been modified (doped) to work better with natural sunlight.

37.8 Conclusion

In conclusion, the recent literature shows that IPCAs have considerable potential as the basis of an efficient water treatment process for the degradation of hazardous organics, including microorganisms. Almost 100 studies describing “proof of concept” IPCAs have been published in the last 14 years. By combining an adsorbent with titanium dioxide it is possible to create a composite that has both high adsorption capacity and photocatalytic activity [72]. These confer several notable process advantages over virgin TiO_2 :

1. IPCAs remove pollutants from the water with or without UV light, while systems based on only TiO_2 require constant irradiation to continue functioning. Moreover, if the IPCA is to be regenerated using sunlight, this allows water treatment process to continue at night.
2. The adsorbent also immobilizes the pollutant near the TiO_2 surface, allowing photodegradation of both pollutants that do not bind to the catalyst surface and intermediate degradation products [17,96,104,113,117].
3. By employing AC with different chemical properties (porosity, point of zero charge, etc.), it is possible to tailor the adsorption properties of IPCAs for different applications [22].

At this point, demonstration of the effectiveness of IPCAs in treating actual water and wastewater samples under typical operating conditions is required. On the theoretical front, given that most batch laboratory-scale IPCA studies with HOPs have been empirical, a mechanistic model that can elucidate the kinetics between different working processes (i.e., adsorption, diffusion, and photocatalysis) within IPCA system is yet to be fully developed. Finally, pilot plant and larger scale reactor design studies are needed to confirm the economic viability of IPCA water/wastewater treatment.

38.1 Introduction: From Switches to Basic Logic Operations

Logic has many implications in everyday life. Especially in our modern society, which is driven by information technology, logic plays a fundamental part in the focus of computing. The concept of logic, commonly based on binary numbers, that is, 0 and 1, is universal. Thus, any type of signal, which is processed by a physical system in a bistable manner, could be imagined for this purpose. This generalization opened the doors for molecular systems as subnanometric building blocks for logic devices. In the context of the pressing need to increase the density of functional units per electronic circuit and, thus, to obtain more powerful computing devices, the miniaturization of building blocks (the so-called bottom-up approach) has found increased attention in recent years [1]. On the other hand, conventional lithographic techniques (top-down approach), which are currently used for microchip fabrication, have physical limits of spatial resolution.

The basic idea to use molecular components for electronics is classically resumed in Aviram's famous "Gedankenexperiment" [2]. Some years later, further ideas were formulated for the specific application of molecules for "memory, logic, and amplification" [3]. The first molecular logic gate was reported by the group of de Silva [4]. They used fluorescence switching through modulation of photoinduced electron transfer (PET) as mechanistic basis for their molecular design. As a point of fact, optical outputs (changes in absorbance, transmission, and fluorescence) are probably the most popular choice for basic molecular logic gates and their combinations in more complex circuits (*vide infra*). In this chapter, we will therefore mainly focus on molecular logic devices based on optical signaling with either only optical outputs or all-photonic devices, that is, optical inputs *and* outputs.

Generally, and if thermodynamically favorable, the excited state emission of a fluorophore linked to *one* PET-active electron-donating receptor (e.g., an amine) via an electronically isolating spacer is quenched when the receptor is not occupied (left state in Scheme 38.1) [5]. This is, for example, true for compound **1**

SCHEME 38.1 Fluorescence switching based on PET.

(shown in Scheme 38.2) [6]. Hence, for the absence of a chemical input (binary 0), the signal output of the system is a binary 0, which is the logic synonym for the *off* state. This situation changes for addition of an input (binary 1), upon which the properties of the receptor change in such a way that PET is now thermodynamically less favorable or even totally blocked (right state in Scheme 38.1). In our example of an amine receptor (e.g., in compound **1**), its electron-donating properties are drastically decreased by protonation with acid and concomitant formation of an ammonium ion. This is accompanied by the enhancement of the fluorophore emission intensity, which corresponds in logic terms to a binary 1 for the output (*on* state). In total, the system behaves like an IDENTITY gate: high-fluorescence output is only observed for high chemical input concentration. This effect can be harnessed for the realization of a two-input logic AND operation. For this purpose, *two* receptors of the kind described earlier are combined with a fluorophore (i.e., an anthracene

SCHEME 38.2 (See color insert.) Family of fluorescent PET switches with one receptor (IDENTITY gate, **1**), two receptors (two-input AND gate, **2**), and three receptors (three-input AND gate, **3**).

derivative). Now, both receptors have to be occupied to switch *off* PET-induced quenching effectively. In the concrete example of the first reported molecular logic gate **2** (Scheme 38.2), an amine and a benzo-15-crown-5 were used as electron-donating receptors, which can be blocked by addition of H^+ and Na^+ ions as chemical inputs, respectively. Indeed, high fluorescence ($\lambda_{obs} = 446\text{ nm}$) is only observed for the simultaneous presence of both inputs, which translates into the function of a two-input logic AND gate [4].

The complexity level of input-induced fluorescence switching via PET can be extended beyond one-input IDENTITY and two-input AND gates by adding a third receptor. This yields a three-input AND operation, for which the de Silva group reported recently a molecular example [7]. The design (compound **3**; Scheme 38.2) relied again on the anthracene fluorophore, this time linked to an amine (for H^+ as input), a benzo-15-crown-5 (for Na^+ ions as input), and an iminodiacetate-type receptor (for Zn^{2+} ions as input). As required for a three-input AND gate, the highest fluorescence of the system is detected for the simultaneous occupation of all receptors with their respective inputs (enhancement factor of ca. 20 with respect to absence of inputs). Noteworthy, an important issue for the successful implementation of these and other two- and three-input AND gates is the avoidance of chemical cross talk between the inputs.

The functions of the aforementioned AND gates are not influenced by the order of input application. The counterpart to this behavior is described as priority AND (PAND) gate, which distinguishes between the sequential orders of input applications. These gates are as well described in terms of sequential logic. An interesting example of a three-input PAND gate, which serves as molecular keypad lock, was described by the Shanzer group and will be discussed later in this chapter [8]. Two-input PAND gates have been also demonstrated, like triad **4** (Scheme 38.3), recently described by the groups of Andréasson and Gust. The triad integrates a porphyrin derivative (P) as fluorescent output unit, which is linked to two photochromes [a fulgimide (FG) and a dithienylethene (DTE)] [9]. The photochromes are converted between their open

SCHEME 38.3 All-photonic two-input PAND gate **4** and chemically driven (H^+ and Na^+) AND gate **5** with singlet oxygen output.

and closed forms by light of different wavelengths as optical inputs. Selecting FGo-P-DTEo as starting state, the fluorescent FGc-P-DTEo form is observed for UV light irradiation ($\lambda = 366\text{ nm}$) followed by application of red light ($\lambda > 580\text{ nm}$). Reversal of the input order produces the nonfluorescent FGc-P-DTEc form. The FGc-P-DTEo form has the highest fluorescence because FGc acts as energy transfer sensitizer of P, while DTEo is an inefficient energy transfer quencher of P. On the other hand, DTEc is a strong energy transfer quencher of P fluorescence. Irradiation with broadband green light enables resetting to the initial state. The molecular setup delivers the fluorescence signal only for application of both irradiation wavelengths (AND) and under the condition that a certain sequential order is maintained (priority). Noteworthy, this example is also a nice demonstration of an all-photonic logic device.

For molecular logic to become a real alternative to silicon circuitry, higher degrees of complexity need to be achieved. In order to combine various logic gates in a comprehensive logic circuit, physical integration through gate-to-gate wiring, that is concatenation, is a common approach in conventional electronics. While electrons need wires to allow gate-to-gate communication, molecular logic gates with all-photonic operation (i.e., optical inputs and outputs) may use photophysical processes like emission/reabsorption [10,11] or resonance energy transfer [12]. On the downside, disadvantages like the multidirectional nature of emitted light or limitations for the maximum number of concatenated elements due to often downhill energy transfer have to be taken into account. However, unlike all-photonic devices, many molecular logic gates are addressed with chemical inputs and produce optical outputs (e.g., fluorescence). This input/output inhomogeneity constitutes a major problem for concatenation. On the other hand, the molecular world offers strategies to bypass physical integration. For example, a unimolecular platform can perform complex logic operations by *functional integration*, without the need to provide a molecular mimic for each required gate (*vide infra*). Also reconfiguration is easily achieved with molecules, because simple changes of observation parameters (e.g., emission wavelengths) may already be sufficient to obtain a different logic operation (*vide infra*). Confessedly, promising progress has been made in the development of programmable logic arrays in conventional electronics. However, in many other cases, wiring between electronic logic gates would have to be simply destroyed in order to achieve reconfiguration.

Besides the future objective of molecular data processing, molecular logic has also important implications in much less distant contexts. The aforementioned three-input AND gate **3** is interesting for multianalyte chemosensing [7]. A rather complex analytical situation of three analytes, with each of them either present or not (eight possible combinations), is translated into a simple answer signal: high (all inputs present) or low fluorescence (for two or less inputs). A different type of application of two-input AND logic was recently discussed by the Akkaya group [13]. Instead of reading the fluorescence as output signal of the gate, they presented a system (**5**) that is set for singlet oxygen production (see structure in Scheme 38.3). For this purpose, a BODIPY chromophore was modified with two types of receptors, pyridine as H^+ acceptor and benzo-15-crown-5 as Na^+ ion acceptor. The pyridines are linked to the chromophore with conjugative ethylene spacers. Thus, pyridine protonation leads to the modulation of internal charge transfer (ICT) properties of the BODIPY derivative, which is accompanied by a redshift of the long wavelength absorption band of the dye. The excitation wavelength of 660 nm coincides with the shifted band. Na^+ ion complexation, on the other hand, leads to blocking of PET, similar to the observations made for the systems **2** and **3** (*vide supra*). Hence, protonation and Na^+ ion addition result in excited triplet state activation of the dye and consequently singlet oxygen formation in the framework of a logic AND operation. This may have very interesting applications for photodynamic therapy. Noteworthy, lower pH and high Na^+ ion concentrations coincide with the differentiation characteristics of cancerous tissues in comparison with healthy cells.

38.2 Molecular Mimics for Basic Logic Gates: A Brief Overview

Before we discuss more complex molecular logic circuits, the most basic logic gates will be briefly overviewed in this section. While numerous examples could be cited for each specific logic gate type, we will concentrate herein on a few selected examples (**6–15** in Scheme 38.4). The interested reader is further referred to a series of excellent and comprehensive reviews on the topic [14–18].

SCHEME 38.4 Examples for basic molecular logic gates and their respective inputs: **6**—NAND, **7**—two-input INH, **8**—three-input INH, **9**—IMP, **10**—OR, **11**—NOR, **12**—XOR, **13**—XNOR, **14a/14b**—EnOR, **15**—EnNOR.

38.2.1 AND–NAND

The AND gate, which was discussed earlier in more detail, has in the NAND its complementary logic gate. That means that the output of an AND gate is simply reversed to yield a NAND. In conventional electronics, the NAND gate is of special importance because it is a universal gate. Every other logic function can be expressed by the combination of various NAND gates. This prime position the NAND gate shares with the NOR gate (*vide infra*).

Akkaya and coworkers provided an example for molecular NAND logic based on hydrogen-bonding interactions between the well-known fluorescent DNA intercalator dye **6** [4',6-diamidino-2-phenylindole (DAPI)] and the monophosphates of deoxyadenosine (dAMP) and deoxythymidine (dTMP) [19]. In presence of dAMP, a blueshift of the dye emission is observed, while addition of dTMP leaves the DAPI fluorescence virtually unaltered with respect to the absence of inputs. For these situations, an iso-emissive point at 455 nm was observed. On the other hand, the formation of a ternary complex between DAPI and the two nucleotides with complementary hydrogen-bonding patterns yields a significant blueshift of the emission spectrum and additionally a drop of the fluorescence intensity (more than twofold decrease at 455 nm). This is in agreement with NAND logic behavior, which yields high output signals (binary 1) for all input combinations, except in the presence of both inputs, that is, dAMP and dTMP in this case.

38.2.2 Inhibit (INH)–Implication (IMP)

The first two-input molecular INH gate was described by Gunnlaugsson et al. [20,21]. The intricate photophysical behavior of a Tb^{3+} -cyclen complex (**7**) with an appended quinoline antenna was interpreted for this purpose. In brief, the antenna acts as efficient energy transfer sensitizer of long-lived Tb^{3+} luminescence ($\tau_{\text{lum}} = 0.98$ ms), when it is in the protonated state and when oxygen is excluded from the solution. In all other situations, the luminescence is lower by a factor of ca. 25–50, depending on the specific input combination. It is well known that the energy level of the excited triplet state of the antenna chromophore is of crucial importance in the energy transfer process. The absence of oxygen is required in order to avoid the quenching of the antenna excited triplet state, which may be populated by back energy transfer from the lanthanide.

The first three-input version of an INH gate (**8**) was described by de Silva et al. [22]. Again, a long-lived excited state emission was used as optical output information, this time in the form of 2-bromonaphthalene phosphorescence ($\tau_{\text{phos}} = 0.14$ ms). A PET-active bis(iminodiacetate) receptor for Ca^{2+} as input was integrated in the dyad, while the quenching of the naphthalene excited triplet state by oxygen and the prevention of bimolecular triplet–triplet annihilation in the supramolecular host–guest complex with β -cyclodextrin constitute the mechanistic basis for the other two inputs. Only in the absence of oxygen, which still could quench the excited triplet state of the host–guest complexed 2-bromonaphthalene moiety, the presence of Ca^{2+} ions (blocking of PET quenching by the receptor), and complexation with β -cyclodextrin, a high output signal is observed. This is reminiscent of a three-input INH logic gate. Interestingly, the required INVERTER gate (for the oxygen input) and the AND gate are functionally integrated in a single molecular entity. This molecular system mimics the functions of two wired logic gates without the need of their physical implementation. Hence, the realized INH gate is a simple case of functional integration with a single molecular platform.

The complementary logic gate of an INH is the IMP. The IMP gate corresponds to an OR gate with one of the inputs being inverted. For this logic function, rather few examples have been published up to date [23,24]. Samanta and coworkers reported system **9**, which integrates the 4-amino-7-nitrobenzoxa[1,3]diazole (ANBD) fluorophore and a pyridine receptor for *d*-block metal ions like Zn^{2+} [23]. The fluorescence properties of ANBD are governed by the ICT character of the emissive excited state. While at neutral pH, the fluorophore shows an intense emission at 558 nm, deprotonation of the amino NH at basic pH yields almost complete fluorescence quenching. On the other hand, addition of $\text{Zn}(\text{ClO}_4)_2$ has no influence on the high

ANBD fluorescence at neutral pH and at basic pH it restores the intense ICT emission. Defining OH^- and Zn^{2+} ions as inputs, the only combination for which a low-output fluorescence is observed is basic pH in absence of Zn^{2+} . Thus, the system operates according to the function of an IMP gate.

38.2.3 OR–NOR

The flexibility of PET-induced fluorescence switching in terms of logic operations was also demonstrated for the logic OR gate. The de Silva group developed a series of dyads, which recognize earth alkali metal ions such as Ca^{2+} or Mg^{2+} . Upon coordination of either metal ion, PET is blocked and the integrated fluorophore (e.g., anthracene) shows an unselective switching-*on* of fluorescence [25]. Hence, addition of either cation or their simultaneous presence yields a high emission output, in accordance with OR logic.

In 2000, the groups of Tucker and Desvergne reported a very interesting variation of a photoactive molecular logic gate, which produces a photochromic reaction as output [26]. The idea is based on the triad **10** with a central bipyridine (bpy) moiety, which contains on each pyridine ring an oligoether sidearm with a terminal anthracene unit. Intrinsically, the molecule is present in its extended conformation, thereby avoiding electronic repulsions between lone pairs of bpy nitrogens and also between oxygen lone pairs of the sidearms. In this situation, the two anthracene moieties are distant from each other and their photoinduced intramolecular [4 + 4] cycloaddition proceeds with a moderate quantum yield of $\Phi_r = 0.23$ for triad **10**. However, metal complexation can improve this situation by exerting a template effect. Hg^{2+} ions bind to bpy, while Na^+ ions stabilize a pseudo crown ether arrangement of the sidearms. For both situations, a triad conformation with the anthracene units in close proximity results. The simultaneous presence of both inputs has the same effect. As a result, the [4 + 4] cycloadduct is formed with considerably higher photoreaction quantum yields (e.g., $\Phi_r = 0.37$ – 0.43 , depending on the metal ion input) in the presence of one or both metal ions. Hence, an OR logic operation is achieved with metal ion inputs and the efficiency of a photoreaction as output.

The NOR logic gate is realized by reversal of the output of an OR gate through serial wiring with an INVERTER gate. The group of de Silva has described system **11**, which enabled the successful functional integration of the two required gates in one molecule [22]. Their starting point was the notion that the INVERTER function corresponds to input-induced fluorescence quenching, while the OR gate is implemented by the nonselective interaction of inputs with the molecular logic system. Hence, nonselective fluorescence quenching by the inputs is a possible photophysical scenario for a molecular logic NOR operation. Compound **11**, as an example for the realization of this straightforward interpretation of photophysical phenomena in terms of molecular logic, is composed of anthracene as fluorophore and a bpy unit linked via an electronically isolating ethylene spacer. Thus, the system fulfills the basic conditions for observing fluorescence quenching via PET. The bpy unit is a weak electron donor in its free state, but turns into a strong electron acceptor upon protonation with acid or complexation with Zn^{2+} ions as chemical inputs. This induces strong fluorescence quenching (>85%) for the presence of either input or both inputs as required for the NOR gate operation.

38.2.4 Exclusive OR (XOR)–Exclusive NOR (XNOR)

The realization of an XOR gate is not trivial, because the highest output signal is observed for the presence of either input, while their simultaneous presence yields again a low signal as also observed for the absence of inputs. Acid–base neutralization is an elegant way of canceling two antagonistic inputs. If a system is encountered, which yields a high signal for the presence of either acid or base, then an XOR gate can be realized in a rather straightforward manner. This has been explored by Credi, Balzani, and Stoddart who reported the first molecular XOR gate [27]. A supramolecular assembly in form of the [2]pseudorotaxane **12** was used. As macrocyclic ring an electron-rich and intrinsically fluorescent 2,3-dinaphtho-30-crown-10 was chosen. The formation of a charge transfer (CT) complex with an electron-poor diazapyrenium dication thread leads to supramolecular recognition and concomitant quenching of the

naphthalene fluorescence ($\lambda_f = 343$ nm). However, dethreading can reverse this quenching and restore the naphthalene fluorescence. As inputs, H^+ (trifluoromethanesulfonic acid) and tri-*n*-butylamine were applied, which compete with the thread or the ring for the complexation of the other component, respectively. Thus, addition of either input disassembles the [2]pseudorotaxane and restores the naphthalene fluorescence. On the other hand, absence of inputs or their simultaneous presence (acid–base neutralization) leaves the supramolecular assembly intact, which results in CT-induced fluorescence quenching. Noteworthy, recently a logically reversible XOR was also reported by the groups of Pischel and Pérez-Inestrosa [28].

An example for an Exclusive NOR (XNOR) gate (complementary gate of XOR) was realized with the [2] pseudorotaxane **13** [29]. Here the roles of electron donor and acceptor were exchanged: an electron-rich thread in the form of a tetrathiafulvalene derivative with oligoether sidearms and the electron-accepting tetracationic cyclophane cyclobis(paraquat-*p*-phenylene) as ring. The supramolecular interaction is mainly defined by CT between these components, which results in a typical strongly redshifted absorption band at λ_{max} ca. 830 nm. The disassembly of the complex causes the disappearance of this optical signal, which constitutes the output of the system. The inputs were defined as positive (+0.5 V) and negative (−0.3 V) potentials, which yield electrochemical oxidation of the thread and reduction of the ring, respectively. For reasons of consistency, the negative potential input signal requires negative logic convention (low signal: binary 1; high signal: binary 0). Both electrochemical processes cause a weakening of the CT interactions and therefore lead to the dissociation of the complex, that is, the CT absorption vanishes. The simultaneous oxidation and reduction (application of both potentials) in the same pseudorotaxane is unlikely. However, the global state of the bulk system remains unchanged for this input situation, that is, the same as in the absence of electrochemical inputs [14].

38.2.5 Enabled OR (EnOR)–Enabled NOR (EnNOR)

An EnOR gate is essentially a two-input OR gate, which has to be enabled in presence of a third input. Such operation requires that the output of an OR gate is fed together with the enabling input into an AND gate. A molecular example for this type of logic was reported by the groups of Pina and Balzani [30]. They used the chalcone/flavylium system **14a/b** and defined irradiation with 365 nm light, addition of H^+ , and addition of SDS (sodium dodecyl sulfate) surfactant as inputs. The output was read as absorption change at 450 nm, which corresponds to the yellow-colored flavylium ion **14b**. The chalcone **14a** is transformed to the flavylium ion by irradiation and protonation. Protonation is either achieved at a bulk pH ≤ 1 (H^+ as input 1) or by presence of SDS surfactant (input 2), which works as H^+ concentrator in the microenvironment of **14a** and thereby facilitates the stabilization of **14b** even at relatively high bulk pH. Thus, the inputs 1 and 2 serve for the OR gate. The irradiation at 365 nm (input 3) plays the role of the enabling input, because the conversion between **14a** and **14b** is a photodriven process.

An example for a molecular enabled NOR (EnNOR) gate, that is, the complementary device of an EnOR gate, has been published by Pischel and coworkers [31]. They used an amino-substituted phthalimide as antenna for Tb^{3+} luminescence sensitization via energy transfer (**15**). The combination of triethylamine as electron donor and oxygen as antenna triplet quencher yielded the NOR operation, which was only enabled in presence of anions, such as chloride, which protect the lanthanide from quenching by water traces. As a result, long-lived Tb^{3+} luminescence ($\tau_{lum} = 1.6$ ms) was observed for the absence of triethylamine and oxygen and presence of chloride. All other combinations led to much lower luminescence outputs, which is compatible with an EnNOR gate.

38.3 Advanced Molecular Logic Circuits

Functional integration is a frequently adopted approach in molecular logic and used to bypass the need for concatenation of individual logic gates in the realization of advanced molecular logic devices [32]. Instructive examples are the encoder/decoder functions (*vide supra*) where the electronic circuitries

SCHEME 38.5 Examples for advanced molecular logic devices for arithmetic processing: HA (**16a/16b**, **17**, **18/19**), HS (**20,21**), molecuator (**22**), password-protected HA/HS (**23**).

consist of four and six individual logic gates, respectively, wired together. Hence, walking in the footsteps of silicon-based devices, it would take four and six separate concatenated molecular gates to accomplish these functions by physical integration. Instead, by using functional integration, the entire functions of both the encoder and the decoder are now loaded onto one and the same molecular species.

In the following sections, it will be described how the functions of a large selection of advanced logic devices have been mimicked by molecular counterparts (see structures **16–30** in Schemes 38.5 and 38.6). In the vast majority of these examples, functional integration has been used, although clever attempts based on concatenation have been described as well [10–12,33].

38.3.1 Half-Adders

The function performed by a half-adder (HA) is the addition of two binary digits. In the 10-based world, the arithmetic operations are the well-known $0 + 0 = 0$, $0 + 1 = 1$, $1 + 0 = 1$, and $1 + 1 = 2$. Translated into

SCHEME 38.6 Examples for a molecular 2:1 MUX/1:2 DEMUX (24, 25), a molecular 4:2 encoder/2:4 decoder (26, 27), molecular keypad locks and memory devices (28, 29), and an OR-gate activated prodrug (30).

binary numbers, the corresponding operations are $0 + 0 = 00$, $0 + 1 = 01$, $1 + 0 = 01$, and $1 + 1 = 10$. Upon closer inspection, it is seen that the least significant bit (the sum bit) is described by the output of an XOR gate, having the two bits to be added as inputs, whereas the carry bit follows the output of an AND gate. Hence, the HA can be realized by the combined action of an XOR and an AND gate with shared input signals. It is worth pointing out that the two gates are run in parallel through output reconfiguration, that is, concatenation is not needed.

The first molecular half-adder was reported in 2000 by de Silva et al. [34]. Here, a “cocktail” approach was used, where two separate molecules perform the XOR and the AND gate functions, respectively, in response to the addition of Ca^{2+} and H^+ (input signals). The push–pull ICT chromophore **16a** used for the XOR gate displays redshifted absorption upon addition of H^+ , whereas Ca^{2+} results in a corresponding blueshift. In the presence of both H^+ and Ca^{2+} , the opposing spectral shifts cancel each other, leaving the absorption spectrum virtually unchanged. Monitoring the transmittance at the maximum of the original absorption spectrum yields the outputs required for an XOR gate. The AND gate **16b** consists of an anthracene fluorescent reporter, covalently attached to H^+ and Ca^{2+} recognizing units. Both these units quench the fluorescence from anthracene by PET in the absence of their respective cation, so that the fluorescence is only switched *on* in the presence of both H^+ and Ca^{2+} . These are the prerequisites for the AND gate.

A more recent example of a HA based on the supramolecular [2]rotaxane **17** equipped with two photoisomerizable units (azobenzene and stilbene) and two stopper chromophores (fluorescent naphthalimide derivatives) was reported by Tian and coworkers [35]. This molecular construct has the advantage of being operated in an all-photonic mode, that is, light is used for both input stimulations and readout of the optical outputs. The azobenzene and the stilbene can be independently photoisomerized, with all four isomeric states (EE, EZ, ZE, and ZZ) being accessible. The α -cyclodextrin macrocycle traversing the photoswitchable subunit is positioned at different positions depending on the isomerization state, which in turn affects the absorption and the emission properties of the rotaxane. By a judicious choice of input and output signals, the system describes the function of an all-photonic HA. The downside with this study is that the function of the XOR gate requires the output signal to be read at different wavelengths, depending on the input combination.

Although the major body of the molecular HA systems reported so far is demonstrated in bulk solution, approaches have been made to take the first steps toward fully miniaturized systems. One such example was recently presented by Park and coworkers, where a microfluidic device was used as the platform for the solutions of the information processing molecules [36]. The underlying chemistry is based on conventional acid–base switching of the emission of two fluorophores (fluorescein and rhodamine B derivatives). The fluorescein derivative **18** displays emission only at neutral pH, whereas the rhodamine B derivative **19** fluoresces exclusively in acidic environment. With a basic solution as the initial state, the XOR and the AND gates were realized by monitoring the emission of the fluorescein and rhodamine derivatives, respectively, using H^+ as degenerate input signals.

38.3.2 Half-Subtractors

Subtraction of binary digits is performed by a half-subtractor (HS). In the binary notation, the arithmetic operations performed are $0 - 0 = 00$, $1 - 0 = 01$, $0 - 1 = 11$, and $1 - 1 = 00$. Hence, the scheme of an HS is realized by representing the least significant bit (difference bit) by the output of an XOR gate, whereas the corresponding borrow bit follows the INHIBIT gate truth table. The first molecular HS was described by Langford and Yan, using the pH-sensitive emission and absorption properties of tetraphenylporphyrin (**20**, TPPH₂) [37,38]. Upon acidification, **20** is doubly protonated to form TPPH₄²⁺, whereas addition of base results in the corresponding deprotonation to form TPP²⁻. The Soret-band absorption of **20** experiences a significant redshift upon both protonation and deprotonation, whereas the Q-band emission is blueshifted upon deprotonation. Monitoring the transmittance and the emission intensity at strategically chosen wavelengths and using acid and base, as inputs, the behavior of

both the XOR and the INHIBIT gate is properly described. It is worth noting that the XOR gate function, as in many other molecular XOR gates (*vide supra*), relies on acid–base neutralization.

Pischel and Heller recently reported another example of a molecular HS [24]. They utilized the electron-donating and the basic properties of a tertiary amine (diisopropyl-3-pentylamine [DiPPA]) together with acid (trifluoroacetic acid [TFA]) to switch the fluorescence emission of the pyridine-substituted naphthalene **21**. The fluorescence from the locally excited (LE) state ($\lambda_{\text{max}} = 353 \text{ nm}$) is quenched by intermolecular electron transfer upon addition of DiPPA. Addition of TFA protonates the pyridine moiety, and the LE state is quenched by formation of a fluorescent ICT state, displaying emission centered at around 470 nm. By monitoring the emission intensities at the aforementioned wavelengths after application of the different input combinations, the function of an HS was described. Again, acid–base neutralization accounted for the (1,1) input situation.

38.3.3 Molecularors

Following de Silva's demonstration of the first molecular HA, there have been a plethora of examples for HA and HS molecules [39]. Despite the clever molecular design behind these constructs, until 2005 none of these molecules were potent enough to perform *both* addition and subtraction. A bit surprisingly, it was the off-shelf compound fluorescein (**22**) that, in the hands of Shanzer's group, proved to fulfill the prerequisites for both HA and HS performance [40]. A year later, the same group incorporated also a third input to the HA and the HS schemes to make fluorescein function as a full-adder and a full-subtractor, adding and subtracting three binary digits, and the term *molecularor* was coined [41].

Compound **22** exists in four ionization states (cation, neutral, monoanion, and dianion), which can be easily interconverted by pH changes. Each of these four states displays a characteristic absorption spectrum. Hence, acid/base proved useful as inputs, and absorbance values at carefully selected wavelengths were chosen as output signals. With the initial state in the charge neutral form and OH^- as degenerate input signals, the monoanion and the dianion were formed, respectively, upon application of one or both input signals. For the HA, monitoring the absorbance at 447 nm gave the XOR gate response, whereas the 501 nm absorbance gave the corresponding AND gate. The same initial situation was used in operation of the HS, although the system had to be reconfigured with respect to the input set, as the HS was operated using OH^- and H^+ as stimuli. This, unfortunately, prevents the system from performing addition and subtraction simultaneously.

Since Shanzer's pioneering paper, there have been many other reported HA + HS molecularors. Some of them have been equipped with various "add-on" functions to make the overall performance even more sophisticated. An interesting example of such a device is the multiswitchable 2-(4-aminophenylethynyl)-5-methoxy-2-(2-pyridyl)thiazole (**23**) fluorophore described by Yan and coworkers [42]. This molecular device is capable of authorizing the use of its HA or HS function by the correct entry of four-digit codes (represented by chemical and photonic inputs). Furthermore, the output signals (sums or differences) may be chemically encrypted.

The numerical calculations performed by the HA and HS play a key role in the machinery of today's processors. There are, however, many other logic operations that must be executed in data processing, such as transmission and compression. These are based on multiplexing/demultiplexing and encoding/decoding of data streams (Section 38.3.4).

38.3.4 Multiplexers/Demultiplexers and Encoders/Decoders

A multiplexer (MUX) is receiving information from several data lines. The information in the data lines is then combined into a common transmission line in the multiplexing process, that is, the MUX is combining two or more input signals into a single output signal for transmission to a receiver. The state of the selector input *Sel* is determining which of the incoming input signals will be transmitted to the common output line at any given time. After multiplexing, the data is again disentangled in the corresponding demultiplexer (DEMUX) by the use of an address input *Ad*.

SCHEME 38.7 All-photonic switching schemes for the 2:1 MUX and 1:2 DEMUX based on triad **24**.

The first molecular MUX representation was reported by the groups of Andréasson and Gust in 2007 using triad **24** consisting of two photochromic switches (a dihydroindolizine SW1 and a dihydropyrene SW2) and a fluorescent porphyrin (P) as reporter [43]. Both photochromic switches exist in two forms: one form that quenches the fluorescence from the porphyrin (denoted q), and one that does not (denoted nq). The prerequisite for the porphyrin to display strong emission is therefore that both switches must be in the non-quenching form, nq. As shown in Scheme 38.7, the initial state for the MUX is SW1(nq)-P-SW2(q), that is, the fluorescence is quenched by SW2. Application of *Sel* (530 nm light) isomerizes the triad to SW1(q)-P-SW2(nq), where SW1 is the sole quencher. Heating the sample will induce the isomerization SW1(q) \rightarrow SW1(nq), whereas exposure to red light isomerizes SW2(q) to SW2(nq). Thus, using red light as input 1 and heat as input 2 makes it possible to switch the fluorescence output to the *on* state using input 1 or input 2, respectively, depending on if *Sel* is applied or not, and the function of a MUX is properly described.

The same triad **24** can be operated as a DEMUX, where the setup is reconfigured to use IR light as *Ad* and green light as data input, respectively, whereas the absorbance and emission intensities at selected wavelengths are read as outputs (see Scheme 38.7) [44]. As presented, the DEMUX cannot function in concert with the MUX, due to the input/output inhomogeneity.

Credi and coworkers used 8-methoxyquinoline (**25**) in their interpretation of a MUX/DEMUX system [45]. Compound **25** and its protonated form **25H⁺** can be excited with a high degree of selectivity and the fluorescence of both species may be read at a common wavelength. At the same time, after excitation at the isosbestic point, the emission of **25** and **25H⁺** may also be monitored selectively. These spectral properties form the functional basis for the MUX and the DEMUX, respectively. This is yet another example of simplicity-guided approaches toward molecular logic, as a simple unimolecular species driven by H⁺ and light is performing the advanced MUX/DEMUX operations. Another example of a molecular DEMUX, based on acidochromic switching of an isoquinoline *N*-oxide system, was reported by the group of Pérez-Inestrosa [46].

A device very similar to the MUX/DEMUX is the encoder/decoder combination. An encoder converts data from one form to another, whereas the information is reverted to the original form in the decoder. This process is frequently used in the compression of data for transmission or storage. One example is the 4:2 encoder/2:4 decoder. This encoder is converting 0, 1, 2, or 3 in 10-base to the binary notation, whereas the corresponding decoder is reversing the operation. Hence, the encoder is processing four inputs into two outputs, whereas the decoder has two inputs and four outputs. The electronic circuit equivalents for an encoder and a decoder are shown in Scheme 38.8. The first molecule designed to perform these operations was the photochromic triad **26**, which incorporates FG and DTE photochromes and which was reported by the groups of Andréasson and Gust [47]. With the use of a light source in the visible and three wavelengths in the UV, the triad may be selectively isomerized to all four isomeric states. Monitoring the absorbance at two wavelengths in the visible region as outputs, the function of the encoder was mimicked. When used as a decoder, two wavelengths in the UV were used as inputs, whereas four separate spectral features constituted the set of outputs. Due to the all-photonic nature of both the encoder and the decoder, the device is operated without any buildup of chemical waste, and applications in rigid or semi-rigid media may be foreseen, because the need for molecular diffusion of chemical inputs is eliminated.

SCHEME 38.8 Electronic representations of a 4:2 encoder and a 2:4 decoder.

Balzani and coworkers recently harnessed the electrochemical and optical properties of the well-characterized ruthenium complex $[\text{Ru}(\text{bpy})_3]^{2+}$ (**27**) to mimic the encoder/decoder function [48]. The functional basis is the different spectral properties displayed by the three oxidation states and the excited state of **27**: $[\text{Ru}(\text{bpy})_3]^{2+}$, $[\text{Ru}(\text{bpy})_3]^{3+}$, $[\text{Ru}(\text{bpy})_3]^+$, and $^*[\text{Ru}(\text{bpy})_3]^{2+}$. By a careful choice of conditions for electrochemical oxidations/reductions and photoexcitation of **27**, a delicate balance between these four forms was achieved, and thus, the function of both the encoder and decoder was described.

38.4 Molecular Logic with Memory

Effect: Sequential Logic Devices

The logic devices described so far have an output that is only dependent on the present inputs. These devices are referred to as combinational logic devices. If instead the output depends on the input history, that is, if the device is remembering also the preceding input application and the respectively generated output, then the device is capable of performing so-called sequential logic operations. In other words, a memory effect applies.

The first molecular approach to sequential logic was the keypad lock described by Shanzer and coworkers [8]. The system used is the Fe^{3+} complex of a fluorescein-linker-pyrene dyad **28**. For the keypad lock function, the emission at 525 nm is monitored upon UV excitation and used as the output signal. The UV light used for readout excitation is mainly being absorbed by pyrene, and the emission at 525 nm is ascribed to the energy-transfer-sensitized fluorescence from the fluorescein dianion. Initially, **28** is set to the Fe^{3+} -complexed form, with fluorescein in the monoanionic state. Hence, before strong emission at 525 nm is to be observed, the monoanion must be deprotonated by the addition of base to form the dianion, and Fe^{3+} must be removed by ethylenediaminetetraacetic acid (EDTA) to suppress Fe^{3+} -induced fluorescence quenching (electron transfer). Due to the fact that the rate of Fe^{3+} extraction is significantly enhanced in acidic media compared to a basic solution, the kinetically favored sequence to

reach the fluorescent form is the addition of EDTA followed by base. If the three input signals are represented by EDTA, base, and UV excitation, the fluorescent output at 525 nm is only switched *on* when the inputs are applied in the aforementioned order. In this system, the sequence dependence is governed by a kinetically controlled process. This may be less desirable, as the output has to be read within a certain time limit. Else, the system response is not unique for a specific input order, and the sequential logic behavior is lost.

The sequential logic system (29) reported by Tian and coworkers is another construct where the underlying mechanism is kinetically controlled [49]. The molecular platform has multiple N-containing binding sites, where one site binds Cu^{2+} and another shows preference for Hg^{2+} . Hg^{2+} coordination results in increased emission intensity, whereas Cu^{2+} efficiently quenches the emission. The binding events are competitive, but the equilibration kinetics occurs on a timescale of several hours, why the first added cation will overrule the effect of the second, given that the readout is done before the system is approaching equilibrium. Hence, the fluorescence output will increase upon the addition of Hg^{2+} followed by Cu^{2+} , but decrease upon Cu^{2+} followed by Hg^{2+} .

Interestingly, molecular Set–Reset memory devices have also been realized recently. For example, the Willner group reported a Set–Reset latch based on a photo-electroswitch in the form of a DTE-type photochrome immobilized on a gold electrode, which can be addressed by light and electrochemical inputs [50].

38.5 Molecular Logic for Bioinspired Applications

In 15 years, molecular logic has developed from single logic gate performance to the mimicry of the most common logic operations of both combinational and sequential type. Nevertheless, the silicon-based predecessors are much ahead, and one can only speculate when and how molecular logic will catch up. Hence, going behind the silicon-based devices may not lead to the soonest real world applications, and it is now being realized that there may be areas of more direct use. Of particular interest are fields with which semiconductor materials are not compatible. Biological systems, for example, the human body, are examples where the logic response from molecules may be used to trigger the activation of drugs, etc. For example, the action of the new-generation cancer drugs is adequately described by AND logic. Here, tumor-specific receptors are being used to guide the inactive drug conjugate to cancer cells. The subsequent activation of the conjugate, that is, the release of the cytotoxic substance, is being dramatically accelerated by intracellular components, for example, enzymes, with high concentrations in tumor cells. Thus, both tumor-specific receptors and high concentrations of the activating component (inputs) are used to switch *on* the output (high cytotoxicity). Another example is system 5, which is described as AND-logic-activated singlet oxygen generator (*vide supra*) [13].

There are several “proof-of-principle” studies that explicitly describe biological applications of molecular logic. It is worth pointing out that biomolecules themselves have been also implemented as platforms for logic operations, in what could be referred to as “biomolecular logic” [51]. This approach will not be described here, but instead the focus will be on organic molecules that may affect biological functions according to logic input schemes.

A recent example is the OR-logic controlled prodrug activation described by Shabat and coworkers [52]. A prodrug is administered in the body in the inactive form, and has thus a low initial level of toxicity. It is then being metabolized into its active form, typically by an enzyme with a high local concentration in the region of the body to be targeted by the drug. In the OR-logic interpretation by Shabat, the drug was covalently attached to a central diethylenetriamine together with two separate enzymatic substrates (a phenylacetamide unit and a retro-aldol retro-Michael substrate) to constitute the prodrug 30. The cleavage of the drug from the two substrates, that is, the activation of the prodrug, is independently triggered by penicillin G amidase or antibody 38C2. Using the Boolean logic language to describe this protocol, the two enzymes serve as inputs, whereas the corresponding output is defined as high toxicity of the liberated drug.

In another study, reported by Stoddart, Zink, and coworkers, an AND-activated drug delivery system is envisioned [53]. Here, the drug is initially encapsulated in the pores of silica nanoparticles. The surface of the nanoparticles is covered by pH-switchable pseudorotaxanes consisting of cucurbit [6] uril rings threaded onto polyammonium stalks forming a lid over the nanopores, thereby preventing the encapsulated drug from being delivered. In addition, the walls of the nanopores are covered with azobenzene nanoimpeller units. Irradiation with 448 nm light triggers a dynamic wagging motion, impelling the encapsulated drug toward the opening of the nanopores. In order to effectuate drug release, irradiation and proper adjustment of pH conditions must be applied, which is compatible with AND logic. Application of only one input leaves the drug immersed in the pores of the silica nanoparticles.

Medical diagnostics is another area where molecular logic may be applicable. An illustrative example of this is the aforementioned three-input AND gate **3** to probe the presence of three different clinically relevant ionic species (H^+ , Na^+ ions, and Zn^{2+} ions), rather than undertake three separate tests to monitor the presence of each of them [7]. Another example of such multiparameter analytics is a method devised by Walt and Konry [54]. In concrete, their system was designed for the detection of different combinations of bacterial DNA and proinflammatory cytokines (e.g., IL-8 protein) by implementation of AND and INHIBIT logic. The motivation for such a logically controlled diagnosis device is that bacterial infections are often accompanied by secretion of specific cytokines. Monoclonal antibody (mAb)-functionalized microspheres form the platform of the device. The mAb-conjugated microspheres were used to capture the IL-8 protein, and the subsequent binding of a capture-probe DNA-sequence to the protein via biotin/avidin chemistry opens up the possibility for sequence specific binding of the bacterial target gene. The bacterial target gene is complementary to a Cy3-labelled oligonucleotide, so that the Cy3 emission is only observed from the microspheres if both the protein and the bacterial DNA are present. In the absence of the target DNA, a Cy5-labelled oligonucleotide binds to the capture probe DNA, and Cy5 emission is instead observed. Hence, the Cy3 and Cy5 emission outputs describe AND logic and INHIBIT logic behavior, respectively, with respect to the IL-8 and bacterial DNA inputs.

38.6 Conclusions

The few herein discussed examples for basic and advanced molecular logic devices serve to demonstrate the importance of photophysical and photochemical engineering for the realization of such functions.* They also illustrate the enormous bandwidth of design possibilities based on a handful of excited state processes such as PET, ICT, energy transfer, and photoisomerizations (e.g., photochromic reactions). The implementation of approaches like functional integration and reconfiguration has helped to reach reasonable levels of complexity realized with unimolecular entities, such as the functions of adders/subtractors, MUXs/DEMUXs, encoders/decoders, or sequential logic. However, for the future objective of molecular computing, much work is waiting ahead, including the organization of molecular logic arrays on surfaces and gate-to-gate communication (i.e., concatenation) within these assemblies. In this context, the all-photonics operation of molecular logic devices seems a very promising approach.

On the other hand, molecular logic is expected to have impact in many other application fields that are at more immediate reach. As briefly highlighted with a few representative examples in Section 38.5, the concept of logic is of high interest for bioinspired applications such as drug delivery and prodrug activation. Here and in other areas, surely further innovative approaches will be reported in the near future.*

* The herein discussed works cover reports until December 2009.

39.1 Introduction

Supramolecular systems are assemblies of two or more individual molecular components, held together through noncovalent forces. These intermolecular interactions can include hydrogen bonds, electrostatic interactions, π -stacking, and the hydrophobic effect.¹⁻⁵ In general, intermolecular interactions are weaker than covalent bonds and thus reversible. Such reversibility is an important feature of supramolecular systems, contributing to the functions that can be obtained, and dictating that dynamics play a crucial role in defining the characteristics of the system.

The characterization of a molecular system is based on structural studies and the determination of the thermodynamics of the system. Almost all molecules are stable, and dynamics are therefore only important in the context of reactivity. Because of the inherent reversibility of supramolecular systems, knowledge of kinetic aspects, as well as the structural and thermodynamic characteristics, is needed. Thermodynamic and structural studies provide information on the equilibrium state of the system: stoichiometry and organization of the complex, as well as complex stability. Study of the system's dynamics reveals information on how fast a complex is formed and how long it exists. Thermodynamic information can be inferred from dynamic studies, but no information on the kinetics of a system can be obtained from thermodynamic or structural studies.

The dynamics of a system can be determined using real-time kinetic techniques to measure absolute rate constants, or by relative rate measurements. In real-time kinetic measurements, the concentration of the species of interest is measured as a function of time and rate constants can be obtained from the

fit of the kinetic data to rate laws derived for the system. Measuring relative rates requires comparison to a standard system for which rate constants are known, and for which the same reaction mechanism is assumed. The relative importance of different intermolecular interactions in supramolecular systems are not understood well enough to determine appropriate standard reactions, and thus relative rate measurements have limited application. Instead kinetic measurements need to be carried out using real-time techniques.

The time scale for the association and dissociation processes involving the various components of a supramolecular system is influenced by the size and complexity of the system. The fastest time scale on which encounter between two molecules completely separated in solution can occur is limited by the rate of diffusion. When reactant concentrations are 0.1 M or less in aqueous solution at 25°C ($k_{\text{dif}} = 7.4 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$)⁶ the association reaction will be slower than 1 ns. Supramolecular systems range in size from 1 to 100 nm, and the size of the supramolecular system determines the fastest reaction that can be expected. The diffusion of a small molecule, such as glucose, in aqueous solution at 25°C takes 3 ns for 1 nm and 30 μs for 100 nm, indicating that dynamics in small supramolecular systems are expected to occur in the nanosecond to microsecond time range.^{7,8} Dissociation of a molecular component from the supramolecular system is a unimolecular process. Rate constants for unimolecular processes are 10^{12} s^{-1} or lower. In supramolecular systems, complete dissociation normally occurs in nanoseconds or slower, while internal processes, such as relocation or solvation changes, occur on faster time scales.⁹⁻¹² The fast processes related to the association/dissociation dynamics necessitate kinetic techniques that cover nanosecond and slower time scales for dynamics studies with supramolecular systems.

Most commonly, real-time kinetic measurements are carried out using methods that involve perturbation of a system, though a few methods do not have this requirement. Subsequent to a perturbation that is faster than the relaxation of the system to a new equilibrium the relaxation kinetics are measured, from which the rate constants for the relevant processes can be obtained. There are a number of ways in which a system can be perturbed, including creation of a new chemical species (excited state) or changes in temperature, pressure, or concentration. Advantages and disadvantages of these techniques have been previously reviewed.¹³ Photophysical methods are inherently applicable to kinetic studies in the nanosecond to microsecond time range and are therefore ideal for the study of supramolecular dynamics.

This chapter provides the conceptual framework on how photophysics can be applied to the determination of dynamics in supramolecular systems. Selected techniques, that is, stopped-flow, fluorescence correlation spectroscopy (FCS), time-resolved fluorescence, and transient absorption, will be included to highlight how kinetic information can be obtained for binding of small guests with representative host systems, that is, micelles, bile salt aggregates, and cyclodextrins (CDs). This chapter focuses on association and dissociation processes in supramolecular systems, occurring on time scales faster than seconds, and does not focus on internal mobility within the system. Examples were chosen to illustrate the concepts and are not intended to provide a comprehensive review.

39.2 Host Systems

39.2.1 Micelles

Micelles are self-assemblies of surfactant molecules (Figure 39.1). Usually the surfactant consists of a hydrophobic chain with an ionic or polar head group. Micelles are formed when the surfactant concentration exceeds a critical micelle concentration (cmc). Guest molecules can be solubilized in the hydrophobic interior of the micelle. Micelles are themselves quite dynamic, with exchange of individual monomers between the micelle and the aqueous phase occurring in microseconds, while the whole assembly has a lifetime of milliseconds.¹⁴ However, on the time scales relevant to guest binding events micelles can generally be viewed as a static host system.

FIGURE 39.1 Structure of sodium dodecyl sulfate (SDS), a typical surfactant, and a cartoon representation of a micelle.

39.2.2 Bile Salt Aggregates

Bile salts are amphiphilic molecules, with a relatively hydrophobic convex face, and a more hydrophilic concave face (Figure 39.2). Bile salt aggregates form in aqueous solution and, as opposed to micelles, the size of the bile salt aggregate increases continuously with concentration (Figure 39.2).^{15–17} The most widely used structural model for the aggregates suggests that small primary aggregates are formed at low concentrations, which provide a hydrophobic binding site for guest molecules.^{18,19} At higher concentrations, further aggregation leads to the formation of secondary aggregates, which provide a relatively more hydrophilic binding site.^{18,19}

39.2.3 Cyclodextrins

Cyclodextrins (CDs) are oligosaccharides consisting of various numbers of glucose units (6, 7, or 8 for α -, β -, and γ -CD) with a relatively rigid, hydrophobic internal cavity in which guests can bind (Figure 39.3).^{20,21} The formation of 1:1 host–guest complexes is common, but higher order complexes, such as 1:2 and 2:2 complexes, can be formed with some guests. The efficiency of complex formation is determined by the hydrophobicity of the guest, as well as steric constraints concerning the fit of the guest in the CD cavity.^{22,23}

FIGURE 39.3 Structure of β -CD and a cartoon representation of a CD.

39.3 Photophysical Techniques for the Study of Supramolecular Dynamics

Photophysical methods can be used either as an analytical tool to monitor the concentration of reactants or products by absorption or emission spectroscopy (e.g., stopped-flow), or to create a perturbation in the system where dynamics of the excited state reveal kinetic information (e.g., laser flash photolysis).

39.3.1 Photophysics as an Analytical Method

When photophysics are used to monitor systems, kinetic measurements are made using continuous irradiation of the sample. For these techniques, the lifetime of the excited state is not relevant to the experiment. Fluorescence is a much more sensitive technique than absorption. Fluorescence is an absolute measurement where light intensity is detected, whereas absorption is a relative measurement where changes in light intensity are detected. For this reason, when a choice between the two techniques is available, fluorescence is generally preferable.

39.3.1.1 Stopped-Flow

Stopped-flow experiments use a concentration jump to examine kinetic processes. Two separate solutions are driven through a mixing chamber where they are thoroughly mixed before flow is stopped abruptly in an observation cell, and further changes in the system are monitored. Mixing of the solutions results in a perturbation of the initial equilibrium states, and relaxation to the new equilibrium state is monitored as a function of time, usually by absorption or fluorescence spectroscopy.^{24,25} The use of fluorescence or absorption requires that either the guest or host have different absorption or fluorescence emission properties when free in solution and when part of the supramolecular complex. Stopped-flow time resolution is generally 1–2 ms,²⁴ and is determined by the time required for mixing and stopping the flow.

Stopped-flow can be employed to study the association and dissociation processes of supramolecular systems, with rate constants for the processes determined from the analysis of the relaxation kinetics obtained following mixing. The simplest kinetic scheme is that for a 1:1 complex formed between a guest (G) and a host (H) (Scheme 39.1).

SCHEME 39.1 Formation of a 1:1 host-guest complex.

The following rate law (Equation 39.1) defines the relaxation kinetics after perturbation:

$$\frac{d[\text{HG}]}{dt} = k_+[\text{H}][\text{G}] - k_-[\text{HG}] \quad (39.1)$$

If one of the components for the bimolecular reaction is in excess (e.g., $[\text{H}] \gg [\text{G}]$) and concentration changes due to the perturbation are small, the kinetics will follow an exponential function, with the observed rate constant (k_{obs}) given by Equation 39.2:

$$k_{\text{obs}} = k_+[\text{H}] + k_- \quad (39.2)$$

In general, the concentration of free host ($[\text{H}]$) is approximately equal to the total host concentration ($[\text{H}]_{\text{T}}$) and the analytical concentration of the host is used. Otherwise, a quadratic expression for the concentration is obtained from the equilibrium constant and the mass balance equations.

The observed rate constant is related to the sum of the rate constants for the pseudo-first-order association process and the rate constant for the dissociation process. The association process can be affected by changes in $[\text{H}]$, but the dissociation rate constant is intrinsic to the system and cannot be manipulated by external factors.

Host-guest interactions involving coupled or sequential first-order or pseudo-first-order reactions can be analyzed using a sum of exponential functions. If the reactions are not first order or pseudo first order, more complex equations have to be derived.^{26,27} In all cases, the rate law is related to both association and dissociation processes, and these processes can never be decoupled when measuring relaxation kinetics.

39.3.1.2 Supramolecular Dynamics from Stopped-Flow Experiments

Stopped-flow experiments have been used to study dynamics of binding to CDs for a number of guest molecules.^{28–43} Several organic molecules, including azo dyes^{34,40} and pyrene^{30,42,43} have been studied, as well as the binding dynamics of some metal ions.^{29,31,41} Generally, only dynamics that occur on time scales slower than milliseconds can be explored, which often results in the study of systems that involve multistep kinetic processes or higher order complexes.

A primary consideration when designing kinetic experiments to probe host-guest dynamics is to choose a guest molecule for which the photophysics are as different as possible for host-guest complexes with different stoichiometries. In the context of studying complexes with higher order stoichiometry, it is important to differentiate between complexes containing one guest and those containing two guest molecules. Guests that show prominent excimer emission, which is due to a complex between the singlet excited state and a ground state molecule, are ideally suited for such studies. Examples where pyrene excimer emission was used to study the dynamics of CDs or micelles follow.

Both 1:1 and 2:2 complexes are formed by pyrene (Scheme 39.2) and γ -CD.^{30,42,43} The dynamics for the formation of the 1:1 pyrene: γ -CD complex occur within the time resolution of the stopped-flow

SCHEME 39.2 Structure of pyrene and a pyrene-substituted triglyceride.

equipment, but the formation of the higher order complex is much slower and suitable for stopped-flow studies. An excimer-like emission was observed for the 2:2 complex, which was redshifted in comparison to the pyrene monomer fluorescence observed for the 1:1 complex and pyrene in water. The excimer-like emission could be used to follow the formation of the 2:2 complex from two 1:1 complexes. The association constant for the 2:2 complex was found to be $6 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$, which is an order of magnitude smaller than the typical association rate constants for 1:1 complexes where the guest fits into the CD cavity (see the following text).³⁰ The dissociation rate constant for the 2:2 complex was 73 s^{-1} , which is up to five orders of magnitude slower than typical dissociation rate constants for a 1:1 complex.³⁰

Exchange of guest molecules between micelles, such as Triton X-100 and SDS, has been studied using stopped-flow methods.^{44–48} Triglyceride pyrene derivatives (Scheme 39.2) were used as water-insoluble probes, so that exit and reentry of the guest is unimportant, and exchange of a guest between micelles will only occur through fusion and fragmentation of two micelles. The concentration of the pyrene derivative employed was sufficient to ensure that a significant number of micelles contained two guest molecules. Pyrene excimer emission will occur when two pyrene moieties are located in the same micelle. The exchange processes could be monitored as a decrease in pyrene excimer fluorescence intensity when, in the stopped-flow experiment, a solution of guest/micelles was mixed with a solution of empty micelles. In this experiment, two relaxation processes were observed. One of these relaxations showed a dependence on the micelle concentration, and was assigned to micelle fusion, a bimolecular reaction involving the collision of two micelles. The other relaxation process was independent of micelle concentration and was assigned to micelle fragmentation, which is a unimolecular process. For the nonionic micelle Triton X-100, the rate constant for fusion was $1.47 \times 10^6 \text{ M}^{-1} \text{ s}^{-1}$, and the rate constant for fragmentation was 12.6 s^{-1} .⁴⁵ In the case of the anionic SDS micelles, the observed rate constants were much slower and showed a dependence on the salt concentration. When the concentration of sodium cations was 140 mM, the rate constant for fusion was $38 \text{ M}^{-1} \text{ s}^{-1}$, while the rate constant for fragmentation was 0.037 s^{-1} .^{44,48}

39.3.1.3 Fluorescence Correlation Spectroscopy

Fluorescence correlation spectroscopy (FCS) does not require a perturbation of the system's equilibrium to measure the host-guest dynamics on a wide range of time domains, from picoseconds to seconds.⁴⁹ This technique is based on the measurement of fluctuations in the fluorescence intensity of individual molecules.^{50–52} A very small volume of the sample is continuously irradiated, and fluctuations in intensity occur because of events that affect the molecule's fluorescence efficiency, such as diffusion out of the detection volume or formation of a dark triplet excited state. Binding dynamics can be measured if the quantum yields for the free and complexed fluorophore are different, since in such a situation association to or dissociation from a supramolecular system would contribute to fluorescence intensity fluctuations.

Data are analyzed from autocorrelation functions, $G(\tau)$, which define the probability of detecting a photon emitted from the same molecule at time zero, and at time τ . A typical correlation curve (Figure 39.4) shows a growth at short times, called antibunching, which is related to the reexcitation of an individual fluorophore.⁴⁹ Decreases in the correlation curve occur due to events that change the probability of forming the molecule's singlet excited state, with an inflection point at a certain time corresponding to each event such as triplet formation or diffusion. Correlation completely disappears when the molecule diffuses out of the detection volume. Host-guest dynamics can be measured on time scales occurring between antibunching and diffusion events.

In order to develop appropriate models to analyze the correlation curve and obtain binding dynamics from the autocorrelation function various mechanistic assumptions have to be made. More comprehensive reviews of the relevant models and mathematical treatments have been recently published.^{13,53} For a 1:1 host-guest complex, the correlation time associated with the host-guest dynamics has a time constant τ_R (Equation 39.3):

$$\tau_R = \frac{1}{k_{\text{obs}}} = \frac{1}{k_+[H] + k_-} \quad (39.3)$$

FIGURE 39.4 Representation of a typical FCS correlation curve showing various processes that occur on different time scales.

39.3.1.4 Supramolecular Dynamics from Florescence Correlation Spectroscopy

The binding of Pyronine Y and Pyronine B (Scheme 39.3) to β -CD has been examined by FCS.^{53,54} A new correlation event was observed in the 1–10 μ s region, with a correlation time that became shorter as the β -CD concentration was increased. This event corresponded to the dynamics of the host-guest complex. Additionally, the correlation time related to diffusion shifted to longer times as CD was added due to the increased molar mass of the host-guest complex compared to free guest. At the highest concentration of CD employed, there was still a significant contribution from the free guest to the diffusion term. Because of the contribution from free guest, the diffusion time of the complex could not be directly determined and the errors associated with fitting individual curves were high. Instead global analysis fits of the entire data set resulted in recovery of k_- values of $5.0 \times 10^5 \text{ s}^{-1}$ for Pyronine Y and $7.6 \times 10^4 \text{ s}^{-1}$ for Pyronine B.^{53,54} The k_+ values of $2 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ for Pyronine Y and $1.5 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ for Pyronine B were then calculated from the equilibrium constants.^{53,54}

Another system that has been studied by FCS is the binding of Rhodamine 123 cations (Scheme 39.4) to the nonionic surfactants Triton X-100 and Brij-35.^{53,55} A cationic guest was used to ensure partition between the micelle and the aqueous phase, while nonionic surfactants were chosen to eliminate contributions from electrostatic interactions. Similar to the CD system discussed earlier, when micelles were present in solution changes were observed in the diffusion term, and a new correlation term, corresponding to the host-guest dynamics, was seen. An additional component had to be considered in this

SCHEME 39.3 Structure of Pyronine Y ($R = \text{CH}_3$) and Pyronine B ($R = \text{CH}_2\text{CH}_3$).

SCHEME 39.4 Structure of the Rhodamine 123 cation.

system as the Rhodamine 123 cation undergoes significant intersystem crossing to the triplet excited state. To differentiate the correlation term for triplet formation from the host-guest dynamics, a series of FCS curves at different excitation powers had to be analyzed. The triplet state population is dependent on excitation power, while host-guest dynamics are affected by micelle concentration. Values of k_- determined by global analysis of a concentration series of FCS correlation curves were $2.2 \times 10^5 \text{ s}^{-1}$ for Triton X-100 and $4 \times 10^5 \text{ s}^{-1}$ for Brij-35.^{53,55} The values for k_+ , $1.4 \times 10^{10} \text{ M}^{-1} \text{ s}^{-1}$ for Triton X-100 and $8 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ for Brij-35, were calculated from the equilibrium constants.^{53,55} The calculated values for the association rate constants are the same as that for a diffusion-controlled process, which is in agreement with what has been observed in other micellar systems (see the following sections).

39.3.2 Photophysics as a Perturbation Method

Excited states and reactive intermediates are species with finite lifetimes. The fast formation of these species, generally by the use of lasers, can be used as the fast perturbation required for real-time kinetic studies. Using excited states adds an extra aspect to the treatment of the kinetic data since the lifetime of the excited state must be taken into account. The lifetimes of excited states can be shorter, longer, or of the same magnitude as the kinetic processes of interest. Each case will be considered later for the simplest host-guest system, with 1:1 binding stoichiometry (Scheme 39.1). It will be assumed that the guest is the species being excited; however, the same conceptual framework applies if the host is excited.

Changes in excited state concentration are generally monitored over time by either time-resolved fluorescence emission measurements, that is, single photon counting, or by transient absorption spectroscopy, that is, laser flash photolysis.

39.3.2.1 Time-Resolved Emission Measurements

Fluorescence is the most common type of emission from excited states of organic molecules. Kinetic data is obtained from time-resolved experiments, of which the most common method is single photon counting.⁵⁶ The fluorophore is excited using a high repetition excitation source and the time for emission of a single photon is measured. A histogram of the number of photons detected as a function of time is built, relying on the concept that the probability distribution for emission of a single photon follows the statistical distribution for all photons emitted as a result of excitation. A large dynamic range is obtained for the intensity, which helps in differentiation of fluorescence species with similar lifetimes.

Fluorescence decay functions are generally exponential or a sum of exponentials (Equation 39.4), where k_i is the decay rate constant of each fluorescent species, i , and its inverse value is equal to the singlet excited state lifetime of the emissive species ($\tau_i = 1/k_i$). A_i is the preexponential factor for each emissive species with a different lifetime, and the sum of all preexponential factors equals 1:

$$I(t) = I_o \sum_1^i A_i e^{-k_i t} \quad (39.4)$$

The preexponential factors are related to the concentration and the excitation efficiency of each species, and can only be related to absolute concentrations if the system is excited at an isosbestic point, or if the molar absorptivity is known for the supramolecular complex.

Time-resolved fluorescence can be used to obtain dynamic information when the lifetime of the excited state is similar to the time scale of the dynamics of interest. The longest time range accessible in time-resolved fluorescence is limited by the lifetime of the excited state being studied. In general, the singlet excited states of organic molecules have lifetimes that are shorter than 100 ns. Information on dynamics can therefore only be obtained from time-resolved fluorescence measurements if the association and dissociation rate constants are very fast, and in most cases the lifetime of the singlet excited state is too short for the guest to move between the bulk solution and the host system.

39.3.2.2 Laser Flash Photolysis

Laser flash photolysis (lfp) experiments use a pulsed laser to form the excited state guest.⁵⁶ Laser irradiation is orthogonal to a monitoring beam that is used to measure the absorption of the sample. Absorption is monitored before and after the laser pulse and changes are related to the difference in absorbance of the transient formed during the laser pulse and absorbance of the system prior to the laser pulse. In studies of supramolecular dynamics, the decays of triplet excited states are usually measured in lfp experiments. Triplet excited states are much longer lived than singlet excited states. Triplet lifetimes in aqueous solution can often be hundreds of nanoseconds or longer, and are generally long enough for relocation of the guest between the bulk solution and the supramolecular system to occur.

The time domains covered by most lfp systems are nanoseconds to hundreds of microseconds, though this can be extended to the millisecond time scale.^{57,58} The longest time range accessible is dependent on the lifetime of the excited state being monitored.

39.3.3 Photophysics with Immobile Excited States

39.3.3.1 Short-Lived Excited States

When an excited state is short-lived, it does not have time to relocate between the host-guest complex and the bulk solution. The excited state acts as a probe for the environment in which it is located since the association and dissociation kinetics are slow in comparison to deactivation of the excited state (Figure 39.5). Each species can be separately identified when the lifetimes for the excited states of the free and bound guest are different.

39.3.3.2 Quenching of Short-Lived Excited States

The fact that most singlet excited state guests do not relocate during their lifetimes means that they can be used to examine the migration of the quencher, and rate constants can be measured for the association of the quencher with the host system (Figure 39.6).^{56,59–64} Quenching is a bimolecular

FIGURE 39.5 Schematic representation of the binding dynamics for a system where the excited state of the guest (gray circles) does not relocate between the bulk solution and the host during its lifetime.

FIGURE 39.6 Schematic representation of the binding dynamics for a system where the excited state of the guest (gray circles) does not relocate between the bulk solution and the host during its lifetime. Quenching of the excited state can occur in the bulk solution or inside the host.

reaction between the excited state and a quencher molecule. It can be viewed as the formation of an encounter complex, followed by quenching, with intrinsic quenching rate constant, k_q^{int} . In general, there are two different quenching scenarios. In the first case, every encounter between the quencher and the excited state in the host leads to deactivation of the excited state ($k_q^{\text{int}} \gg k_-^Q$). This is most likely the case for smaller hosts, such as CDs, with a confined volume for binding. In the second, scenario the quencher has a finite probability of exiting the host before encountering the bound guest ($k_q^{\text{int}} \sim k_-^Q$ or $k_q^{\text{int}} \ll k_-^Q$). This is more likely the case for larger hosts, such as micelles, where the quencher and excited state guest can be incorporated in the same micelle at some distance from each other.

39.3.3.3 Deactivation of Every Encounter in the Host

The excited state lifetimes of the guest bound to the host and in the bulk solution are often different, with a longer lifetime usually observed for the guest in the host. In such a case, the fluorescence decay will be a sum of exponentials when appreciable amounts of guest are located in each environment (Equation 39.4). Quenching leads to an increase in the observed decay rate constant for each component (k_{obs}^i), and a linear relationship with respect to the quencher concentration is observed (Equation 39.5):

$$k_{\text{obs}}^i = k_o^i + k_q^i[\text{Q}] \quad (39.5)$$

The quenching rate constant for the guest bound to the host is related to the association rate constant of the quencher with the host, k_+^Q , the intrinsic intra-micellar quenching rate constant, k_q^{int} , and the rate constant for the dissociation of the quencher from the host, k_-^Q (Equation 39.6):

$$k_q^H = \frac{k_+^Q k_q^{\text{int}}}{k_-^Q + k_q^{\text{int}}} \quad (39.6)$$

When every inclusion of quencher in the host leads to quenching, that is, k_-^Q is much smaller than k_q^{int} , the quenching rate constant of the guest in the host, k_q^H , is equal to the association rate constant of the quencher with the host, k_+^Q . It should be noted that time-resolved measurements cannot be used if static quenching occurs due to the guest and quencher being located in close proximity prior to excitation.

39.3.3.4 Competition between Quenching and Exit from the Host

Quenching efficiencies of less than 100% are observed when exit of the quencher from the host competes with quenching of the guest in the host. The simplest model that has been developed to analyze the fluorescence decay of an excited guest in the host assumes that all guest molecules are bound to the host, and that the rate constants for quencher association with and dissociation from a host are independent of guest population in the host. In the absence of quencher, the fluorescence decay follows an exponential function with a rate constant of k_o (Equation 39.4). In the presence of quencher, the decay is nonexponential (Equation 39.7), with parameters A to D defined in Equations 39.8 through 39.11^{59,60–63}:

$$I(t) = Ae^{[-Bt - C(1 - e^{-Dt})]} \quad (39.7)$$

$$A = I_o \quad (39.8)$$

$$B = k_o + \left[\frac{k_q^{\text{int}} k_+^Q}{(k_q^{\text{int}} + k_-^Q)(1 + K_Q[\text{H}])} \right] [\text{Q}] \quad (39.9)$$

$$C = \left[\frac{(k_q^{\text{int}})^2 k_+^Q}{(k_q^{\text{int}} + k_-^Q)^2 k_-^Q (1 + K_Q[\text{H}])} \right] [\text{Q}] \quad (39.10)$$

$$D = k_q^{\text{int}} + k_-^Q \quad (39.11)$$

Parameters B and C are dependent on the quencher concentration, so measurements of the fluorescence decay at different quencher concentrations allows recovery of all relevant rate constants. This model has been expanded to describe more complex mechanisms, for example, inclusion of additional processes such as exchange of quencher or guest between micelles during the lifetime of the guest.⁵⁹

39.3.3.5 Supramolecular Dynamics from Quenching Short-Lived Excited States

For the case in which every encounter in the host between quencher and excited state guest leads to quenching of the excited state, the quenching rate constant is equivalent to the association rate constant for the quencher with the host. This quenching methodology has been used in the study of singlet excited state guest molecules bound to bile salt aggregates.^{65–67} In the presence of 10 mM sodium cholate (NaCh), some of the guest is bound to the aggregate, while some guest remains in the aqueous solution. Incorporation of the guest into the bile salt aggregate leads to a lengthening of its singlet excited state lifetime and the fluorescence decays were fit to the sum of two exponentials (Equation 39.4). The lifetime for the excited guest in water was shortened to a greater extent in the presence of iodide anions when compared to the lifetime for the guest in the aggregate, leading to an enhancement of the curvature in the semilog decay plot (Figure 39.7).

FIGURE 39.7 Fluorescence decays for 1-ethylnaphthalene in the presence of 10 mM NaCh in the absence of iodide anions (a, black) and in the presence of 20 mM iodide anion (b, gray) used as a quencher for the singlet excited state of 1-ethylnaphthalene. The instrument response function of the singlet photon counter is shown as c. The residual plot between the data and the fit to a sum of two exponentials in the absence of iodide anions is shown in the middle plot, while the residuals for the fit in the presence of iodide anions is shown in the lower plot. SCHEME 39.5 Structures of (a) naphthalene, (b) 1-ethylnaphthalene, (c) acenaphthene, and (d) 1-naphthyl-1-ethanol.

Values for the quenching rate constant for quenching by iodide anions were determined by analysis of the lifetime for the excited guest in the aggregate at different quencher concentrations using Equation 39.5. The quenching rate constants change with both the structure of the guest and of the host. These changes have been used to make inferences about the structure of the bile salt aggregates, as can be illustrated with the series naphthalene, 1-ethylnaphthalene, acenaphthene, and 1-naphthyl-1-ethanol (Scheme 39.5) in the presence of NaCh and NaDC bile salt aggregates (Table 39.1).⁶⁶ Naphthalene, 1-ethylnaphthalene, and acenaphthene all bind to the primary aggregate but significantly different quenching rate constants were obtained, suggesting that the primary aggregate structure is affected by the structure of the bound guest. The quenching rate constants for 1-naphthyl-1-ethanol, which resides in the secondary aggregate, were much greater than those for the other naphthalenes, showing that association of iodide anions to primary aggregates is much slower than association with secondary aggregates. Quenching rate constants were higher for the trihydroxyl bile salt (NaCh) than for the dihydroxyl bile salt (NaDC). This increased access of the iodide anions to the aggregates of the trihydroxyl bile salts indicates that they are more loosely packed than the dihydroxyl bile salts.

The extensive use of the model described in Equations 39.7 through 39.11 to study the binding dynamics of quenchers with micelles has been previously reviewed.^{8,59} This model is employed when quenching of the guest inside the micelle is competitive with exit of the quencher from the micelle, and rate constants are recovered from the four-parameter fit of the fluorescence decay in the presence of quencher. At high micelle concentrations, deviations from this model have been seen, as parameter *D* (Equation 39.11) shows a dependence on micelle concentration.^{68,69} However, comparison of rate constants obtained at low micelle concentrations should not be affected.

An illustrative example of this method is the quenching of pyrene (Scheme 39.2) in SDS micelles by alkyl iodides of different chain lengths.⁷⁰ The association rate constants recovered from the fit to Equation 39.7 were close to diffusion controlled for all chain lengths (Table 39.2). Chain length had a much greater effect on the dissociation rate constant, with a 20-fold decrease as the length of the chain was increased from ethyl to octyl (Table 39.2). The same trends are seen for most quencher/micelle systems: diffusion-controlled association rate constants are obtained whenever there is no electrostatic

TABLE 39.1 Quenching Rate Constants (k_q) for Quenching the Singlet Excited States of Guests by Iodide Anions in NaCh and NaDC (10 and 40 mM)

SCHEME 39.6 Structure of 2-naphthol.

interaction between the quencher and the micelle, and dissociation rate constants are determined by the hydrophobicity of the guest.^{8,60,70,71}

This model has also been applied to bile salt aggregates by studying the access of the quencher *N,N*-dimethylaniline to pyrene in sodium taurocholate aggregates in the presence of 1.0 M NaCl.⁷² An association rate constant of $1.4 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ and a dissociation rate constant of $3.8 \times 10^6 \text{ s}^{-1}$ were recovered for this quencher.⁷² These rate constants are of the same magnitude as those obtained for quenching of pyrene by *N,N*-dimethylaniline in SDS micelles, suggesting that access of this neutral quencher is similar in bile salt aggregate and conventional micelles.

In some specific cases, global compartmental analysis can be used to recover association and dissociation rate constants from quenching studies, even when the excited state is short-lived in comparison to the binding dynamics. Such an analysis, for the quenching of 2-naphthol (Scheme 39.6) bound to β -CD by iodide anions, was possible because the observed lifetimes changed with host concentration.⁷³ The recovered association and dissociation rate constants were, respectively, $2.5 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$ and 520 s^{-1} .⁷³ The k_- value obtained in this experiment is much smaller than has been observed for other guest molecules (see the following text).

39.3.4 Photophysics with Mobile Excited States

39.3.4.1 Excited States with Lifetime of Similar Magnitude to the Kinetics of Interest

Triplet excited states of organic molecules often have lifetimes of the same magnitude as the time scale for binding dynamics in host-guest systems. Triplet state kinetics are usually measured by following transient absorption in lfp experiments; the same conceptual framework can be applied to time-resolved fluorescence experiments, when long-lived singlet excited states occur.

Perturbation of the supramolecular system occurs when the excited state is formed. Excited states have different properties from their ground states, for example, different geometries or different dipole moments. These differences will lead to reequilibration of the host-guest system upon formation of the excited state. When the lifetime of the excited state is of the same order of magnitude as the dynamics of interest, that is, $k_o, k_o^{\text{H}} \sim k_+^*, k_-^*$, relocation of the excited state guest between the host and the bulk solution can occur. In this case, coupled kinetics are observed (Figure 39.8), and the observed rate constant, k_{obs} , will include the reequilibration of the excited state guest with the host and the decays of the excited state guest in the bulk solution and bound to the host.

FIGURE 39.8 Schematic representation for the binding dynamics of an excited state guest (gray circles) when reequilibration of the excited guest between the bulk solution and the host is competitive with the decay of the excited state to the ground state.

If a property of the guest, for example, absorption, is different when free in bulk solution and when bound to the guest, then changes in relative concentration can be measured, and relocation of the guest can be followed directly. The kinetic decay can be fit to a sum of two exponentials (Equation 39.12) using a mathematical treatment that is equivalent to that developed for the dynamics of excimer emission⁷⁴:

$$\Delta A = A_1 e^{-\gamma_1 t} + A_2 e^{-\gamma_2 t} \quad (39.12)$$

The two exponential factors, γ_1 and γ_2 , are related to the intrinsic decay rate constants for the excited guest in bulk solution and in the host, and the association and dissociation rate constants for the excited state guest with the host (Equations 39.13 through 39.16)^{74,75}:

$$\gamma_{1,2} = -\frac{1}{2} \left[(A + B) \pm \sqrt{(A - B)^2 + 4C} \right] \quad (39.13)$$

$$A = k_o + k_+^*[H] \quad (39.14)$$

$$B = k_o^H + k_-^* \quad (39.15)$$

$$C = k_- k_+^*[H] \quad (39.16)$$

The sum and product of the exponential factors γ_1 and γ_2 are related to the individual rate constants by Equations 39.17 and 39.18⁷⁵:

$$\gamma_1 + \gamma_2 = k_o + k_o^H + k_-^* + k_+^*[H] \quad (39.17)$$

$$\gamma_1 \gamma_2 = k_o (k_o^H + k_-^*) + k_o^H k_+^*[H] \quad (39.18)$$

39.3.4.2 Excited States with Lifetimes Longer Than the Kinetics of Interest

The formation of an excited state that has a lifetime that is much longer than the binding dynamics, that is, $k_o, k_o^H \ll k_+^*, k_-^*$, simplifies the aforementioned treatment. In this case, the perturbation can be viewed as permanent, and the kinetics are only related to the reequilibration of the excited state. Under these conditions, γ_2 is zero and Equation 39.17 is simplified to Equation 39.19, which is equivalent to a relaxation process:

$$\gamma_1 = k_{\text{obs}} = k_+^*[H] + k_-^* \quad (39.19)$$

SCHEME 39.7 Structure of xanthone.

39.3.4.3 Supramolecular Dynamics from Long-Lived Excited States

Direct measurement of supramolecular dynamics using a long-lived triplet excited state requires that an observable property of the excited state change when bound and when free in solution. To date, xanthone (Scheme 39.7) is the only molecule for which relocation of the excited state has been directly monitored.^{76,77} The xanthone triplet–triplet absorption spectrum shifts to shorter wavelengths on binding to CD because the spectrum is very sensitive to solvent polarity.^{78,79} Additionally, the basicity⁸⁰ and dipole moment^{76,79} of xanthone are higher for the triplet excited state, leading to significant relocation of this guest from the host following excitation. Kinetic measurements were made at various concentrations of β -CD. Since the triplet lifetime of xanthone is significantly longer than the binding dynamics, analysis of the kinetics could be carried out using the simplified Equation 39.19.^{77,81,82} The recovered association and dissociation rate constants for the triplet excited state of xanthone with β -CD were respectively $5 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ and $8.1 \times 10^6 \text{ s}^{-1}$.⁸²

39.3.4.4 Quenching Studies with Long-Lived Excited States

Quenching experiments can also be employed with long-lived excited states.^{7,8,83,84} A competitive deactivation pathway for the excited state is introduced when a quencher is added to the system (Figure 39.9). If the quenching rate constants for the excited state in bulk solution, k_q , and bound to the host, k_q^H , are different then information on binding dynamics can be elucidated even if the bound and free guest do not have different molar absorptivities. This greatly broadens the number of systems for which supramolecular dynamics can be studied.

Generally, quenchers that reside primarily in the bulk solution are employed so that the quenching efficiency of excited state guests in the aqueous phase is higher than that for guests bound to the host. If the concentration of free guest is small in comparison to the amount of bound guest, then the kinetics

FIGURE 39.9 Schematic representation for the binding dynamics of an excited state guest (gray circles) when reequilibration of the excited guest between the bulk solution and the host is competitive with the decay of the excited state to the ground state. The lifetime of the excited state is shortened with the addition of a quencher.

FIGURE 39.10 Linear quenching plot for the excited state guest in bulk solution and curved quenching plot for the excited state guest in the presence of host (Equation 39.20). At high quencher concentrations, the linear portion of the graph corresponds to the dissociation rate constant of the excited guest from the host (intercept of the dashed line) and the quenching rate constant for the guest bound in the host (slope). (Reprinted with permission from Li, R., Carpentier, E., Newell, E. D., Olague, L. M., Heafey, E., and Yihwa, C., *Langmuir*, 25, 13800–13808, 2009. Copyright 2009 American Chemical Society.)

are pseudo-first-order and follow a monoexponential decay, and the observed rate constant is given by Equation 39.20^{83,84}:

$$k_{\text{obs}} = k_o^{\text{H}} + k_* + k_q^{\text{H}}[\text{Q}] - \frac{k_*k_+^*[\text{H}]}{k_o + k_q[\text{Q}] + k_+^*[\text{H}]} \quad (39.20)$$

The dependence of k_{obs} on quencher concentration is nonlinear. Conceptually, this arises when $k_q \gg k_q^{\text{H}}$ because, at higher quencher concentrations, the rate-limiting step for quenching becomes exit of the guest from the host or its intrinsic decay within the host. Qualitatively, larger differences between the linear quenching plots obtained in bulk solution and the curved plots obtained in the presence of host indicate slower binding dynamics for the host-guest system (Figure 39.10).

39.3.4.5 Supramolecular Dynamics from Quenching Long-Lived Excited States

Generally, the singlet excited state lifetime is too short for relocation of the excited state between the bulk solution and the binding site in the host. However, in special cases where the lifetime of the singlet excited state is quite long, time-resolved fluorescence experiments can be used to recover kinetic information related to complex formation. The singlet excited state of 2,3-diazabicyclo[2.2.2]oct-2-ene (DBO, Scheme 39.8) has a very long lifetime in aqueous and deuterated aqueous solutions (420 and 730 ns, respectively) and can be used to measure binding dynamics to CDs.^{85,86} The lifetime of DBO is sensitive to the presence of abstractable hydrogens, as the DBO singlet excited state can be quenched by an “aborted” hydrogen abstraction.⁸⁵ When this guest binds to CDs, it is in close proximity to a number of abstractable hydrogens from the glucose units; the lifetime of the singlet excited state is greatly decreased, and exit of the excited state from the CD does not occur. The quenching rate constant of DBO by CD is therefore directly related to the association rate constant of singlet excited DBO with CDs, k_+^* . The k_+^* values were determined to be $1.9 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$, $4.0 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$, and $0.78 \times 10^8 \text{ M}^{-1} \text{ s}^{-1}$ for α -, β -, and γ -CD, respectively.⁸⁶ Qualitatively these values parallel the trends observed for the ground state equilibrium constant (50 M^{-1} , 1100 M^{-1} , and 6 M^{-1} for α -, β -, and γ -CD, respectively).⁸⁶

SCHEME 39.8 Structure of DBO.

SCHEME 39.9 Structure of 1-bromonaphthalene.

Triplet excited states are typically much longer lived than singlet excited states and quenching methodologies can be more generally applied in the determination of binding dynamics for these excited states. The triplet quenching methodology (Equation 39.20) was developed originally to study the binding dynamics of polycyclic aromatic guests with SDS micelles.⁸³ The dissociation rate constant for 1-bromonaphthalene (Scheme 39.9) determined by analysis of the quenching plot ($2.5 \times 10^4 \text{ s}^{-1}$) was similar to the dissociation rate constant calculated from the equilibrium constant, assuming a diffusion-controlled rate constant for the association reaction.⁸³ The dissociation rate constants for other aromatic guests calculated in the same way were found to decrease as the hydrophobicity of the guest was increased.

A similar trend was seen in the investigation of a series of ketone guests with SDS micelles.^{87,88} Quenching of these triplet excited state guests was carried out using γ -methylvalerophenone, which resides in the micelle, or nitrite anions, which reside in the aqueous solution. Binding dynamics were determined from quenching experiments; the association rate constants were diffusion controlled for all guests, while the dissociation rate constants varied and were faster for the more polar ketones.

The quenching methodology has been employed in the determination of binding dynamics of a number of guests with CDs.^{7,84} The binding dynamics of the triplet excited states of xanthone (Scheme 39.7), chromone, flavone, and 2-naphthyl-1-ethanol (Scheme 39.10) with β -CD have been studied using metal cation quenchers.^{89,90} Curved quenching plots were analyzed using Equation 39.20 to recover association and dissociation rate constants for the triplet excited states of these guests with β -CD (Table 39.3). Analysis of this data showed that binding mode and guest size have some effect on the binding dynamics.

SCHEME 39.10 Structures for (a) chromone, (b) flavone, and (c) 2-naphthyl-1-ethanol.

TABLE 39.3 Values for Association (k_+^*) and Dissociation (k_-^*) Rate Constants for the Triplet Excited State Determined from the Triplet Quenching of Xanthone, Chromone, Flavone, and 2-Naphthyl-1-Ethanol by Metal Ions in the Presence of β -CD

Guest	$k_+^*/10^9 \text{ M}^{-1} \text{ s}^{-1}$	$k_-^*/10^6 \text{ s}^{-1}$	K_{11}^T/M^{-1}	K_{11}/M^{-1}
Xanthone	1.1	12	90	1100
Chromone	3	21	140	240

2-Naphthyl-1-ethanol	0.29	0.18	1600	1800

Sources: Barros, T.C. et al., *J. Phys. Chem. A*, 102, 5639, 1998; Christoff, M. et al., *J. Photochem. Photobiol. A Chem.*, 134, 169, 2000.

The triplet-state equilibrium constants (K_{11}^T) were calculated from the values of k_+^* and k_-^* , and the ground-state equilibrium constants (K_{11}) were determined from fluorescence or absorption experiments.

For instance, 2-naphthyl-1-ethanol is deeply included in the CD cavity,⁹¹ and exhibits slower dynamics than xanthone, which is known to bind to the CD rim.⁹² The association rate constants for xanthone, chromone, and flavone are of the same magnitude, but the dissociation rate constant for flavone is an order of magnitude smaller. It was proposed that the pendant phenyl ring of flavone is incorporated into the CD cavity, slowing down dissociation of the flavone: CD complex. The equilibrium constants for the triplet excited state, calculated from the ratio of rate constants (Scheme 39.1), are lower than the equilibrium constants for the ground state in the case of the ketones, while similar equilibrium constants were obtained for both electronic states of the naphthalene (Table 39.3). This analysis shows that equilibrium constants can be different depending on the nature of the excited state and care should be taken for calculations where rate constants and equilibrium constants for different electronic states are combined.

The association and dissociation rate constants for the triplet excited state of xanthone with β -CD recovered from these quenching experiments are higher than those determined using the direct method (see earlier). Reasons for this overestimation of the rate constants are unknown, but comparisons of binding dynamics for different guests can be made as long as the quencher used is similar.

The quenching methodology has also been employed to study the binding dynamics of a number of triplet excited state guests with bile salt aggregates.^{65–67,93} Analysis of the obtained curved plots for nitrite quenching using Equation 39.20 allows recovery of k^* and k_q^H . Dissociation rate constants of $0.18 \times 10^6 \text{ s}^{-1}$ and $5.5 \times 10^6 \text{ s}^{-1}$ were obtained for the triplet excited states of 1-ethylnaphthalene and 1-naphthyl-1-ethanol (Scheme 39.5), respectively from NaCh aggregates.^{66,93} The quenching plots for 1-naphthyl-1-ethanol showed no curvature at bile salt concentrations where primary aggregates are present, but secondary aggregates have not yet formed. This observation, and the notably faster dissociation rate constant for this guest led to the proposal that 1-naphthyl-1-ethanol binds in the secondary aggregate, while 1-ethylnaphthalene is bound in the primary aggregate.

The different dynamics for the binding of triplet naphthalene (Scheme 39.5) with NaCh and NaDC are exemplified by the different quenching plots observed when nitrite anions were used as quenchers (Figure 39.11).⁶⁶ The larger deviation of the quenching plot for NaDC from the quenching plot in water showed that the binding dynamics were slower for this bile salt than for NaCh, which is consistent with the larger dissociation rate constant of $1.4 \times 10^6 \text{ s}^{-1}$ in the case of NaCh when compared to that of $7 \times 10^5 \text{ s}^{-1}$ for NaDC.⁶⁶ In addition, the slopes for the quenching plots at high nitrite concentrations were different because the access of nitrite anions to triplet naphthalene was easier in the NaCh aggregate

FIGURE 39.11 Quenching plots for triplet naphthalene quenching by nitrite anions in water (black triangles, only the points at low quencher concentration are shown for clarity; $k_q = 3.6 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$), in the presence of 10 mM NaCh (open circles) and in the presence of 10 mM NaDC (solid circles). The data in water were fit to Equation 39.5 and the data in the presence of both bile salts were fit to Equation 39.20. (Adapted with permission from Li, R., Carpentier, E., Newell, E. D., Olague, L. M., Heafey, E., and Yihwa, C., *Langmuir*, 25, 13800–13808, 2009. Copyright 2009 American Chemical Society.)

($k_q^H = 4 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$) than the access in the NaDC aggregate ($k_q^H = 1.4 \times 10^7 \text{ M}^{-1} \text{ s}^{-1}$).⁶⁶ These results are in agreement with the quenching studies of the singlet excited states where the quenching rate constant for iodide anions was smaller for the dihydroxyl bile salt NaDC compared to the trihydroxyl bile salt NaCh (see earlier).

39.4 Conclusions

Photophysics can be used in the determination of dynamics in supramolecular systems either as an analytical tool or as a source of perturbation in the system. This chapter outlined the fast kinetic techniques and the analysis methods necessary when applying photophysics to studies of supramolecular dynamics. Examples in CD, micelle, and bile salt aggregate systems were presented to highlight the potential applications of the various methods discussed.

Acknowledgments

CB would like to thank the Natural Sciences and Engineering Research Council of Canada (NSERC) for the continued support of her supramolecular dynamics research program in the form of discovery and equipment grants. TCSP would like to thank the University of Victoria and NSERC (CGS-D) for fellowships while in graduate school.

40.1 Introduction

Drugs and drug products are exposed to a number of environmental elements such as heat, moisture, oxygen, and light with combinations of these stresses causing complex behavior. The photostability of drugs has been reviewed over the years by a number of authors [1–5]. For this chapter, the literature has been explored to review the photostability of drugs and drug products, published since 2005.

The photodegradation of drug substances has previously been the major focus of drug photostability studies, with structural elucidation of photoproducts providing information to allow photodegradation pathways to be proposed. However, much of this research in the past has been conducted in solution (methanolic or aqueous), with more recent studies focusing on the photostability of solid-state drug substances.

In drug products, the presence of excipients further complicates the stability profile of drug substances within these products, as they may increase, have no effect on, or decrease the inherent stability of the drug substances. This has prompted an investigation into excipients, such as cyclodextrins, which have been included into drug products to improve the photostability of drug substances. Delivery systems such as liposomes, nanocapsules, and solid lipid nanoparticles have also been researched because of their ability to not only improve the delivery of the drug but also alter its stability. In some cases, these formulations or formulation excipients may result in the appearance of different photoproducts and photodegradation pathways, making this an important consideration from a regulatory perspective.

Since human exposure to sunlight is associated with skin damage, the application of sunscreens is important to protect against the development of skin cancer. These sunscreens in the past have presented with unique formulations of ultraviolet (UV) absorbers to protect against UV-B-induced skin damage. Recent developments have indicated that protection against UV-A has the ability to delay the aging process and reduce photodamage. New formulation challenges include that sunscreens should contain not only ingredients that are effective against UV-B and UV-A damage but also UV absorbers that have antioxidant properties.

Recent developments in repackaging of drugs from original manufacturers' packaging have stimulated discussion on in-use photostability of drug substances and drug products, which is not accounted for in the International Committee on Harmonisation (ICH) Photostability Testing Protocol. An example includes the repackaging of drugs into dose administration aids (DAAs), which is employed to improve compliance of patients worldwide. These new areas of photostability have shifted the focus from that of just photodegradation studies of drug substances more to that of drug products with the challenge to provide quality products that are stable, effective, and safe in-use for patients.

40.2 Photostability of Drug Substances

40.2.1 Introduction

Although drugs degrade on exposure to light, heat, moisture, and oxygen, it is a combination of these conditions, which may cause extremely complex behavior. Many studies have reported on the behavior of drugs in the presence of light, most commonly the photodegradation of drugs in aqueous solution, with photoreactions (Table 40.1) of drugs in the solid-state being even more complex.

Light-induced decomposition of drugs may result not only in a loss of potency and decreased therapeutic efficacy but also in the formation of toxic photodegradants, which have the potential to cause adverse effects in patients. It is thus important to determine the photostability of drugs in order to elucidate photodegradants and predict the potential for the occurrence of these adverse effects on patients. Photosafety [6] refers to a number of photobiological reactions caused by drugs in the presence of light: phototoxicity, photoallergy, photogenotoxicity, and photocarcinogenicity. Since the evaluation of photosafety is now a regulatory requirement for all drug substances, the focus on the absorption of light by drugs in the 290–700 nm region is a key factor, in addition to the presence of the drug in exposed tissue. However, the Q1B Photostability Protocol [7] focuses on overall photoinstability, packaging, labeling, and storage of photolabile drugs and not on photosafety. Measurement of a molar extinction coefficient (MEC) of known photosensitive compounds would then provide information to support thresholds, which could be utilized in risk assessments to evaluate the photosafety of drugs. Although this study puts forward a suggestion that drugs with MEC thresholds above $1000 \text{ L mol}^{-1} \text{ cm}^{-1}$ should be assessed for photosafety, a correlation between photolability and photosafety could not be established. Onoue and Tsuda [8] have reported on an effective screening method in order to predict the ability of a drug and/or its photodegradants to cause unwanted adverse effects on patients,

TABLE 40.1 Photoreactions of Drugs

Types of Photoreactions	
Cyclization	Photoreduction/photosubstitution
Rearrangement	Hydroxylation
Photooxidation	Decarbonylation
Isomerization	Dehalogenation
N-Dealkylation	Ring dealkylation
Polymerization	Dehydroxylation
Photohydrolysis	Decarboxylation

which may be broadly described as photosensitivity effects. Methodology involved UV spectral analyses and photostability studies of known photosensitive drugs and some weakly or nonphotosensitive drugs. Their ability to generate reactive oxygen species (ROS) and photooxidize linoleic acid was also monitored. The results of this study were a strong correlation between the ability to generate ROS and known photosensitivity, giving rise to a predictive model which could be used to recognize the potential for drugs to cause photosensitivity reactions. The concern that the ICH guidelines published in November of 1996 do not focus on photosafety has been confirmed by Baertschi et al., who make comment that although it has been a useful basic protocol, it fails to cover the photostability of drugs under conditions of patient use and should be revised [9].

40.2.2 Photodegradation of Nitrofurazone

Nitrofurazone's use as an antibacterial agent has declined over the years, and nowadays, it is mainly used topically as a local anti-infective. However, its use in topical preparations presents a problem due to its susceptibility to light and the potential loss of pharmacological activity as a result of exposure to light. Although the photodegradation of nitrofurazone has been previously studied [10,11], the mechanism of its photodegradation remains unclear. A study to describe the kinetic model of nitrofurazone photodegradation by hybrid hard-soft multivariate resolution (HS-MCR) was undertaken by De Luca et al. [12]. The authors applied the HS-MCR method to UV spectrophotometric data in order to interpret the complete kinetic pathway. The photodegradation of nitrofurazone is seen to occur through rapid isomerization to the *syn*-form (Figure 40.1) and subsequent further degradation to a series of unstable colored compounds, which in addition to arising from the parent drug can also result from the azine and hydrazone derivatives, themselves not detected in the final photoproducts. Despite the rapid photodegradation of nitrofurazone making characterization of photodegradants very difficult, the use of this modeling technique has allowed a photodegradation pathway to be proposed.

40.2.3 Photodegradation of Metoclopramide

A recent study [13] investigating the photodegradation of metoclopramide (Figure 40.2) has been undertaken to elucidate its photoproducts, not only because of potential adverse effects to patients but also because of importance of gaining insight into the fate of pharmaceuticals in the environment. Photolytic degradation using a photoreactor equipped with a 254 nm UV lamp showed that metoclopramide is highly susceptible to photodegradation, which followed first-order kinetics in solution. The major degradation pathway involved cleavage of the chlorine with subsequent hydroxylation and formation of high-molecular-weight products, which proved to be dimers and trimers of metoclopramide. Examples of drugs in the literature, which lose their chlorine substituent on exposure to light are many [14,15] and as mentioned, this occurs through homolysis resulting in the formation of dimers and heterolysis with the formation of hydroxylated products. However, in these previous studies, the photosubstituted and photoreduced products were reported to be the major degradation products with very little mention made of high-molecular-weight photoproducts.

FIGURE 40.1 Photodegradation of nitrofurazone.

FIGURE 40.2 Chemical structure of metoclopramide.

40.2.4 Photodegradation of Pitavastatin

The reason for investigating the photostability of drug molecules is twofold: first to determine the effect of light on the stability of the drug substance and product in order to inform storage, packaging, and labeling, and second to determine possible biological effects, which may result in photosensitivity reactions in patients. Many of the statins used extensively in the treatment of elevated cholesterol levels have proved to be highly photochemically reactive [16–18]. Pitavastatin, a synthetic 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase inhibitor, used in the reduction of serum cholesterol in patients was studied to determine its photochemical transformation in solution to identify its main photoproducts. Pitavastatin [19] was found to degrade by first-order kinetics with the main photodegradation pathway (Figure 40.3) involving cleavage of the side chain at the double bond with subsequent photocyclization resulting in the formation of a tetracyclic photoproduct. The formation of these photoproducts is of significance due to the ability of such products to interact with biological molecules.

40.2.5 Photodegradation of Seratrodist

Although the photodegradation of seratrodist, a quinone derivative known to inhibit bronchoconstriction, has been previously reported by Ohta et al. [20], there was a lack of detail especially in respect of the photodegradation pathway as the study essentially focused on the high-performance liquid chromatography method (HPLC) of analysis. In a recent study [21], the authors have elucidated the major photoproducts and proposed a possible photodegradation pathway. Although seratrodist was found to be stable in the solid-state, photodegradation in solution occurred by first-order kinetics resulting in three main photoproducts 1, 2, and 3 (Figure 40.4). The formation of these three photoproducts is proposed to occur via a zwitterion–diradical, a spirocyclopropyl intermediate, and a zwitterion.

40.2.6 Photodegradation of Primaquine

The antimalarial drug, primaquine, an 8-aminoquinoline, is photolabile and decomposes to several photoproducts at physiological pH in the presence of oxygen [22–25]. Recent research [26] looked to gain further insight into the mechanism of photodecomposition of primaquine by characterizing primary excited states, which may be transient.

FIGURE 40.3 Photodegradation of pitavastatin.

FIGURE 40.4 Photodegradation of seratrodist.

FIGURE 40.5 Photodegradation of primaquine.

The photochemical decomposition of primaquine is reported to occur by $^1\text{O}_2$ formed through a sensitized reaction with a synthetic impurity present in the bulk drug. Formation of primaquine $^{2+}$ (Figure 40.5) is likely to occur *in vivo* in the presence of free radicals, and because of its relatively long lifetime, susceptibility to oxidative reactions is enhanced.

40.2.7 Photodegradation of Flurbiprofen

Flurbiprofen (Figure 40.6) belongs to the aryl propionic acid derivatives and is widely used as an analgesic, antipyretic, and anti-inflammatory agent. Because of the presence of the biphenyl moiety within the drug structure causing it to be highly lipophilic, the photoproducts formed in the skin after exposure to light have the potential to cause photoallergic contact dermatitis.

Because flurbiprofen [27] exists mainly in the deprotonated form at physiological pH, decarboxylation, which is likely to occur from the triplet excited state, will be the dominant initial degradation pathway (Figure 40.6). The interaction of the photoproduct with a biological membrane will result in abstraction of hydrogen from a lipid molecule with subsequent addition of molecular oxygen to a lipid radical causing radical damage to be propagated. With the occurrence of a number of photoreactions subsequent to decarboxylation, such as generating singlet oxygen and superoxide radicals, it is the formation of peroxyl radicals that explains the contact dermatitis, which occurs in patients taking flurbiprofen.

FIGURE 40.6 Photodegradation of flurbiprofen.

40.2.8 Photodegradation of Amlodipine

The photostability of the 1,4-dihydropyridines especially nifedipine [28] has been studied because of their ability to absorb UV-A light with photoreactions occurring with ease due to the presence of an hydrogen, which interacts with the nitro group. The photoreactivity of amlodipine [29] was studied due to the absence of the nitro group and the presence of a chloro group in this position in addition to an aliphatic amino group in the side chain. Irradiation of amlodipine resulted in the formation of the aromatized pyridine photoproduct (Figure 40.7) as the major degradant. In the case of amlodipine, the H-transfer has been facilitated by the presence of the amino group in the side chain, which was similarly observed in nicardipine [30] that also possesses this group in the side chain.

40.2.9 Photodegradation of Memoquin

The drug memoquin, a 1,4-benzoquinone (Figure 40.8) derivative, has been rationally designed for the treatment of Alzheimer's disease and neurodegeneration [31]. Quinones are known to be sensitive to light, and since memoquin has been designed to affect certain mechanisms relevant to Alzheimer's

FIGURE 40.7 Photodegradation of amlodipine.

FIGURE 40.8 Chemical structure of memoquin.

disease such as the formation of ROS, it is important that exposure to light does not reduce its potency. It is however thought that the presence of two long, symmetric polyamine side chains may increase the stability and offer protection against light-induced decomposition.

Results show that memquin degrades by first-order kinetics and that the photodegradation reactions involve the benzylamino groups in the side chains and not the antioxidant center (1,4-benzoquinone), which is important for its activity. This therefore illustrates the successful design of a light stable drug for the treatment of Alzheimer's disease.

40.2.10 Photodegradation of Montelukast

Montelukast, a light-sensitive drug, has been shown to be effective in the treatment of chronic asthma [32]. Montelukast in solution (methanol) is reported to degrade rapidly in daylight and UV light. About 30% of the drug was converted to the *cis*-isomer after only 15 min of exposure, increasing to 77% after 4 h. However, storage of the solution in amber flasks resulted in a reduction of the *cis*-isomer from 77% to 10% after 4 h. Since montelukast absorbs light at wavelengths over 400 nm, it was found to be more stable when exposed to sodium or neon lights (wavelength < 500 nm). Although most drugs in the solid-state are usually relatively stable to light, this was not the case for montelukast, which showed a 20% reduction in drug content after being exposed to daylight for 1 week, with the formation of the *cis*-isomer and the S-oxide as the major photoproducts (Figure 40.9). When tablets were exposed to daylight for 2 weeks, degradation to about 90% of the drug content occurred. This was however not observed with the film-coated tablets, indicating that the film coating was in fact providing some protection against its light degradation. Since the major photoproduct in solution is the *cis*-isomer as opposed to the S-oxide in the solid-state, it may be suggested that the solvents used are favoring photoisomerization rather than photooxidation. The predominance of the S-oxide as a thermal degradation product as well suggests that antioxidants may be used to stabilize montelukast against oxidation to facilitate better handling and storage.

FIGURE 40.9 Photodegradation of montelukast.

FIGURE 40.10 Chemical structure of guaiazulene.

40.2.11 Photodegradation of Guaiazulene

Guaiazulene (Figure 40.10), an alkyl derivative of azulene, is a natural product which is gaining popularity for inclusion into cosmetic products [33]. The rationale for its inclusion is its ability to act as a skin conditioning product. Guaiazulene has been found to be photochemically reactive [34], being able to inhibit lipid peroxidation and scavenge free radicals. A more recent report [35] has also implicated guaiazulene in photomutagenicity in *Salmonella typhimurium* bacteria strains.

The photochemical stability of guaiazulene was assessed in an emollient cream exposed to simulated natural light. Results indicated that after 3 h exposure only 21% of guaiazulene remained, indicating the inability of the cream base to protect guaiazulene against photodegradation.

40.2.12 Photodegradation of Aloe Vera

Since exposure to UV-A light can cause the generation of ROS, the fact that aloe vera extract [36], containing anthraquinones also capable of generating ROS, is incorporated in many commercial products is cause for concern. This is especially the case since many of these products are applied as cosmetics to large areas of skin exposed to sunlight. Aloe vera-derived anthraquinones have shown photooxidative damage to both cellular RNA and DNA attributed to the generation of ROS and the formation of stable photoproducts.

40.2.13 Conclusions

The photostability of drug substances in recent years has focused on detecting the ability of photoproducts to cause adverse reactions in patients and on issues of photosafety, rather than drug content. New initiatives have involved the rational design of drugs such as memoquin, where the inclusion of polyamine side chains has offered protection against light and thus preserved potency.

40.3 Photostability of Drug Products

40.3.1 Introduction

The stability of a drug product is important to ensure safety and efficacy for patients because instability due to exposure to light may result not only in a loss of the potency of the active ingredient but also the potential presence of toxic photodegradants. During the preformulation stage, the selection of the solid form (polymorph) of the active pharmaceutical ingredient (API) is undertaken, so that transformation of polymorphs or pseudopolymorphs does not occur under storage conditions relating to temperature, light, and humidity. In addition to the choice of a polymorphic form of the drug for optimum photostability, cyclodextrins as formulation excipients have played a role in the photostabilization of drugs. The other excipient currently of interest is titanium dioxide because of its photocatalytic ability and routine inclusion in pharmaceuticals as a coating agent and in sunscreens as a physical blocker.

FIGURE 40.11 Chemical structure of tamoxifen citrate.

40.3.2 Polymorphism

Polymorphism has the ability to affect the physical and chemical stability of drug substances and thus drug products due to differences in the molecular arrangement. The photostability of drugs in the solid-state depends on surface area, irradiation conditions such as spectral irradiation energy and the type of the light source, and most importantly the photochemical properties of the sample drug, which may be different for different polymorphs. Although the relationship between crystal forms and photostability has been reported on [37–42], the exact nature of this relationship has not been fully elucidated. The solid-state photochemistry of tamoxifen citrate (Figure 40.11), an antiestrogenic agent for the treatment of breast cancer, has been investigated with a view to providing some insight into a potential relationship between the photostability and spectroscopic properties of the polymorphs A and B.

Polymorph A appeared to be photosensitive (Table 40.2), whereas B was quite resistant to photodegradation [43].

A ΔE value of 54.5 and 33.6 for A and B respectively on irradiation, indicated that form A discolored more than form B, with results also showing that penetration of light was greater for A than for B. Diffuse-reflectance solid-state UV data showed that form B absorbed mainly in the UV-B and UV-C regions, while A absorbed mainly in the UV-A region resulting in A absorbing more photoenergy than B and thus exhibiting greater photodegradation. This result is attributed to differences in the molecular arrangement of the crystal lattice of A and B and the resulting different energy states. Based on these photostability results, form B would be the polymorph of choice in drug product development.

40.3.3 Cyclodextrins

Cyclodextrins in drug formulations have been indicated not only to improve the physicochemical properties of drug substances but also to improve their pharmacological, pharmacokinetic, and/or adverse effect profiles. The most characteristic property of cyclodextrins is their ability to form inclusion complexes with a variety of guest molecules resulting in increased solubility and dissolution rates of poorly water-soluble drugs. Cyclodextrin inclusion complexation may influence drug stability in three ways: Depending on the inclusion mode of the drug in the cyclodextrin cavity, degradation may either be retarded, accelerated, or unchanged with the stereochemistry and/or stoichiometry of the guest–host interaction influencing the stabilizing/destabilizing effects of complexation. The photochemistry and photophysics within the cyclodextrin cavity involves features quite distinct from that of uncomplexed substances, since the interior of the cavity constitutes an isolated environment where

TABLE 40.2 Polymorphs A and B Remaining (%) on Photoirradiation (30,000 Lux)

Tamoxifen Citrate	0 Days	10 Days	20 Days	30 Days
A	100	94	92	87
B	100	99	99	100

included species are usually present as single molecules. The photochemistry is therefore generally restricted to intramolecular events except in cases of double or multiple occupancy. The effects of cyclodextrin inclusion complexation on drug photostability are in many ways similar to its impact on general drug stability in that it may increase, decrease, or have no effect on the rate of photodegradation [44]. Curcumin, a naturally occurring compound indicated in the treatment of a number of diseases including cancer, HIV infections, and cystic fibrosis is susceptible to photochemical degradation. In addition, curcumin has been used as a pharmaceutical excipient to stabilize photolabile drugs in solution and in topical preparations. Because of the susceptibility of curcumin to both alkaline hydrolysis and light degradation, inclusion complexation with cyclodextrins was investigated to stabilize curcumin toward these conditions. Although the hydrolytic stability of curcumin under alkaline conditions was improved, the photodecomposition was increased compared to a curcumin solution in organic solvents [45]. Recently, Tomren et al. have extended their study to the interaction of other curcuminoids with hydroxypropyl-beta-cyclodextrin, 2-O-methyl-beta-cyclodextrin, and hydroxypropyl-gamma-cyclodextrin, with the larger size of the hydroxypropyl-gamma-cyclodextrin cavity allowing a study on the effect of the cavity size. Results were again similar to those previously achieved, with decreased photostability observed [46].

Nicardipine (Figure 40.12), a calcium channel blocking agent like other 1,4-dihydropyridines, is poorly water soluble and susceptible to photochemical decomposition. The effect of cyclodextrins (including the natural cyclodextrins, alpha, beta, and gamma and the chemically modified hydroxypropyl, hydroxyethyl, and methyl-cyclodextrin) and complexation on photochemical decomposition has been investigated using capillary electrophoresis. This is due to the ability of this technique to be used to evaluate cyclodextrin-induced enantioselective effects in the photodegradation process.

Although a photoprotective effect was observed for some cyclodextrins, some did not affect the photostability, and in the case of gamma-cyclodextrin, photodegradation was increased. Cyclodextrin-mediated stereoselective photodegradation was seen only for the beta-cyclodextrin complex with different photodegradation profiles and kinetic constants observed for the two enantiomers [47].

Although sunscreens are effective in providing protection against solar radiation, they need to be applied prior to exposure to sun. Secondary photoprotective agents, such as the anti-inflammatory drug ibuprofen (Figure 40.13), have the ability to reduce the effects of solar radiation after sun exposure. Cyclodextrins such as hydroxypropyl-beta-cyclodextrin have the ability to alter not only the drug penetration into the skin but also its ability for secondary photoprotection. In this case, the cyclodextrin increased ibuprofen's aqueous solubility and flux across and accumulation in the skin to a maximum

FIGURE 40.12 Chemical structure of nicardipine.

FIGURE 40.13 Chemical structure of ibuprofen.

FIGURE 40.14 Chemical structure of 13-*cis*-retinoic acid.

at a 10% concentration of the cyclodextrin. This correlated with the greatest photoprotection being afforded by the ibuprofen–cyclodextrin formulation, which delivered the greatest amount of ibuprofen to the skin [48].

13-*cis*-Retinoic acid (isotretinoin) commonly used in the treatment of acne is very poorly water soluble and is highly photosensitive making it an excellent candidate for inclusion complexation with cyclodextrins. In a study by Yap et al. [49], the effect of selected cyclodextrins on the photostability of isotretinoin (Figure 40.14) was investigated. Hydroxypropyl-beta-cyclodextrin proved to be effective in retarding the photodegradation of isotretinoin in solution. This effect can be explained by the mode of inclusion of the isotretinoin molecule into the cavity of the cyclodextrin. The molecular modeling studies indicated that the alkyl chain which is susceptible to isomerization on exposure to light was included into the cavity, thus explaining the improved photostability.

Altered photodegradation pathways and different photodegradants in the presence of cyclodextrins were also observed in a study undertaken by Lebetet et al. [50].

The effect of randomly methylated beta-cyclodextrin (RAMEB) as an excipient on the rate of photodegradation of midazolam and the nature of the photoproducts was determined. Results indicated that the kinetics of degradation could not be fitted to a specific order with the initial stages acceleratory, suggesting autocatalysis by the degradants. The rate constants determined by the application of the power law were found to be 0.137 and 0.154 h⁻¹ in the absence and the presence of RAMEB, respectively. The photodegradation pathway (Figure 40.15) is altered in the presence of the cyclodextrin by the formation of a dimer (photoproduct 2) and an intermediate (photoproduct 1) not isolated in the absence of RAMEB due to its ability to provide conformational control and to stabilize free radicals.

These findings present an important consideration for pharmaceutical scientists to be aware of the presence of unexplained photodegradants if cyclodextrin and possibly other excipients are included in formulations.

40.3.4 Titanium Dioxide

The photostability of drugs may be altered in various formulations, whether they are suspensions, creams, tablets, or gels. This altered photostability, which may be increased or decreased, is often attributed to the effect of excipients within the formulation. It is therefore not surprising that interest has been focused on the effect of excipients on the photostability of drugs.

Titanium dioxide is a naturally occurring oxide of titanium, which is widely used as a filler and coating with range of applications from paint to sunscreens. Due to its high refractive index, it is often used as a physical blocker in sunscreens; however, the particles are often required to be coated with silica or alumina because of its ability to create radicals, which are carcinogenic in a photocatalytic reaction. The crystal structure determines its photocatalytic ability with the anatase form particularly photocatalytic to UV light [51]. Recently, there has been much said about the use of nanomaterials especially ultrafine titanium dioxide in cosmetics and sunscreens due to their transparent appearance and aesthetic appeal. The ultrafine titanium dioxide occurs in three different crystalline forms namely, rutile, anatase, and brookite, with the rutile and anatase forms being used commercially. Although these fine particles have the advantage in enhancing the photostability of sunscreens and preventing the discoloration of the pigment, there is some concern about their ability to form free radicals and thus cause oxidative

FIGURE 40.15 Photodegradation of midazolam in the presence of RAMEB.

damage to DNA. It is thought that the enhanced penetration of these ultrafine particles is responsible due to photocatalysis, DNA damage, and skin cancer following exposure to sunlight. This has however been refuted as it is doubtful whether penetration occurs beyond the stratum corneum. Theogaraj et al. investigated the photo-clastogenic potential of titanium dioxide using the Chinese hamster ovary and proved a lack of photochemical genotoxicity in this model [52].

Titanium dioxide has been used in pharmaceutical products as a coating material, with a required purity as specified by the United States Pharmacopoeia of 99.0%. Because of its known photocatalytic activity, it is important to evaluate its effect on the photodecomposition of drug substances to ensure the quality of the resulting drug products.

Researchers have focused on the solid-state reactions between titanium dioxide and selected drug substances. In a study on the H_2 blocker, famotidine (Figure 40.16) with titanium dioxide, discoloration was observed on exposure to light, and the photocatalytic activity of titanium dioxide was affected by the relative humidity (RH) of the environment. Therefore, it is important to take into account the exposure of pharmaceuticals to moisture in terms of storage and repackaging as this can affect the quality of pharmaceuticals delivered to patients [53].

FIGURE 40.16 Chemical structure of famotidine.

FIGURE 40.17 Chemical structure of mequitazine and its photodegradants.

It is therefore important during preformulation to determine whether there is any relationship between titanium dioxide and the photodecomposition of drug substances. Mequitazine [54], an H_1 receptor antagonist, presented as a good candidate due to its discoloration on exposure to light as it is possible that the presence of titanium dioxide might photocatalyze the degradation of the mequitazine. Results confirmed that the presence of titanium dioxide especially in the anatase form caused significant photodegradation of the drug. Although photodegradation occurred using a near-UV lamp as a light source, it is significant that degradation of the mequitazine also occurred on exposure to the D65 source, which is routinely used in photostability testing of pharmaceuticals. Similar to the results achieved with the famotidine, the degradation was accelerated with increasing RH.

The photodegradation resulted in the formation of three photodegradants: mequitazine-N-oxide, mequitazine-S-oxide, and mequitazine-sulfone (Figure 40.17). Photooxidation of mequitazine resulted in the N-oxide while the other two products were proven to be a result the photocatalytic effects of the titanium dioxide.

These findings present an important consideration for pharmaceutical scientists to be aware of the presence of unexplained photodegradants if titanium dioxide is included as an excipient or in the coating of tablets.

The photocatalytic activity of titanium dioxide on the photodegradation of the commonly used calcium channel blocker drug, nisoldipine [55], has also been examined. Results indicated that the differing photodegradation observed in the presence of titanium dioxide was attributed to its photocatalytic activity and that this activity is not only dependant on the crystal form of the titanium dioxide.

Although exposure of nisoldipine (Figure 40.18) to light results in two photodegradants: the nitropyridine and nitrosopyridine derivatives, the nitrosopyridine derivative arises from direct photooxidation on exposure to artificial daylight or white fluorescent light, while the nitropyridine derivative occurs even on exposure to light sources of low irradiation energy. This photodegradant results due to the photocatalytic effect of the titanium dioxide.

40.3.5 Photostability of Formulations

There are many reasons why drug substances are formulated in a dosage form. In general, this is to provide a mechanism for the safe, convenient delivery of accurate dosages to patients. Specifically, drug

FIGURE 40.18 Chemical structure of nisoldipine and its photodegradants.

substances are formulated in dosage forms to provide protection from destructive influences such as atmospheric oxygen, moisture, heat, and light.

In recent years, a number of delivery systems have been developed not only to enhance the photostability of drug substances, but also to optimize their therapeutic efficacy. Examples of these include the inclusion of UV filters, nanoparticles, nanocapsules, solid lipid nanoparticles, liposomes, and lipid microparticles.

Although UV filters are most commonly associated with sunscreens, there are many other formulations which contain UV filters for the purpose of improving hydration of the skin and promoting antiaging. It is therefore important to evaluate the effect of these UV filters on the photostability of other active ingredients in these formulations. The role of antioxidants such as vitamins A, C, and E in topical formulations is to act as photoprotectants and maintain a healthy skin barrier. Topical application has the advantage in that these antioxidants are targeted at the site of action. Gaspar and Maia Campos conducted a study evaluating the effect of UV filters (unstable—combination octyl methoxycinnamate, avobenzene, 4-methylbenzilidene camphor; *stable*—combination octyl methoxycinnamate, benzophenone, octocrylene) on the photostability of a formulation containing vitamins A, C, and E [56]. Although the UV filters did not influence the hydration and antiaging effects of the formulations, they played a role on the reduction of skin irritation attributed to both the protective effect of these lipid soluble molecules in the stratum corneum but also due to reduction in the conversion of vitamin A to isotretinoin, a skin irritant. In terms of the photostability study, only the stability of the vitamin A was improved by the UV filters especially the photostable UV filters.

Formulation of drug substances which are sensitive to UV radiation in topical dosage forms may in turn improve the photostability of the drug substance. Hydrocortisone acetate which is used both topically and systemically is susceptible to photodegradation. Exposure of hydrocortisone acetate to UV-B radiation resulted in the formation of a number of photoproducts. However, the photolysis of hydrocortisone acetate in a commercial topical cream resulted in 20% degradation with the formation of only one photoproduct, the 4-androstene-11 β -ol-3,17 dione (Figure 40.19).

Hydrocortisone acetate [57] was more stable to light in the cream formulation than in solution, and this was attributed to the light-scattering properties of the cream base and/or the protecting effect of the excipients in the cream. Since any modification in corticosteroids especially in the side chain results in loss of anti-inflammatory activity, the photolability of the hydrocortisone acetate even in the cream base confirms the requirement for light protection of this drug.

Curcuminoids [58] are the yellow bioactive compounds of turmeric. Together with their lipophilicity and low bioavailability, there are also issues associated with the stability of the curcuminoids, namely,

FIGURE 40.19 Chemical structure of hydrocortisone acetate and its photodegradant.

their alkaline degradation and instability to light. There have already been many studies to address the formulation and stability problems of the curcuminoids [45,58–62]. Mulik et al. [58] have loaded poly(butyl) cyanocrylate nanoparticles coated with poloxamer in order to improve the release profile and the photostability of these curcuminoids. The stability study revealed, that although the curcuminoids showed a good stability profile by remaining within the nanoparticles at 40°C/75% RH, in the absence of light the concentration range was between 87% and 93%, while in the presence of sunlight this was reduced to 79%–89%. However, when the stability of the curcuminoids in the nanoparticles was compared to curcuminoids solubilized in a surfactant solution, there was a 30% improvement in stability, both in the presence and in the absence of light. This highlights the role of the poly(butyl) cyanocrylate nanoparticles not only in improving the delivery of this lipophilic drug but also providing a much improved stability profile for the curcuminoids.

Both tretinoin and isotretinoin are degraded when exposed to light, with the UV-A in solar-simulated light largely responsible [63]. Since UV-A penetrates the skin, the adverse effects associated with this therapy such as photosensitivity reactions can therefore be attributed to this UV-A light. Therefore, any improvements in formulations as well as the use of UV-A sunscreens which eliminate this adverse effect will make a positive contribution to therapy. Since both tretinoin and isotretinoin are biologically active, their disappearance on exposure to light was monitored. Both of these two drugs underwent photoisomerization and photolysis on exposure to solar simulated light with greater degradation in a cream formulation than in ethanol occurring. The effect is thought to be due to the multiple components present in the cream, and a strategy for improvement would need problematic ingredients to be identified, removed, and replaced. This concurs with findings by another group of researchers [64]. While these studies suggest that the use of UV-A sunscreens might have a positive effect in reducing the adverse effects associated with this therapy. Brisaert and Plaizier-Vercammen [64] reported that although tretinoin had the highest efficacy when formulated as a lotion, photodegradation was rapid until an equilibrium called a photo stationary state, involving 80% isomerization, was achieved. Although the principal isomerization product isotretinoin is therapeutically active, 40% of the tretinoin is isomerized to inactive products. Selection of the various components of the cream involved the emulsifying agent; but very importantly the oil and a number of candidates, including castor oil, olive oil, maize oil, Miglyol 812, and isopropyl myristate, were chosen for their dissolving and penetration-enhancing properties. Results indicated that tretinoin was most soluble in castor oil and less soluble in isopropyl myristate, Miglyol 812, maize oil, and olive oil. There appears to be some relationship between this solubility and the photostability of tretinoin, which proved to be the highest in the castor oil. When tested in the cream formulation, the results achieved contradicted those in the oils with the olive oil and castor oil creams proving to be the most stable. These anomalous results achieved for the olive oil were explained by the presence of tretinoin crystals in the cream on microscopic examination and the obvious difference in degradation kinetics between the solid-state and the dissolved molecule. The conclusion drawn from this study is that castor oil is the chosen oil for the formulation of the cream both in terms of the solubility and the photostability of tretinoin. Other authors [65–67] concurred that incorporation of

tretinoin into vesicles, liposome, and liposome complexes results in slower photodegradation compared to tretinoin dissolved in methanol.

Kumar et al. [68] investigated the incorporation of tretinoin into solid lipid nanoparticles in a gel with a view not only of improving its delivery but also its photostability. Solid lipid nanoparticles are suggested as a delivery option in preference, for example, to liposomes due to enhanced physical stability and reduced costs compared to the phospholipids. The photostability of tretinoin in a methanolic solution resulted in initial rapid degradation, which then slowed but continued to only 12% remaining after 180 min. The photodegradation of tretinoin in this case was accompanied by a shift in the maximum peak from 344 to 360 nm. Inclusion of the tretinoin into the nanoparticles in comparison dramatically reduced the photodegradation with 71% remaining after the same time of exposure, without the shift in the maximum peak. Since it might be more appropriate to compare the photodegradation in the solid lipid nanoparticles to that of tretinoin in a cream, it was observed that a study conducted by Nighland et al. [69] reported 81% degradation in a commercial product after light exposure for 120 min. This confirms that tretinoin incorporated into solid lipid nanoparticles provides a good alternative to those existing tretinoin formulations not only in terms of patient acceptability but also photostability.

Polymeric nanocapsules, [70] in which drugs can be dissolved or dispersed, used as drug carriers are characterized by a lipophilic core surrounded by a polymeric layer. Two types of tretinoin-loaded nanocapsules (capric/caprylic triglyceride mixture/sunflower seed oil) have been prepared to improve both the delivery and photostability of tretinoin. Although the photodegradation profile of tretinoin in methanol (half-life 40 min) followed first-order kinetics, for the tretinoin-loaded nanocapsules (half-life 85–100 min) zero-order kinetics were observed. Although the photostability of tretinoin was improved in a nanoemulsion (half-life 69–82 min), it is obvious that the polymer in the nanocapsules is important in improving the photodegradation profile of tretinoin. This result is attributed to the crystallinity of the polymer reflecting and scattering UV light. These results achieved are independent of the type of oil used and present another option for the delivery of tretinoin.

Pantoprazole [71] is a proton pump inhibitor (Figure 40.20) used extensively for various gastric conditions. This drug is however unstable in solution, and therefore, it is important to compare its stability to light in solution and on microencapsulation using or a blend of poly(ϵ -caprolactone) or hydroxypropyl methylcellulose (HPMC). Photodegradation in a methanolic solution resulted in reduction in the concentration to only 1.7% after 120 min, with a resulting yellow coloration. Although solid-state photostability of pantoprazole was improved, the results were not significant with 27% drug remaining after 10 days. However, microencapsulation using Eudragit® S 100 showed increasing photostability for pantoprazole with 56% of the drug remaining after the same irradiation period, with no significant improvement resulting from the use of the polymer blends.

Lipid microparticles, using tristearin as lipid and phosphatidylcholine as emulsifier, have also been investigated to improve the stability of the photoprotective agent and antioxidant, quercetin (Figure 40.21) [72]. The study is important by virtue of the potential application of quercetin in the protection of the skin against oxidative damage. A comparative study was conducted on a cream containing nonencapsulated and encapsulated quercetin, which was irradiated for 2 h using a solar simulator maintained at 500 W m^{-2} . Results indicated that 23% of the unencapsulated quercetin was degraded, compared to 11.9% for the encapsulated quercetin, a 48.5% improvement.

FIGURE 40.20 Chemical structure of pantoprazole.

FIGURE 40.21 Chemical structure of quercetin.

FIGURE 40.22 Chemical structures of ciprofloxacin, ofloxacin, and lomefloxacin.

Fluoroquinolone antibiotics (Figure 40.22) extensively used have the adverse side effect of an acute phototoxic reaction induced by light. These compounds are capable of undergoing a number of photochemical reactions, including generation of singlet oxygen and superoxide, in addition to those fluorinated quinolones undergoing defluorination on exposure to UV-A radiation. Liposomes have been used in order to increase the bioavailability of the fluoroquinolones but it was also thought important to investigate the ability of these liposomes to reduce the phototoxicity of these molecules. Although results indicated that lomefloxacin was the most photolabile drug, the most important findings were that the lipids did not increase the rate of degradation but altered the photodegradation pathway and the resulting photoproducts. In the α -L-dipalmitoylphosphatidylcholine liposomes, double defluorination occurred differently from the degradation in aqueous solution. Thus, the presence and the type of the lipids had an effect on the photodegradation process [73].

40.3.6 Photostability of Sunscreens

Sunscreens are designed to protect the skin from UV radiation. In the design of these drug products, molecules which both absorb and reflect light are included. However, there have been some developments to include substances in these products, which prevent, reduce, or repair sun-induced skin damage [74].

A sunscreen should be designed to fulfill the following criteria [75]:

- Provide protection against both UV-B and UV-A radiation. Initially, broad spectrum protection was achieved by chemical absorbers in the UV-B range, and for the UV-A, protection was achieved by using physical blockers such as titanium dioxide and zinc oxide. However, in recent years, the trend has been to include UV-A chemical absorbers into sunscreens. This increasing complexity has provided a challenge for the formulation scientist as well the regulatory authorities such as the Therapeutics Goods Administration (TGA) in Australia and the American Food and Drug Administration (FDA).
- Be stable to heat and light and be user friendly, cost-effective and allow for both ease of formulation and reapplication.

Recently, the role of free radical scavengers in delaying the aging process and reducing the damage caused by excessive exposure to sun has been investigated. It is suggested that new formulations contain both UV-B and UV-A absorbers, which also display antioxidant properties. This prompted Venditti et al. [76] to design a new derivative of one of the most commonly used sunscreens, ethylhexyl methoxycinnamate, attaching a nitroxide moiety to impart antioxidant activity (Figure 40.23).

This new compound possesses the cinnamate group, which has UV-B absorbing properties and the ethylhexyl group, which confers solubility in oil and resistance to water, which is an important feature of all sunscreens. Replacement of the methoxy group by the pyrrolidine nitroxide is strategic in conferring the antioxidant activity in the design of sunscreens. Photostability of sunscreens is important not only to retain their activity but also because of the potential for their photodegradants to cause genotoxic reactions and photo aging.

While most UV-B absorbers are photostable to the UV-B wavelengths, there was some concern about their stability when exposed to the UV-A range. The fact that these compounds would then lose their photoprotective effect posed a safety hazard to their use. This study concluded that this designed sunscreen showed that it was photostable to UV-A radiation. Most important was its ability to scavenge free radicals with comparable antioxidant activity to that of vitamin E and butylated hydroxytoluene. The safety profile was good with proven noncytotoxicity to the human skin.

The sun protection factor (SPF) is widely accepted to measure sunscreen efficacy and has been defined as the sun radiation dose to produce a minimal erythral dose after the application of 2 mg/cm² of sunscreen, for example, an SPF of 2 absorbs 50% of UV radiation [77]. However, in August 2007, this SPF was altered to stand for sunburn protection factor [78]. To account for the importance of sunscreens to protect against ROS in skin, a new SPF, the radical protection factor (RPF) has also been suggested.

FIGURE 40.23 Chemical structures of ethylhexyl methoxycinnamate and the nitroxide derivative.

Inorganic sunscreens such as titanium dioxide and zinc oxide reflect and scatter UV and visible radiation, and they have the advantage in that they do not react with organic sunscreens. However, because of the fact that they are opaque and occlusive has caused some resistance to their use. This problem has been overcome in recent years by reduction in the particle size of these agents leading to a more aesthetically pleasing product. Concerns about the safety of these compounds due to their potential penetration deeper than the stratum corneum have been proven to be unfounded [77].

These findings were confirmed by Newman et al. [79] who investigated the use of nanosized particles of titanium dioxide and zinc oxide in sunscreens. Although it was discovered that there was no significant penetration beyond the stratum corneum, there is however concern that this might not be the case on the sunburned skin and under extreme UV conditions. In addition, it will be important to measure the penetration of ROS formed on the stratum corneum as a result of exposure of these nanosized particles to UV light on the surface of the skin. The photocatalytic effect of titanium dioxide involves an electron-hole pair photogeneration and a subsequent energy transfer process, which results in the generation of ROS. There is therefore a possibility that titanium dioxide included into commercial sunscreens may be photoactive. This is therefore the rationale for the inclusion of additional antioxidants, for example, vitamin E, ascorbic acid, or beta-carotene in these products [80]. Photoreactivity of titanium dioxide in three different products was compared to the whole product and phenalenone, which is an efficient singlet oxygen photosensitizer. There is an important question to be answered. Is titanium dioxide in commercial sunscreens responsible for singlet oxygen generation? The outcome has significant implications for the safety and efficacy of these commercial products. In order to assess the photocatalytic activity, the photodegradation of 4-chlorophenol and azur B (Figure 40.24) was monitored, and in addition, the photocatalytic oxidation of α -terpinene was determined. The photocatalytic oxidation in this case resulted in the formation of the endoperoxide ascaridol (Figure 40.25).

Although the photodegradation of the 4-chlorophenol and azur showed low efficiency in the generation of ROS, there appeared to be other reactions taking place, which can result in the production of singlet oxygen. A significant finding was that even when the rutile form, which is much less reactive than the anatase form, of titanium dioxide was used, photoactivity resulted, especially in the presence of zinc oxide. Thus, even though singlet oxygen scavengers are included in commercially products, it is recommended that the photoactivity of the titanium dioxide be evaluated.

FIGURE 40.24 Chemical structures of 4-chlorophenol and azur B.

FIGURE 40.25 Chemical structures of α -terpinene and ascaridol.

FIGURE 40.26 Chemical structure of butyl methoxy dibenzoylmethane, showing the diketo and enol forms.

FIGURE 40.27 Butyl methoxy dibenzoylmethane–titanium dioxide complex.

Egerton et al. [81] evaluated the interaction between the organic UV absorber, butyl methoxy dibenzoylmethane (Figure 40.26), and nanoparticles of coated titanium dioxide.

The yellowing caused by the addition of butyl methoxy dibenzoylmethane to titanium dioxide was reduced by silica coatings deposited on the titanium dioxide, with the more uniform the coating the greater the reduction in the coloring. Infrared (IR) studies showed the enol form to predominate in solution and that the yellowing is caused by a complex which is formed (Figure 40.27).

Since the actual particle size of these inorganic agents is critical, it is important to be able to monitor the particle size and to ensure that this size remains the same in the formulations [82]. Both titanium dioxide raw material and finished products were evaluated for particle size and particle size distribution using scanning electron microscopy. Results indicated that the titanium dioxide particles maintain their size and size distribution in the sunscreen products, suggesting that the formulation process did not affect particle size.

Although the photostability of commercially sunscreens can be determined by conventional methods using a solar simulator followed by HPLC analysis, Scalia et al. [83] are proposing a comparative evaluation of polymethylmethacrylate plates and Transpore™ tape. On application of the sunscreen to the plates and the tape, factors such as SPF and UV-A protection factor were measured by transmission spectroscopy before and after irradiation. When compared with HPLC analysis of the ethylhexyl methoxycinnamate, the photo-unstable UV-B filter, the results from the polymethylmethacrylate plates compared favorably, whereas this was not the case for the Transpore™ plates.

40.4 Drugs and Drug Products: Repackaging

40.4.1 Introduction

The stability of a pharmaceutical product may be defined as the capability of a particular formulation, in a specific container to maintain its physical, chemical microbiological, therapeutic, and toxicological specifications [84]. The stability of manufactured dosage forms is routinely confirmed by the manufacturer as per regulatory requirements [85], where stability studies on packaged dosage forms are conducted by means of real-time, long-term tests and accelerated stability tests at specific temperatures and RHs representing storage conditions experienced in the various climatic zone(s). Manufacturers' packaging does not guarantee the stability of the drug substance and the drug product on removal, manipulation, and repackaging. Recently, Baertschi et al. [9] have critically assessed the

ICH Guideline on Photostability Testing, commenting on its usefulness as a protocol for testing new drug substances and products. However, now that the Pharmaceutical Industry has had considerable experience in photostability testing, the question is posed about the photostability of drugs under in-use conditions. Although the stability of a dosage form is often seen to be the responsibility of the manufacturer, this does not include removal from the original packaging. In electing to repack a drug product, healthcare professionals must consider the implications on drug stability of the transfer to a nonmanufacturer pack.

Because of their known light instability, frusemide and prochlorperazine tablets have been investigated [47].

40.4.2 Frusemide

Frusemide (Figure 40.28) used in the treatment of cardiac events and hypertension is commonly repacked into DAAs. Because of the susceptibility of frusemide to photodegradation, Bowen et al. [86] evaluated both the chemical and physical stability of frusemide tablets repackaged into a DAA.

Frusemide tablets were repackaged into DAAs and evaluated for physicochemical stability over an 8 week period at a controlled room temperature ($25^{\circ}\text{C} \pm 2^{\circ}\text{C}$) and other relevant in-use conditions. In addition, photostability studies were performed according to the ICH guidelines.

Chemical stability was confirmed for all storage conditions, including for those light ICH conditions. However, storage in a simulated pharmacy environment and exposure to ICH light conditions resulted in a yellow coloration of the tablets, with this discoloration being unacceptable.

40.4.3 Prochlorperazine

Prochlorperazine tablets [87] were stored repackaged in DAAs and in their original packaging for 8 weeks at ambient ($25^{\circ}\text{C} \pm 1^{\circ}\text{C}$; $60\% \pm 1.5\% \text{ RH}$), accelerated ($40^{\circ}\text{C} \pm 1^{\circ}\text{C}$; $75\% \pm 1.5\% \text{ RH}$), and *in-use* conditions encountered *in situ* both in a pharmacy and the patients' home. These tablets in the DAA were assessed for chemical stability, and photostability testing was undertaken under ICH conditions. Although their chemical and physical stability was confirmed, there were, however, noticeable organoleptic changes occurring in the tablets stored under *in-use* conditions with a progressive gray discoloration over the 8 week period. Because of the discoloration of the prochlorperazine (Figure 40.29) tablets, this needs to be taken into account in their repackaging and storage into DAAs.

FIGURE 40.28 Chemical structure of frusemide.

FIGURE 40.29 Chemical structure of prochlorperazine.

40.5 Conclusions

The photostability of drug substances continues to be an important consideration, not only because of the drug content of dosage forms but also because the photodegradation of these substances may result in the formation of photoproducts, which cause adverse effects in patients. Although photostability testing focuses on the overall photoinstability, packaging, labeling, and storage of photolabile drugs, the challenge is to address the cause of the photoinstability in drug products and the role of excipients in this process. Photosafety especially related to the effect of toxic photoproducts on patients, including those that may arise from commercially available sunscreens also needs to be addressed. Recently, the issue associated with the in-use photostability of drugs and drug products has been reported on by Baertschi et al. [9] as an important challenge for the future.

The photodegradation of a number of drug substances has been described: nitrofurazone, metoclopramide, pitavastatin, seratrovast, primaquine, flurbiprofen, amlodipine, memquin, montelukast, guaiazulene, and aloe vera, illustrating a diversity of photoreactions occurring on exposure to light. The effect of drug structure on photostability has been highlighted with the photodegradation of amlodipine occurring similarly to nifedipine because of the presence of an amino group in the side chain of both of these drugs.

The photostability of drugs in drug products has been complicated by not only the polymorphic forms of drug substances, but also the inclusion of excipients. Cyclodextrins, for example, have the ability to increase or decrease the rate of photodegradation in the addition to altering the photodegradation pathway. The appearance of photoproducts not isolated in the absence of the cyclodextrin provides a challenge to the pharmaceutical scientist in terms of analytical method development and validation and photostability studies. Drug formulations and delivery systems also play a role in improving the delivery of drug substances and their photostability. The inclusion of UV filters and the delivery of drug substances in nanoparticles, nanocapsules, solid lipid nanoparticles, liposomes, and lipid particles have to a large extent improved the photostability of drug substances, such as curcuminoids, tretinoin, and isotretinoin, pantoprazole, and selected fluoroquinolone antibiotics.

Sunscreens are required to provide protection against both UV-B and UV-A radiation and in addition often include antioxidants and physical blockers, such as titanium dioxide. Because of the complexity of these broad spectrum products and the known photocatalytic activity of titanium dioxide, it is important that photostability tests be conducted to ensure that these products are both safe and effective. Some recent formulations have involved the inclusion of nanoparticles of coated titanium dioxide in order to reduce the potential for interaction with the UV absorber, butyl methoxy dibenzoylmethane. Understanding the potential interaction has provided the information required to reduce its occurrence, highlighting the need for further research into sunscreen products.

Baertschi et al. [9] have reported on the need to revisit the ICH Photostability Guidelines with the view to including in-use testing. This has been confirmed by the research group of Glass and Haywood [86,87] in their investigations on the photostability of repackaged drugs. Since repackaging of drugs is on the increase worldwide, this suggests the need for further studies in the future into the in-use photostability of drugs and drug products.

41.1 Introduction

When a thermally equilibrated chromophore is promoted to an excited electronic state by light absorption, nuclear motion is triggered. The evolution of the original molecular and electronic structures determines the fate of the absorbed light energy that can either be released (via internal conversion/luminescence) or exploited to drive a change in the original chromophore structure (i.e., a photochemical reaction). Throughout these processes, the initially populated Franck–Condon (FC) active modes couple to other available normal modes, this coupling rendered even more effective by the anharmonicity of molecular vibrations.^{1,2} Computational chemists view such events in terms of the evolution of the chromophore's nuclear coordinates on different 3N-6 dimensional potential energy surfaces, where N is the number of atoms. These are rigorously defined on the basis of the Born–Oppenheimer (BO) approximation,^{3,4} which states that the relatively large mass of a nucleus, as compared to that of an electron, permits the separation of electronic and nuclear motions. A consequence of the BO approximation is that for any molecular system, there exists a different potential energy surface for each electronic state. Since in these processes, the initial excited state electronic structure ultimately evolves into a ground state electronic structure, the computational description of light-energy wastage and exploitation at the molecular level requires the mapping of different potential energy surfaces. Most importantly, one has to attain an understanding of *how and where potential energy surfaces connect*.

To describe the connection between potential energy surfaces, one has to be able to locate the points (i.e., the molecular and electronic structures) where the decay probability from an upper (excited state) surface to a lower (e.g., ground state) surface is largest. These points are termed “photochemical funnels,”⁵ and their existence is required to explain the events occurring after the deactivation of an excited state. A funnel is a critical structure where species evolving on an excited state potential energy surface will hop to a lower surface (associated either with a different excited state or with the ground state) on a time scale shorter than the typical radiative decay times (ns). Such decay either initiates the formation of a transient/photoproduct or the relaxation to the original reactant. When considering organic reaction mechanisms, funnels provide a structurally (e.g., describing the reaction stereochemistry) and electronically (e.g., describing the homolytic or heterolytic nature of bond-breaking events) well defined *connection* between different electronic states of the reacting species.

More than 40 years ago, the aforementioned concepts were introduced in seminal papers by Van der Lugt and Oosterhoff⁶ and later by Grimbert.⁷ In their work, a minimum located on a spectroscopically forbidden singlet potential energy surface (see [Figure 41.1a](#)) was proposed to provide the funnel mediating the photochemical conversion of butadiene into cyclobutane. The minimum was found to be associated with an avoided crossing with the ground state. Therefore, the authors' conclusions seemed to be consistent with the idea that potential energy curves of electronic states of the same symmetry (such as the 1A and 2A electronic states of a butadiene with Cs symmetry) should obey the noncrossing rule.⁸ However, at the time of the Van der Lugt and Oosterhoff calculation, the only quantity that could be computed was the potential energy of the relevant electronic states. No first or second derivatives of the potential energy surface (with respect to the nuclear coordinates) could be calculated. Since these quantities are instrumental for the numerical methods used to follow downhill paths along a potential energy surface and, therefore, to locate local minima (a process known as geometry optimization), the authors had to assume that the funnel was located along a linear path connecting reactant to product and consistent with the photochemically allowed (disrotatory) electrocyclic ring closure of the diene.

An excited state decay time corresponding to the avoided crossing energy gap (ca. 30 kcal mol⁻¹) estimated by Van der Lugt and Oosterhoff is on the order of nanoseconds, comparable to typical fluorescence lifetimes.⁹ However, the weak or absent fluorescence observed in many chromophores¹⁰ and, most importantly, the discovery of ultrafast photochemical reactions^{11,12} indicate that the energy gap between excited and ground states is smaller than a few kilocalories per mole. Early versions of the theory of radiationless transitions were dominated by the application of Fermi's golden rule^{13–15} and seemed to

FIGURE 41.1 The Van der Lugt and Oosterhoff (i.e., avoided crossing) vs. the CI model. (a) Schematic representation of the Van der Lugt and Oosterhoff avoided crossing mechanism resulting from the calculations of Ref. [6]. (b) The Van der Lugt and Oosterhoff path appears as a 1D cross section of more complex potential energy surfaces, which has the shape of a double cone and a CI as the excited state minimum. The broken line represents the reaction path starting from the Franck-Condon point (FC) and going to the products via the CI. The computed and fully asymmetric structure of the CI [20] mediating the electrocyclic ring closure of butadiene is also shown.

provide a good description for the weak coupling cases where the time scales for internal conversion and fluorescence are comparable. However, such theoretical framework cannot explain ultrafast events.

The search for photochemical funnels that could explain the apparent selectivity of photochemical reactions led Zimmerman,¹⁶ Michl,¹⁷ and Salem¹⁸ to independently suggest that the formation of photochemical products can be explained by the presence of *conical intersections* (CIs). Unlike an avoided crossing, a CI structure or point corresponds to an actual crossing of the potential energy surfaces associated with two electronic states of the same spin multiplicity. The concept had already been outlined by Teller¹⁹ who proposed that (1) the noncrossing rule, which is valid for diatomic systems, fails in polyatomic molecules where two states, even when they have the same symmetry, are allowed to cross and (2) this crossing is conical rather than linear. Teller also suggested that radiationless decay in the vicinity of intersection spaces takes place within a single vibrational period.

Nowadays, we know that the photochemical conversion of butadiene to cyclobutene is mediated by a CI (see Figure 41.1b).^{20,21} We also know that the CI is fully asymmetric and that the two intersecting states therefore belong to the same space and spin symmetry. These results have been produced after much progress in the development of *ab initio* multiconfigurational quantum chemistry methods. These methods currently allow for the computation of both potential energies and their first and second derivatives at a level of accuracy that makes them comparable with the observed spectroscopic data. Notice that this class of quantum chemical methods has been widely applied in photochemical studies. As we will explain later, this is due to the flexibility and unbiased nature of the associated wavefunctions. Techniques such as time-dependent density functional theory (TD-DFT)²² have been used in photochemical studies²³ and successfully applied to the investigation of a number of spectroscopic problems in systems as large as porphyrins^{24,25} and phthalocyanins.²⁶ However, the present TD-DFT functionals are accurate only for excited states dominated by single excitations, failing to correctly describe regions near CI.²⁷ Until these problems are solved by the development of new functionals, this method has very limited applications in the study of photochemical processes. Therefore, all the studies revisited in the present chapter will focus on the *ab initio* quantum chemical methods mentioned earlier with a special

emphasis on the complete active space self-consistent field (CASSCF) and complete active space second order perturbation theory (e.g., CASPT2) methodologies.

The relationship between the avoided crossing found by Van der Lugt and Oosterhoff and the computed butadiene/cyclobutene CI is schematically illustrated in Figure 41.1b. Constraining the reaction path to follow a linear coordinate is equivalent to slicing the potential energy surfaces along a specific one-dimensional cross section where the CI degeneracy appears to be lifted and is replaced by an avoided crossing. When this constraint is released, and the potential energy is minimized along all possible $3N-6$ molecular modes, it is found that the local minimum corresponds to a real crossing (i.e., a CI). However, in the following, we will see that not all CIs mediating photochemical processes are readily accessible or correspond to local minima on the excited state potential energy surface.

While the existence of CIs was predicted by Teller,²⁸ Longuet-Higgins,²⁹ and Herzberg,³⁰ their importance for the control of photochemical reactivity was proposed later. In the 1970s, Salem^{18,31} introduced state correlation diagrams that illustrate the occurrence of CIs at symmetric geometries along the photochemical reaction path of carbonyl compounds. Salem's work on photochemical reactions of carbonyl compounds was developed from Zimmerman's early qualitative notions.¹⁶ Exchange of ideas between Salem, Turro, and Dauben³² led to the development of a comprehensive classification of photochemical reactions soon after.³³ Using numerical computations and *ab initio* procedures, the geometries of a few CIs were subsequently computed for Schiff base cis–trans isomerization processes by Bonačić-Koutecký and Michl.³⁴ A model of biradicaloid electronic structures was also introduced to permit a qualitative prediction of the geometries at which S_1/S_0 CIs take place.^{35,36} Although the presence of CIs seemed to account for ultrafast radiationless decay in at least a few polyatomic molecules, CIs were regarded as being “extremely rare” and/or “too high in energy” to be of practical value. However, as outlined earlier, advances in *ab initio* multireference quantum chemical methods and the implementation of analytical gradients of the CASSCF method allowed for a systematic mapping of the excited state potential energy surfaces of several organic chromophores. The results revealed that CIs are abundant and, similar to transition structures, their electronic and structural features explain the outcome of a variety of photochemical transformations.⁵

The ability to map excited state potential energy surfaces was influential in shaping the field of computational photochemistry.³⁷ Potential energy surfaces can only be computed numerically. This means that their mapping (e.g., the search for energy minima, transition structures, CIs, and the calculations of reaction paths and trajectories) relies on the independent or sequential calculation of a finite number of points of the potential energy surface and of their first derivatives (the gradient) and second derivatives (the hessian) with respect to the nuclear coordinates. Thus, the emergence of computational photochemistry cannot be solely attributed to the increase in availability of computing power. The coding of efficient and more accurate methods for computing the potential energy, the gradient, and the hessian of electronically excited states as well as the development of suitable geometry optimization methods³⁸ have rendered the computational investigations of excited state species practical. Nowadays, this technology is available in a variety of software packages including Gaussian,³⁹ Molcas,^{40,41} Gamess US,^{42,43} Columbus,⁴⁴ Molpro,⁴⁵ and Q-Chem,⁴⁶ among others.

41.2 Computational Photochemistry

As mentioned earlier one of the basic ideas behind the development of tools for *mapping* and *connecting* excited and ground state potential energy surfaces is that certain excited state critical structures prompt a surface hop. Since a hop involves the breaking of the BO approximation, this event is also referred to as a nonadiabatic transition. Potential energy surface crossings such as CIs (between states with the same spin multiplicity) and singlet–triplet crossings (an example of crossings between states of different spin multiplicity) represent “natural” loci for nonadiabatic transitions.

If a quantum mechanical (QM) method can be used to (a) evaluate excited state energies and (b) calculate excited state gradients with respect to nuclear coordinates, then it can be used to map the surface and locate crossing regions (the hessian is presently too expensive to be employed in systematic mapping and

is only used to get information—such as vibrational frequencies—for important points along the energy surfaces). However, such a method needs to be able to describe the change in the weights of the electronic configurations that describe the ground and excited state bonding character, as well as the bond-breaking and/or bond-forming processes. The wavefunction must thus be flexible enough to provide a balanced treatment of the different possible electronic configurations. The *ab initio* multiconfigurational self-consistent field (MCSCF) method and, more specifically, its variant the *ab initio* CASSCF method originally developed by Wahl and coworkers,⁴⁷ but implemented in a practical form by M. A. Robb⁴⁸ and B. O. Roos⁴⁹ independently, serve well in this regard. The CASSCF⁵⁰ method is one of the most commonly used multiconfigurational wavefunction methods in computational photochemistry. At the CASSCF level, static electron correlation is taken into account, allowing for the treatment of situations involving partially broken bonds and the development of diradical character. However, in order to reproduce the spectroscopic parameters (e.g., absorption and fluorescence maximum), the remaining electron correlation effects need to be treated. This can be achieved, for instance, using the CASPT2⁵¹ method already mentioned. The CASPT2//CASSCF protocol, where one carries out the potential energy surface mapping at the CASSCF level and then corrects the energies of chemically meaningful points (e.g., energy minima and CIs) by running single-point CASPT2 calculations, has been extensively used in the past and has been shown to reproduce experimental observations within a few kilocalories per mole.^{5,52}

The first application of the *ab initio* CASSCF method to a photochemical problem in organic reactivity was reported in the early 1990s.^{53,54} The aim was to investigate photoinduced $[2\pi + 2\pi]$ cycloaddition: a simple model for a variety of observed cycloaddition reactions with well-defined stereochemistry (Figure 41.2). It was demonstrated that excited state species are funneled to the product through a CI. The molecular structure of the characterized CI correlates well with the observed photoproduct

FIGURE 41.2 The first CI located for an organic $[2\pi + 2\pi]$ photochemical cycloaddition reaction. (a) The cycloaddition reaction between *trans*-stilbene and tetramethylethylene (two substituted ethylenes). The structure of the photochemical funnel must be consistent with the observed *supra-supra* stereospecificity (demonstrated by the formation of a *trans* cyclobutane) of the reaction. (b) The computed molecular structure for the CI mediating the *supra-supra* cycloaddition of two ethylene molecules. This structure provides a connection between the 2A_1 and 1A_1 (i.e., ground state) potential energy surfaces, consistently with a hindered rotation along the two C–C bonds leading to the observed *supra-supra* stereochemistry. The University of London CRAY-XMP machine where the original calculation was carried out (Ref. [53]) is also shown.

stereochemistry and also with the fact that it is possible to produce tetramethylene intermediates. At that time, the calculation (a scan of the first excited state along two different coordinates) required an unconventional computational effort that was carried out by M. A. Robb's group at King's College London, UK, using the CRAY X-MP operating at the University of London Computer Center.⁵⁵ This work provided strong support for the existence of Salem, Zimmerman, and Michl's photochemical funnels. Over the past few decades, different groups, including ours, employed the CASPT2//CASSCF approach to document the existence of low-lying CIs in different classes of organic chromophores and biological photoreceptors.^{43,56,57} On the other hand, the rise of the field of femtochemistry at the experimental front^{11,12} revealed that ultrafast radiationless deactivation channels are commonly encountered, and nowadays considered as a manifestation of decay through CIs.⁵

Radiationless deactivation at a CI implies that (a) ultrafast internal conversion processes may be up to 100% efficient (a Landau–Zener decay of unity),⁵⁸ (b) delayed internal conversion or slower reaction rates are indications of the presence of an excited state energy barrier that separates excited state species in the FC region from the CI region, and (c) in photochemical (as opposed to photophysical) transformations, the structure of the intersection point correlates with the structure of the photoproduct. As documented in recent photochemistry textbooks,^{9,10} CIs in singlet reactions and singlet–triplet crossings in triplet reactions are as abundant as transition states (in thermal processes). Regrettably, the structural and electronic complexity of these features still hinders a prompt understanding of their fundamental role in the control of photochemical processes at the molecular level. More basic theoretical work is needed.

41.2.1 Photochemical Reaction Paths and the Branching Plane

A photochemical reaction path⁵⁹ is a minimum energy path (MEP) connecting the FC point on the potential energy surface of the light-absorbing state to one or more photoproduct minima on the ground state surface via one or more surface crossings. A basic photochemical reaction path (Figure 41.3a) involves an excited state MEP⁶⁰ connecting the FC point to two ground state MEPs through a CI, one

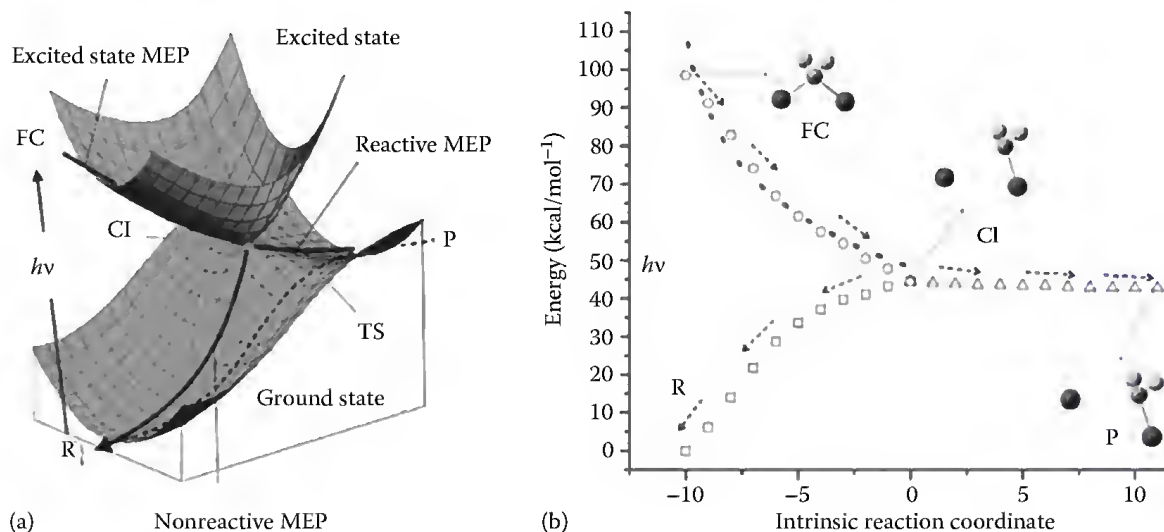

FIGURE 41.3 The photochemical reaction path. (a) Schematic representation of the photochemical reaction path (full lines) for an ultrafast photochemical reaction (i.e., with a barrierless excited state MEP). The dashed line represents a thermal path controlled by the transition state TS. (b) The computed photochemical reaction path (three different MEPs—open circles, open triangles, and open squares—computed in terms of IRCs) for the photofragmentation of CF₂I₂. The FC, the CI, the I...CF₂I van der Waals complex (P), and the reactant (R) are connected by MEPs computed at the CAS(8,6)/3-21G** level of theory. The dotted line (showing an IRC computed at the superior CAS(12,8)/Sadlej-pvtz level) shows that the use of an approximate basis set and of a reduced active space does not affect the conclusions.

MEP describing the relaxation of the system back to the initial reactant (an aborted photochemical reaction) and another MEP describing the relaxation of the system to the photoproduct in a successful photochemical reaction. Notice that aborted photochemical reaction paths describe a form of far-from-equilibrium internal conversion, distinct from the traditional process controlled by FC factors in the weak coupling regime. A computed reaction path for the photolysis (involving the breaking of a C–I bond) of a simple halogenated compound⁶¹ is given in Figure 41.3b.

While the regions of the excited state potential energy surface located far from intersections can be investigated using the same geometry optimization and MEP computation methods used for investigating (thermal) ground state reactions, the characterization of the CI region and of the associated relaxation path(s) require not only the location of the *photochemically relevant* CI point but also the calculation of the branching plane defined by the X_1 and X_2 vectors.^{5,62,63} These vectors correspond to the only two molecular modes capable of splitting the energy degeneracy at the intersection (Section 2.2). They have chemical significance because they provide information on the bond-breaking/bond-forming processes mediated by the CI. X_1 corresponds to the difference of the gradients of the upper and lower state potential energies and is called “gradient difference” or “g vector.” X_2 corresponds to the projection of the gradient of the upper state wavefunction on the lower state wavefunction and is called “derivative coupling” or “h vector.”⁶³

The decay from the CI can be understood by plotting the upper and lower state potential energies along the branching plane (i.e., along the plane defined by the suitably normalized X_1 and X_2 vectors), which yields a double cone shape (Figure 41.4). The results of the CF_2I_2 computation already seen in Figure 41.3b⁶¹ are used to illustrate how the analysis of the branching plane can be used to locate the valleys (the exit channels A and B in Figure 41.4) collecting the reacting molecule immediately after the decay.

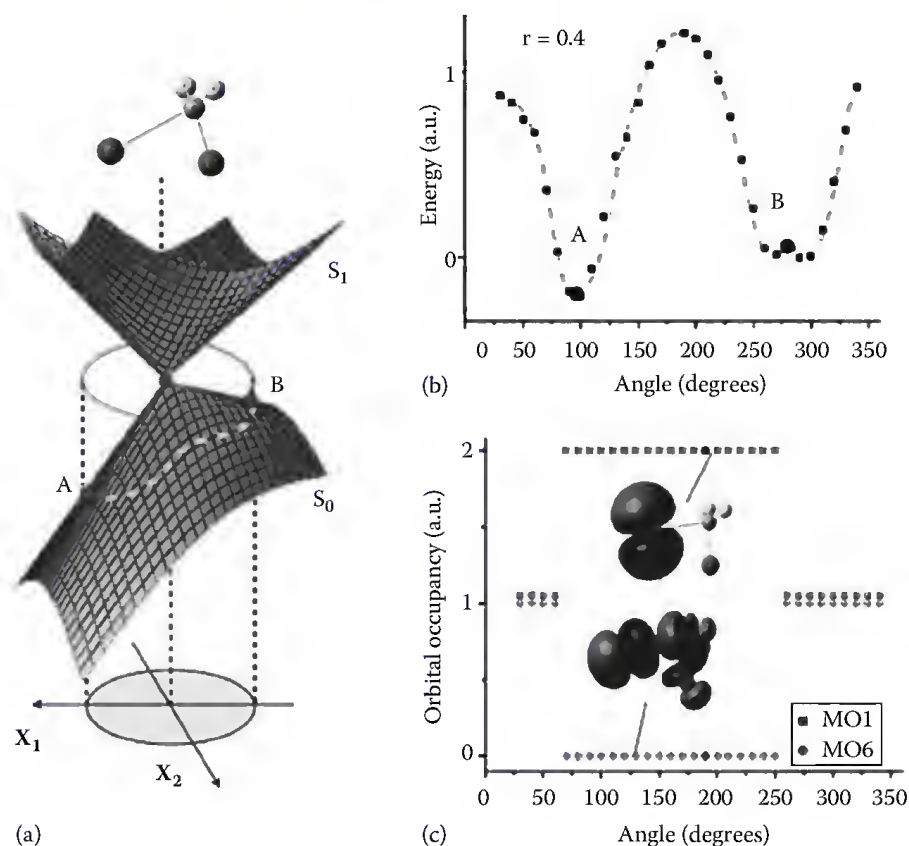

FIGURE 41.4 The branching plane. (a) Shape of an “elliptical” peaked CI. The structure on top refers to the CI driving the photofragmentation of CF_2I_2 (see also Figure 41.3b). (b) Ground state energy profile for a $r = 0.4 \text{ \AA}$ loop centered at the CI. The exit channels A and B correspond to the energy minima along the profile. (c) The change in the wavefunction along the same loop described in terms of change in orbital occupancy.

FIGURE 41.5 A branching diagram describing the chemical meaning of the derivative coupling and gradient difference vectors for the CI driving the photofragmentation of CF_2I_2 . These vectors can be used to predict or rationalize the possible outcome of the photochemical reaction driven by the associated CI. This outcome can be described in terms of both geometrical deformation and change in electronic structure and must be consistent with the results shown in [Figure 41.4a and c](#).

As mentioned earlier, these valleys are ultimately computed in terms of ground state MEPs describing the ground state relaxation from a CI. A scan along a circular cross section centered at the CI and spanning the associated branching plane reveals two exit channels. The scan can be achieved, for example, using the Moplot graphical interface program⁶⁴ that reads the gradient difference and derivative coupling vectors computed with the program package Gaussian.³⁹ Single point calculations are then performed to determine the S_0 energy profile along the circular scan ([Figure 41.4](#)). In this particular case, two channels (channels A and B) were found at a radial distance of about 180° . At the CI, the MEP calculations yielding the reactive and nonreactive paths of [Figure 41.3](#) are started along the direction connecting the CI to the cross-section energy minima. The actual \mathbf{X}_1 and \mathbf{X}_2 vectors for the CF_2I_2 case are pictorially shown in the branching plane diagram of [Figure 41.5](#) in terms of both structural and electronic displacements.⁶¹

The changes in electronic wavefunction along the circular cross section can also be monitored. These reveal very rapid changes in electronic structure along the loop (for the theory associated with these changes and general properties of CIs, see Ref. 62). As shown in [Figure 41.4](#), the changes are described by looking at the occupancy of the molecular orbital describing the reactive and excitation processes (an alternative approach is to plot the change in the weight of the electronic configurations along the loop). In this example, at an angle of 100° (corresponding to channel R), the electronic configuration is such that molecular orbital MO1 is doubly occupied and molecular orbital MO6 is empty. This reflects the ground state electronic configuration of the reactant R, and confirms that this channel leads to the reformation of the reactant. On the other hand, both orbitals are singly occupied at an angle of about 280° (corresponding to channel B) reflecting the electronic configuration of the excited state that is maintained along the ground state channel leading to the product. The change in occupancy along the loop of [Figure 41.4](#) is consistent with the change in Lewis structures described in the branching diagram of [Figure 41.5](#).

41.2.2 Minimum Energy Conical Intersections and the Intersection Space

Any CI structure is an element of a $3N-8$ dimensional subspace (the intersection space) of the configuration space, which is formed by an infinite collection of CIs.^{37,63} The intersection space is locally orthogonal to the branching plane. If the value of one branching plane vector (e.g., \mathbf{X}_1) at any CI point

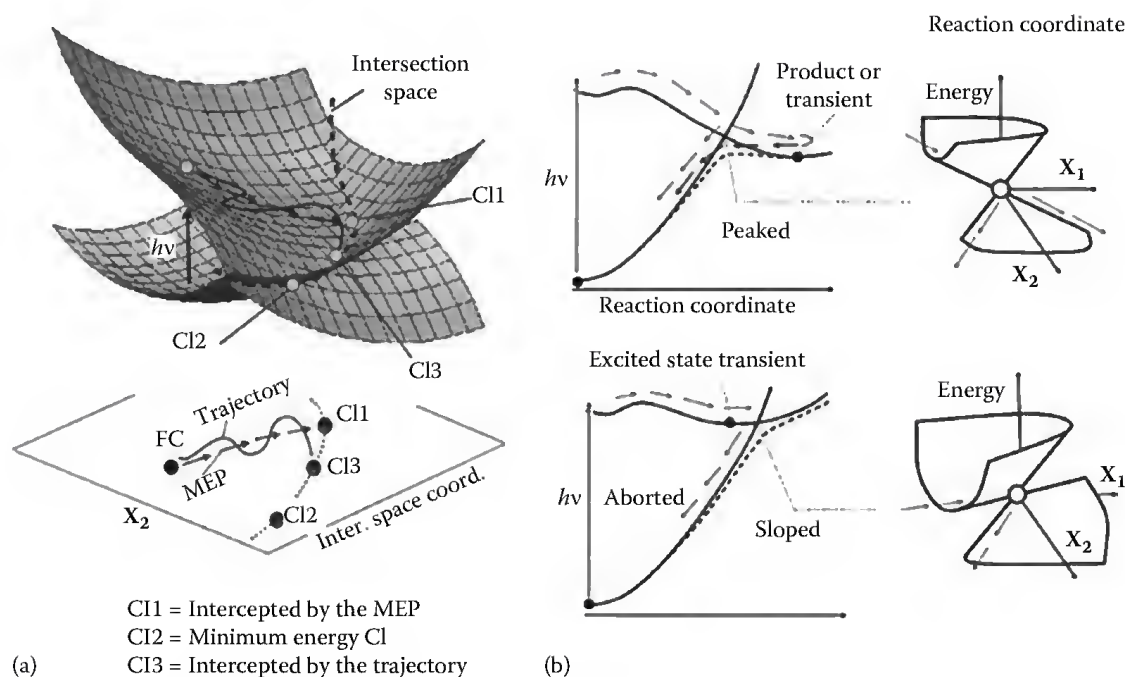

FIGURE 41.6 The intersection space. (a) A pictorial representation of the intersection space between two energy surfaces (see text). The CI1, CI2, and CI3 refer to the intersection space points located via excited state MEP calculation, CI optimization (the MECI), and with trajectory computation, respectively. (b) Shape of the photochemical reaction path and CI region for paths leading to peaked (a) and sloped (b) CIs.

is kept fixed and the energy is plotted along a plane formed by the other vector (e.g., X_2) and by one of the remaining $3N-8$ molecular modes then a plot of the upper and lower potential energy must display a seam of intersection points (Figure 41.6a). The decay to the lower potential energy surface may, in principle, occur from any point of the seam (which is a local representation of the intersection space).

The description of the photochemical funnel of a specific reaction requires the definition of the most chemically significant CI point belonging to the intersection space of the reacting system. One possibility is to assume that the excited state reactant is funneled to the ground state through the lowest energy point of the seam (the minimum energy conical intersection, MECI). Methods for locating MECI points^{38,65–68} have been reported and are available in computer packages such as Gaussian,³⁹ Molcas,⁴¹ and Columbus.⁴⁴ CI optimization and branching plane analysis reveal the widespread existence of qualitatively different MECIs (Figure 41.6b), which were initially predicted by Ruedenberg and coworkers on the basis of theoretical work.⁶² In the case of a peaked CI, excited state species can be channeled to the ground state in two or even more directions. As a consequence, one or more photoproducts can be formed together with the original reactant. On the other hand, a sloped CI implies, almost exclusively, an internal conversion (i.e., nonchemical) event where the original reactant structure is reconstituted.

MECIs do not necessarily correspond to the point reached by a MEP starting at the FC point. This means that they may not be part of the photochemical reaction path even if they are computationally convenient. For this reason, when possible, meaningful CI points are defined as the first point of degeneracy intercepted by an excited state MEP (Figure 41.6a). This point may differ significantly from the MECI especially in those cases where the MEP is not orthogonal to the intersection space.

41.2.3 Complexity of Conical Intersections

This section focuses on a computationally well-documented case to illustrate the potential complexity of the processes mediated by a single CI. In particular, we show that CIs can describe fundamental processes such as intermolecular electron transfer, proton transfer, and H-atom transfer. We also show

FIGURE 41.7 Fluorescence quenching in azoalkanes. (a) The measured fluorescence lifetime of DBO in contact with chloroform or triethylamine (i.e., the quenchers). (b) CI structure and branching plane vectors (full arrows and dashed arrows) of the CI responsible for the quenching of pyrazoline, a reduced model of DBO.

that the analysis of the wavefunction along a loop centered at the CI yields a level of understanding that is difficult to achieve with spectroscopic measurements.

We discuss the quenching of a “photochemically reluctant” azoalkane (reluctant because its singlet n, π^* excited state is long-lived compared to those of other azoalkanes that rapidly denitrogenate). Upon photoexcitation, 2,3-diazobicyclo[2.2.2]oct-2-ene (DBO) becomes strongly fluorescent (Figure 41.7). However, the emission is rapidly quenched in the presence of electron or hydrogen donors.⁶⁹

Structures corresponding to the fluorescent excited state minima, transition states, and MECIs for the interaction of an isolated n, π^* pyrazoline molecule with methylene chloride (the hydrogen donor) and trimethylamine (the electron donor) have been optimized. This system provides a computationally effective model of DBO in the presence of chloroform⁷⁰ or trimethylamine.⁷¹ For methylene chloride, an excited state reaction coordinate was found corresponding to a hydrogen atom transfer from a C–H bond of the chlorinated hydrocarbon to one of the nitrogens of pyrazoline. A transition structure separates the FC point from a CI, which clearly shows an almost completely transferred hydrogen. Indeed, at the CI (see Figure 41.7 for the molecular structure and associated branching plane vectors), the N–H bond is nearly formed (1.02 Å), but the N=N bond still has double bond character (1.30 Å), and the $\text{CHCl}_2\text{--H}$ bond is still not completely broken (2.01 Å). The CI is peaked (Figure 41.7b) and the process can either be immediately aborted (leading to back formation of the reactant) or can proceed toward the production of a radical pair intermediate. It is found that the radical pair intermediate (assumed to be solvent caged) can revert back to the original reactant pair along a ground state path, thus completing the quenching process.

To understand the nature of this bimodal quenching (i.e., occurring via the aborted process and the radical pair intermediate), it is necessary to look at the ground state wavefunction (i.e., the electronic structure of the system) along a loop centered at the CI as done for the CF_2I_2 system in Figure 41.4. Starting from the radical pair side, one finds that after traversing a path spanning 180° along the loop, the wavefunction changes character, describing an ion pair with a protonated pyrazoline and a deprotonated methylene chloride (Figure 41.8). The behavior of the excited state wavefunction along the same loop is exactly reversed. The wavefunction is a biradical in the direction of the FC point but describes an ion pair at the primary photoproduct position. This analysis implies that at the CI, excited state systems that decay back to the ground state reactant produce initially a transient ion pair via a sudden electron transfer from the azoalkane to the CH_2Cl_2 (i.e., the CI mediates an electron transfer). During the following relaxation, the protonated azoalkane then transfers the proton back to the methylene chloride anion thus reconstituting the original reactant. (This mechanism is consistent with the established harpoon model proposed by Polanyi.⁷²) In contrast, the excited state pair that evolves in the direction of the radical pair never experiences a change in its electron distribution (i.e., the wavefunction maintains its character moving adiabatically from the excited state to the ground state through the intersection). On the other hand, the radical pair returning to the original reactant through a ground state transition structure located in close proximity to the CI (dotted line in Figure 41.8) must undergo an electron transfer that generates the same transient ion pair.

FIGURE 41.8 Relationship between hydrogen atom transfer and proton transfer during pyrazoline (a DBO model) quenching. Two different quenching mechanisms are described: direct, via decay through the intersection on the reactant side, and indirect, via formation of a transient diradical pair that then undergoes a thermal coupled electron/proton transfer.

The mechanism of trimethylamine quenching⁷³ is similar but simpler. It is shown that when trimethylamine moves close to n,π^* pyrazoline, it forms an exciplex via partial excited state intermolecular electron transfer (i.e., the exciplex has an incipient radical cation/radical anion pair character). The exciplex is located in the vicinity of a sloped CI that corresponds to a structure where the electron transfer has been completed, and that mediates its return to the ground state via back electron transfer.

The aforementioned azoalkanes provide one example of deactivation, which took place via quenching. Among other fluorophores, temperature-dependent radiationless decay has been reported for closed-shell hydrocarbons such as benzene,⁷⁴ octatetraene,^{75,76} indacene,⁷⁷ pentalene,⁷⁸ fulvene,⁷⁹ azulene,⁸⁰ annulene,⁸¹ heterocycles (like chromene),⁸² closed-shell cations (like cyanine dyes),⁸³ and even for biological chromophores such as cytosine⁸⁴ and the HBDI anion.⁸⁵ As for open-shell systems, the presence of CIs on the potential energy surfaces of radical cations was first detected and investigated by Bally and coworkers^{86,87} using matrix isolation techniques as well as suitable quantum chemical calculations. Recently, Bearpark and colleagues have shown that ultrafast thermal deactivation of the excited states in such open-shell species as naphthalene⁸⁸ and pyrene⁸⁹ radicals happens via two consecutive sloped D_2/D_1 and D_1/D_0 CIs.

41.2.4 Photochemical Trajectories

Photochemical reaction path computations provide valuable information on the spectroscopy (excitation energies), energetics (reaction barriers and excess vibrational energy), and mechanisms of a photochemical reaction.⁵⁹ On the other hand, this information is only valid under the well-known assumption that the center of the excited state population (e.g., a laser generated vibrational wavepacket) would, on average, follow a path close to the MEP. This is considered to be a fair approximation in cases where the potential energy valleys are deep. However, photochemical reaction paths do not provide information on the time scale of ultrafast photochemical or internal conversion processes⁵⁹ that are characterized by

FIGURE 41.9 Energy profile along a set of seven CASPT2/ANO-RCC-VDZP trajectories released in the vicinity of the FC point of the CF_2I radical. Each trajectory corresponds to a different geometrical displacement along the n_2 vibrational mode of the reactant. Since the n_2 mode displacement is not orthogonal to the intersection space [it has minor components on the branching plane computed for the MECI (located ca. 28 kcal mol $^{-1}$ above the ground state reactant)], the intersection space is visualized as a series of intersection points.

a very small excited state reaction barrier (or no barrier at all) to control the reaction kinetics. In these cases, the mechanism and dynamics of the process can be investigated by computing excited state classical or semiclassical trajectories.⁹⁰ Trajectory computations are still computationally demanding but they have been shown to provide predictions and rationalizations of observed time scales even for proteins. A single classical trajectory released from the FC point with no initial velocities (from now on called “FC trajectory”) provides a better representation of the average motion of the center of the excited state population and, for this reason, is a tool superior to MEP computations. Moreover, this tool remains valid even when the upper and lower state potential energy valleys are shallow and the motion of the center of the vibrational wavepacket deviates significantly from the reaction path. In these cases, an FC trajectory represents a better way to locate the most chemically relevant CI point along the intersection space (CI3 in Figure 41.6b). An example is provided in Figure 41.9 where we show the results of several excited state trajectories computations exploring the photochemistry of the radical CF_2I .⁹¹ The FC trajectory intercepts a CI point after 16 fs. This CI is about 20 kcal mol $^{-1}$ higher in energy than the MECI and it displays a structure further from planarity. These classical trajectories can be used to explore and “visualize” the intersection space. For instance, a group of trajectories can be released from a set of structures that are displaced along a specific vibrational mode. In Figure 41.9, it can be seen that CF_2I trajectories released from points obtained by distorting the FC structure along the totally symmetric mode n_2 intercept a segment of the intersection space higher in energy than the MECI. This result can be understood on the basis of the schematic representation of Figure 41.10. n_2 is a vibrational mode with a large projection on the intersection space (since it is orthogonal to modes n_1 and n_3 that have significant projections on the branching plane). Therefore, a distortion along this mode is expected to “scan” the intersection space of the molecule.

FIGURE 41.10 Three-dimensional pictorial interpretation of the calculation of [Figure 41.9](#). The trajectories are released along the n_2 mode and accelerate (roughly) along the branching plane vector X_1 that has significant components along mode n_3 .

Another application of classical excited state trajectory computations focuses on the photoinduced double bond isomerization of a retinal chromophore embedded in a protein environment. The methodology required for computing the potential energy in large molecules featuring a small reactive part will be discussed in the next subsection that will deal with the simulation of biological photoreceptors. The excited state lifetimes of the visual receptor bovine Rhodopsin (Rh),⁹² its reactive intermediate Bathorhodopsin (Batho-Rh),⁹³ and its isomer Isorhodopsin (Iso-Rh)⁹⁴ have been estimated by computing the time necessary to reach a CI starting from the FC point ([Figure 41.11](#)). This also corresponds to the time required for the excited state isomerization of the covalently attached chromophores (the 11-*cis*, all-*trans*, and 9-*cis* isomers of the protonated Schiff base of retinal, respectively) of these proteins. The ca. 100 fs observed lifetime of Rh has been reproduced while the trajectory for Iso-Rh is shown up to 450 fs with a decreasing energy gap. This is in agreement with the observed lifetime of 600 fs. Batho-Rh ([Figure 41.11a](#), right) is predicted to have an extremely short lifetime (ca. 70 fs) consistently with the distorted nature of its all-*trans* chromophore. In [Figure 41.11c](#), we report a comparison between the energy profiles along the FC trajectory of Rh and other excited state classical trajectories computed with different initial conditions where the initial geometry is displaced from the FC geometry in different ways. It is clear that the trajectories are all similar.

In the past, a number of groups,^{95–106} including ours,⁹² have reported nonadiabatic semiclassical trajectories computed using simple surface-hop methods.^{107,108} This type of trajectory provides a description of the entire photoinduced molecular motion (within a certain time scale that is usually shorter than 1 ps) and simulates the hop from the upper to a lower potential energy surface that usually occurs in the vicinity of an intersection space. Not only do they simulate the decay but they also allow us to follow the evolution of the system along the lower potential energy surface toward a photoproduct or toward the original reactant. Thus, nonadiabatic trajectory calculations provide information not only on the excited state lifetime already provided by classical trajectories (see earlier) but also on the time scale for the formation of the product that may be compared with the observed photoproduct appearance time. One example of such a calculation is given in [Figure 41.12](#) for the gas-phase 3-*cis* pentadieniminium cation (a minimal model of the retinal chromophore of Rh).⁹⁸

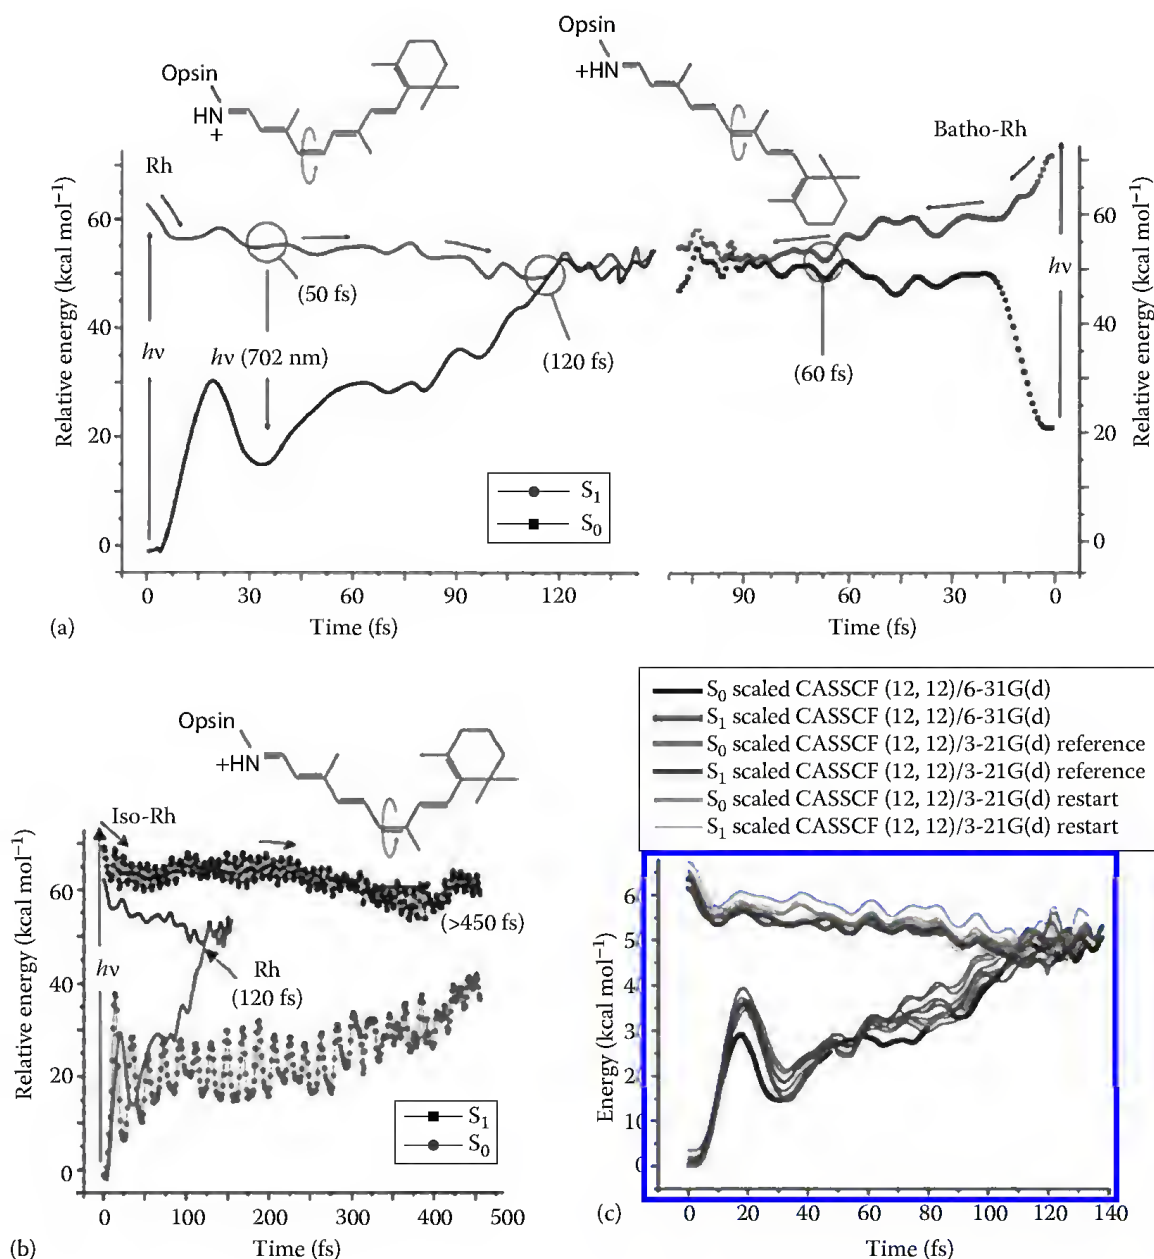

FIGURE 41.11 Rh and Batho-Rh form a photochromic system at 77 K, where the Batho-Rh intermediate (the first isolable intermediate in the Rh visual cycle) cannot undergo further conformational changes. (a) Excited state classical trajectories for the Rh→Batho-Rh (left) and Batho-Rh→Rh (right) photochemical interconversion. The trajectories are released from the corresponding FC point without initial velocities. The structures of the retinal chromophore in Rh and Batho-Rh are given. (b) Comparison of the excited state classical trajectory of Rh and Iso-Rh. The structure of the retinal chromophore in Iso-Rh is given. (c) Excited and ground state energy profiles for a set of excited state Rh trajectories computed with different initial conditions..

In the figure, the energy values at different surface-hopping points are reported for a set of trajectories defined by different initial conditions. It is apparent that the decay takes place at energies significantly above the lowest-lying cross section of the intersection space of the molecule (represented by the curve at the bottom of the diagram) and featuring an average torsional angle different from the one of the MECI. Such a cross section contains the MECI point (CI_{90°}) and also a low-lying CI point obtained via a constrained geometry optimization with a fixed 70° torsional angle about the isomerizing bond (the CI_{70°} of Figure 41.12).

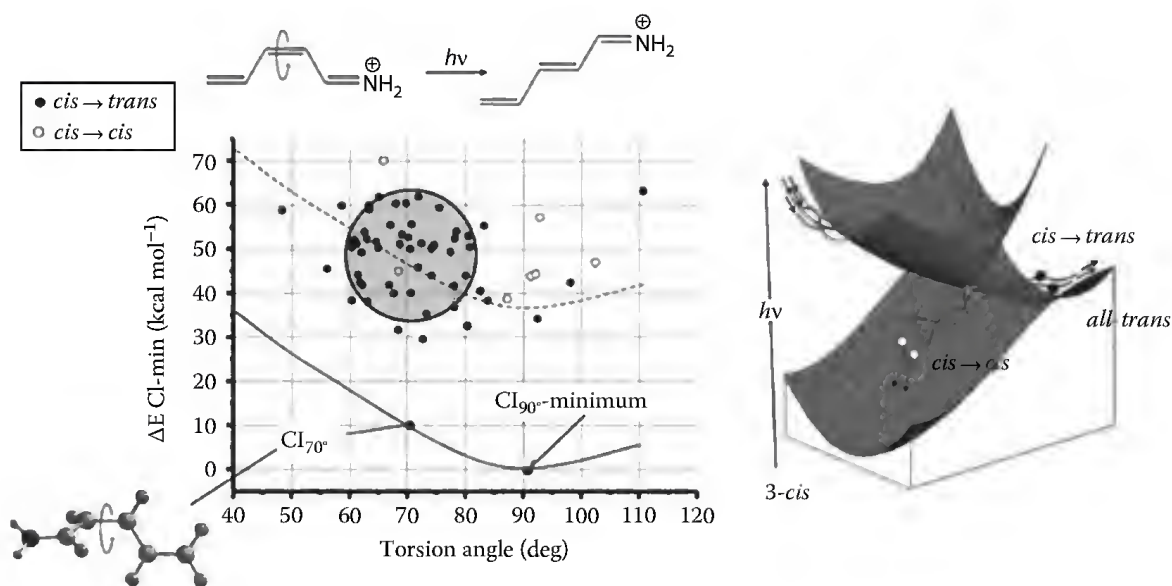

FIGURE 41.12 Energy and torsional angle distribution at the decay (hop) point for a set of 60 trajectories predicting a 80% quantum yield for gas-phase 3-*cis* pentadieniminium cation (a minimal model for the chromophore of Rh). Each trajectory is associated to a different set of initial conditions, and is released from the FC point region. A pictorial interpretation of the computational results is given on the right side where the corresponding successful (*cis*→*trans*) and unsuccessful (*cis*→*cis*) isomerizations are marked with full and opened circles, respectively.

We will discuss the use of single nonadiabatic trajectories in Section 41.3. Unfortunately, the calculation of a single nonadiabatic trajectory will not provide solid statistical information because the trajectory does not necessarily describe the average motion of the whole reacting population. This is especially true after the decay when the population may split into different directions as demonstrated in Figure 41.12.

As we will emphasize in the conclusion and perspective section, the increasing availability of multi-processor facilities like parallel computers, clusters, and computer farms is presently paving the way for computations of statistically meaningful trajectory ensembles.^{96,102,109} Therefore, the difficulties associated with the use of single trajectories could be, in principle, overcome by computing statistical properties (including quantum yields) over tens or hundreds of semiclassical trajectories.¹¹⁰

41.2.5 Photochemistry in Solution and in Proteins

While multiconfigurational quantum chemical methods have been successfully applied to sizable organic molecules, their computational cost renders the calculation of large and/or complex molecular systems impossible. These systems include chromophores in solution and chromophores embedded in a protein environment such as the visual photoreceptors discussed in Section 2.4. The underlying idea is to combine the accuracy of QM methods and the low computational cost of molecular mechanics (MM) methods. The methodology that has become increasingly popular is the hybrid QM/MM method.¹¹¹ The history of hybrid methods starts around 30 years ago with Warshel's work on lysozyme, where a MM method was coupled to semiempirical QM calculations.¹¹² This type of calculation was soon after applied to the study of visual pigments¹¹³ and therefore to photobiology.

In a QM/MM setup, the part of the system (QM subsystem), which is responsible for the reactivity, spectroscopy, photophysics, and photochemistry, is described by a suitable quantum chemical method. The remaining part (MM subsystem), such as a box of solvent molecules or the protein hosting the QM

subsystem, is described in a computationally inexpensive way at the MM level (i.e., using parametrized classical force fields). The total (relative) potential energy of the system can be described by the additive relation¹¹¹:

$$E_{\text{Total}} = E_{\text{QM}} + E_{\text{MM}} + E_{\text{QM/MM}}$$

While the first two terms account for the contributions coming from noninteracting QM and MM subsystems, the third term describes their interaction. Notice that there are different E_{QM} and $E_{\text{QM/MM}}$ terms for each electronic state while the E_{MM} remains the same. The general classification of QM/MM methods is based on the formulation of the $E_{\text{QM/MM}}$ term and on the scheme adopted to describe the boundary region between the QM part and the MM part. Depending on the way in which electrostatic interactions are treated, the QM/MM schemes can be divided into two classes: mechanical embedding (ME) and electrostatic embedding (EE).¹¹⁴ In photochemical and photobiological studies, we need to use an EE method. In these methods, the QM computation is carried out in the presence of the MM subsystem by including the description of the electrostatic interactions between the two subsystems in the one-electron operators of the QM Hamiltonian. The remaining nonbonding (Van der Waals) interactions and bonding (stretching, bending, and torsional) interactions are treated at the MM level. It is usually convenient to represent the MM atoms by atomic-centered partial point charges for the purpose of calculating electrostatic interactions. Sets of these point charges have been calculated and incorporated into popular MM force fields, like Chemistry at Harvard Molecular Mechanics (CHARMM)¹¹⁵ or Assisted Model Building with Energy Refinement (AMBER).¹¹⁶ Some advantages of using these MM charges are that they have been validated extensively and have been parametrized to give accurate MM energies.

In cases where there is direct bonding between the QM and MM subsystems, such as when a chromophore is covalently linked to the protein (e.g., fluorescent proteins or visual pigments), the $E_{\text{QM/MM}}$ term also includes bond, angle, and torsional parameters accounting for the treatment of the frontier bond (the bond that connects the QM and MM moieties). The simplest and most popular approach to treat the frontier bond is the “link-atom”^{117,118} scheme, where the free valencies of the “frontier atoms” are saturated with one or more hydrogen atoms that are included in the quantum chemical treatment of the QM fragment.

The parts of a QM/MM model for the microbial sensory receptor from the fresh water cyanobacterium *Anabaena* (*Nostoc*) sp. PCC 7120¹¹⁹ are shown in Figure 41.13. The position of the frontier bond and link-atom is highlighted. The tube representation indicates the QM subsystem (the retinal chromophore of the Rh) and the covalently linked amino acid side chain included in the MM subsystem. These two regions are separated by a link-atom represented as a circle. The ball and stick representation highlights the backbone of the same residue. In computational photobiology studies, not all of the atoms of the photoreceptors (originally taken from the available crystallographic structure) are free to relax during the geometry optimization (i.e., to search for an excited state or ground state energy minimum). To make the optimization more effective without losing accuracy, only the QM subsystem and the part of the MM subsystem significantly interacting with it (including nearby residues, waters, or waters connected to the QM subsystem via hydrogen bonds) are incorporated in the set of nuclear coordinates allowed to be relaxed.

QM/MM models of an assortment of retinal proteins have been constructed and investigated by different research groups. As shown in Figure 41.13, these offer a good demonstration of the level of complexity that a QM/MM model can achieve. The information that the models provide has been partially discussed earlier for the photoreceptor Rh and will be further discussed in Section 41.3. A more complex model of a water soluble retinal protein mimic¹²⁰ is currently under investigation in our lab. On the basis of the available x-ray crystallographic structure, we have constructed (using a protocol similar to the one used to reproduce the spectra of the soluble protein monellin)¹²¹ a QM/MM model of the KLE-CRABPII construct¹²⁰ in water solution. Figure 41.14a provides an overview of the complexity of the model. The protein (Figure 41.14b) is embedded in a large rectangular solvent (water) box. The model features 7040 waters, forming a $62 \times 58 \times 71 \text{ \AA}^3$ box that extends at least 10.0 \AA from any atom of the

FIGURE 41.13 Partial view of the CASPT2//CASSCF/AMBER (QM/MM) model used for simulating the spectroscopy and photochemistry of a biological photoreceptor (e.g., the microbial sensory Rh from the cyanobacterium *Anabaena* displayed in the figure). The protein backbone and the cavity residues (the study of the photochemical step in these systems requires subpicosecond simulations that do not allow for important displacements of the cavity residues) are kept fixed at their crystallographic positions. The table reports the excitation energies in kcal/mol computed with a basic model with fixed water hydrogens (Model 1) and an improved model (Model 2) with relaxed water hydrogens (thus allowing a reorganization of the hydrogen bond network).

protein. To correctly account for the solvent, a 1 ns molecular dynamics (MD) simulation of all the water molecules was initially performed. Coordinates from the last (equilibrated) part of the simulation were used to build different QM/MM models. In turn, these were used to compute the system absorption maxima and for successive excited state reactivity studies. To accomplish this, for each chosen snapshot, a CASSCF/AMBER geometry optimization was performed, where CASSCF/AMBER method used to compute the equilibrium structure and AMBER indicates the MM force field used. The coordinates of the retinal chromophore (the QM subsystem), the glutamate counterion, and water molecules within 5 Å from any given QM atoms were relaxed. The rest of the protein is held fixed at the crystal structure. The achieved accuracy is illustrated in Figure 41.14c¹²² that reports the computed absorption λ_{\max} value. This is computed as an average of the predicted λ_{\max} values for several minimum energy configurations generated with an MM based ground state molecular dynamics simulation (using a parametrized

FIGURE 41.14 (a) QM/MM model for CRABPII-KLE in solution. (b) Parts of the protein model. (c) Prediction of the absorption maximum (see text) using MS-CASPT2//CASSCF/AMBER calculations. Each data point represents a different geometry sampled from the MD simulation with the chromophore and waters within 5.0 Å optimized at the QM/MM level.

retinal chromophore) and determined at the CASSCF/AMBER level. These values are computed via single point MS-CASPT2//CASSCF/AMBER computations. It is shown that the observed absorption λ_{max} is reproduced within 3 kilocalories per mole (less than a 20 nm error).

CASPT2//CASSCF/AMBER models can also be used for simulating or predicting spectroscopic and photochemical properties of organic chromophores in solution. A recent example is provided by an N-alkyl indanylidene-pyrroline (NAIP) molecular switch that has been shown to mimic different aspects of the photoisomerization of the retinal chromophore in Rh. In Figure 41.15, we show the core of a QM/MM model featuring a solvent box of methanol entrapping the chromophore unit.¹²³ Comparison of the computed and observed λ_{max} values for three electronic transitions shows that the model can reproduce the spectra correctly.

FIGURE 41.15 A low-energy CASSCF/AMBER configuration (only the first solvation shell is displayed) of a zwitterionic NAIP switch in methanol solution studied in Ref. [123]. Room temperature experimental absorption spectra of the Z isomer (λ_{\max} 397 nm) and E isomer (λ_{\max} 391 nm) of the same switch in MeOH.

41.3 Computational Photobiology

We have earlier seen that the mapping of the excited state potential energy surface¹²⁴ and CIs³⁷ requires methods that can deal with electronic structures featuring a changing mixture of open-shell and charge transfer characters. The aforementioned CASPT2//CASSCF method offers maximum flexibility for an unbiased description of the electronic and equilibrium structures of the ground and excited states of a molecule.

In the past, we have shown (Figure 41.16) that, when used as part of the QM/MM method described earlier, CASPT2//CASSCF quantum chemical computations allow to model the spectra of different proteins incorporating cationic, anionic, and neutral chromophores.^{121,125–129} This method has already been mentioned earlier for the case of the visual pigment Rh, the soluble KLE-CRABP II Rh mimic, and the biomimetic NAIP switch in methanol solution. For the membrane protein Rh,^{125,126,130} which is the visual pigment of vertebrates, the observed absorption maximum of its retinal chromophore embedded in the apoprotein opsin was reproduced with an error of less than 3 kcal mol⁻¹ in excitation energy. Furthermore, we were able to reproduce¹²⁶ the λ_{\max} values of one isomer and two mutants of Rh with less than 2 kcal mol⁻¹ error. Similarly, the computed change in oscillator strength (*f*) at λ_{\max} for those proteins has been found to be consistent with the corresponding experimental change in the extinction coefficients (ϵ). These results have been confirmed by others^{131,132} and extended to microbial Rh¹³³, to the retinal chromophore in solution^{134–138} and to other photoactive systems, such as luciferase,¹³⁹ phytochrome,¹⁴⁰ and the GFP-like protein Dronpa.¹⁴¹ While these studies have also prompted the investigation of different *ab initio* multiconfigurational quantum chemistry-based QM/MM protocols,^{136,142} the CASPT2//CASSCF is arguably the only method allowing a description of spectra, excited state reaction paths, CIs, and trajectories on a consistent basis.^{59,124,128} While CASPT2 geometry optimizations would be more accurate, they are unfeasible for a retinal chromophore due to the very high computational cost. That is why realistic trajectory computations (i.e., the double bond isomerization dynamics) are currently carried out at the scaled-CASSCF level⁹² to account for the CASPT2 correction in an approximate way.

These studies have focused on different photoreceptor properties including spectra (for instance, as a function of mutations¹²⁶), the structure of the CI (either obtained via geometry optimization, MEP computation,¹²⁴ and/or trajectory computation⁹⁸), the topology of the intersection space, and, ultimately, reactivity using classical (Figure 41.11) and semiclassical trajectory computations. Most recently, as anticipated earlier, the use of whole sets of semiclassical trajectory computations has been used to tackle the problem of predicting photoisomerization quantum yields.^{103,110}

FIGURE 41.16 In our group the CASPT2/CASSCF/MM method (see text) has successfully reproduced the excitation energies of a set of pigments related to bovine Rh (Rh and related isomers and mutants), bacteriorhodopsin (bR), *Anabaena* sensory rhodopsin (ASR), the green fluorescent protein (GFP), the photoactive yellow protein (PYP), the tryptophan containing proteins parvalbumin (Parv), and monellin (Mone). These data are indicated with filled shapes and full lines. By using the same method, other groups have obtained the excitation energies of Rh-related proteins, along with luciferase, phytochrome and the GFP-like protein Dronpa. These data are indicated in the chart with empty shapes and broken lines.

In Figure 41.17, we schematically show the results of our study on the control of the absorption maxima in Rh¹²⁶ featuring a chromophore incorporated in a tight protein cavity. It is shown that the rationale behind the changes in λ_{\max} value induced by a change in amino acid composition is based on the established difference^{143–145} in singlet ground (S_0) and excited state (S_1) charge distributions. As reported¹²⁵ for bovine Rh (Figure 41.17a), upon excitation of the chromophore, the positive charge located on the Schiff base moiety is spread toward the β -ionone ring. This is due to the charge transfer nature of the S_1 state. Thus, polar residues located in the Schiff base region will affect the λ_{\max} value stabilizing (or destabilizing) S_0 with respect to S_1 , thus inducing a shortening (or lengthening) of the absorption wavelength. The direction of this effect depends on the sign of the *change* in electrostatic potential “projected” by the residues on the Schiff base region. Replacement with a residue increasing the positive potential will result in a destabilization of S_0 and stabilization of S_1 causing a red shift of the chromophore absorption. In contrast, a replacement imposing a decrease of the positive potential will yield a larger S_0 – S_1 gap, thus causing a blue shift.

In Figure 41.18, we show a mapping of the excited state potential energy surface of Rh¹²⁴ produced using a relaxed scan approximating the MEP, driven by the twisting of the reactive 11-*cis* bond and ultimately leading to the production of Batho-Rh. It is shown that, in its last part, the MEP runs along a path that maintains the energy degeneracy. This suggests that, at the bottom of the excited state potential energy surface of the photoreceptor, there is a segment of the intersection space. This is also confirmed by the result of excited state trajectory computations. Indeed, as shown in Figure 41.11a, a classical trajectory (i.e., a trajectory that cannot computationally hop to the ground state) detects an intersection space segment in its last part. Similarly, the trajectory simulating the reverse isomerization reaction (i.e., from Batho-Rh to Rh) also detects a similar near degeneracy region that most probably belongs to the

FIGURE 41.17 (a) Change in the charge distribution along the backbone of the 11-*cis* chromophore of Rh upon photoexcitation. It is shown that <30% shift of the positive charge occurs upon vertical transition to the first excited singlet state. (b) Electrostatic potential (numbers give the maximum and minimum values in atomic units) generated by the opsin partial charges (excluding the counterion) on the retinal chromophore centers of Rh. Bottom. Change in electrostatic potential (numbers give the maximum and minimum values in atomic units) on the atoms of the chromophores of the mutant G121L with respect to the wild type. (c) A mutated rhodopsin (e.g., ASR) cavity imposing a more positive potential on the chromophore C=N segment or a more negative potential on the β-ionone segment will red shift the λ_{max}^a value.

FIGURE 41.18 MEP along the excited state photoisomerization path of Rh. Notice that the excited and ground states are degenerate in the 70–90 region, suggesting that the reaction path is parallel to a small segment of the intersection space. The QM/MM Rh and Batho-Rh models used for these studies have been validated by comparing the computed excitation energies with the observed ones.

FIGURE 41.19 Scaled-CASSCF/Amber semiclassical trajectories for Batho-Rh and Rh. The S_1 and S_0 energy profiles along the trajectory of Rh are given on the left. The data for Batho-Rh are given on the right.

same intersection space. Indeed, in a recent work, we have shown that the same intersection space is also connected to the CI reached during the photoisomerization of Iso-Rh.¹⁴⁶

The aforementioned results are useful to interpret the more realistic semiclassical trajectory computations. For instance, in [Figure 41.19](#), we show that the semiclassical trajectories computed for Rh and Batho-Rh, and describing the low-temperature (77 K) photochromic interconversion of these receptors, clearly reach the intersection region as well as the region of their vibrationally hot photoproducts on a subpicosecond time scale. It is evident that in the case of Rh, the trajectories remain close to the intersection region immediately after its decay. This does not happen for Batho-Rh where the intersection space is immediately abandoned and the evolution on lower energy regions of the ground state potential energy surface is directly initiated. We believe that in the future, the understanding of these differences at the level of the single molecular vibrational modes driving the excited state dynamics and the hop event will become of great importance.

41.4 Conclusions and Perspectives

A correct formulation of the mechanism of a photochemical reaction requires the computation of real crossings, like CIs and singlet–triplet crossings, between different potential energy surfaces. In ultrafast reactions, these *critical* structures are reached by the excited state reactant on the time scale of a few vibrational periods. However, slower processes can also be mediated by CI channels. In fact, as documented in [Section 2.3](#), there are cases where the access to a CI is controlled by a non-negligible excited state barrier. In other words, the involvement of CIs in chemistry may go considerably beyond the field of femtochemistry and comprise processes such as photoinduced electron transfer, quenching, and internal conversion. From this conclusion, it is evident that a growing need to effectively locate and calculate chemically meaningful CIs, and thus rigorously connect different potential energy surfaces, will drive further research.

We have earlier clarified that MECIs are, in general, crude representations of photochemical funnels. This is due to the fact that CI points are elements of complex intersection spaces. Two more effective strategies to locate meaningful photochemical funnels have been revised. These are photochemical reaction paths and trajectories. However, single (classical or semiclassical) trajectories only yield an approximation of the most meaningful CI. In fact, such a structure has a statistical meaning and can only be computed in terms of an average value that can be derived by analyzing a set of different trajectories. It is therefore apparent that the future of computational photochemistry and photobiology is associated with the development of efficient methods for the computation of entire sets of semiclassical trajectories. These methods are characterized by (1) the way in which the initial set of geometries and velocities are generated, (2) the way in which the hop decision is taken for each trajectory, and (3) the QM/MM protocol used for computing the potential energy and energy gradients.

For the formulation of the QM/MM protocol to be used in photochemical and photobiological studies, one would want to use quantitative methods such as the *ab initio* CASPT2 (or the more advanced MS-CASPT2) or MRCI methods. In principle, these methods will ensure that the forces acting on the nuclear coordinates and driving both the excited state dynamics and the following ground state relaxation are realistic. In this way, one could avoid non-negligible errors coming from the difficulties of parametrizing and validating semiempirical methods, scaling the energies and gradients of CASSCF, or formulating/parametrizing novel functionals for TD-DFT calculations. However, even these advanced methods need further performance improvements. In particular, CASPT2 analytical gradients are not available and both geometry optimizations and trajectory computations can only be performed for relatively small molecular systems.^{91,147–149} Furthermore, the validity of CASPT2 energies and gradients in the strict vicinity of a CI requires a careful analysis. The more reliable MRCI method has, however, a much higher computational cost and it is presently of limited applicability to sizable organic systems.

The search for realistic and computationally effective QM/MM excited state force fields is perhaps the most important technical challenge that modern computational photochemistry and photobiology have to face. The availability of such force fields would make possible the exploitation of the constantly expanding computational facilities available for chemical research. In particular, facilities going from in-house computer clusters up to the extensive computer farms available at state or federal computer centers are particularly suited for the *simultaneous* investigation of large families of different molecular systems or for the *simultaneous* computations of statistically meaningful sets of trajectories of a given chromophore. It is apparent that this last target will have a significant impact in our understanding and future engineering of the light energy exploitation at the molecular level and, therefore, in the development of new functional materials.

The use of a computer farm for the simultaneous investigation of a chromophore or a family of related chromophores in solution or in a complex protein environment is reminiscent of the way in which one of the fathers of modern photochemistry used to carry out his research. In Figure 41.20, we see how Giacomo Ciamician used to expose entire sets of different organic compounds to sunlight on a balcony of his laboratory in Bologna (Italy).¹⁵⁰ In a sense, the opportunities described earlier are shifting this effective way of carrying out photochemical research to the virtual (*in silico*) world revealing, once again, the extraordinary link between the past and the future of photochemistry.

FIGURE 41.20 “Parallel” photochemical research in Giacomo Ciamician’s lab (from 1889 to 1921) in Bologna, Italy, and a modern computer farm. In both cases, different sets of compounds are investigated simultaneously either experimentally or *in silico*.

42.1 Introduction

Talking about fluorescence with respect to DNA, one usually refers to fluorescent labels used extensively in biology and genetics. Yet DNA does emit fluorescence albeit with a low quantum yield, on the order of 10^{-4} . Such weak emission, which so far prevented large-scale technological applications, may be precious in many respects provided that its properties are well understood. For example, it can contribute to elucidate questions such as the following: How did the building blocks of the genetic code “survive” when intense ultraviolet (UV) radiation was reaching the earth? What are the primary events leading to photochemical reactions that induce carcinogenic mutations? This is possible because following the time behavior of fluorescence brings information about the singlet electronic excited states and their relaxation.

Although the first articles reporting room-temperature fluorescence of DNA components were published already in 1971,^{1,2} a thorough study of the emitting states was limited by the time resolution. It is only during the past few years that the development of femtosecond techniques, mainly based on fluorescence upconversion (FU) and allowing excitation and detection in the UV spectral domain, gave an important impulse to this field.

Here, we tackle studies that have appeared since the turn of the twenty-first century. We mention that two recent reviews deal with the excited-state dynamics of nucleic acids with particular emphasis on transient absorption studies.^{3,4} In the present chapter, we present the fluorescence behavior of these systems in more detail, and we address the main problems and outcomes related to such investigations.

We examine successively the monomeric building blocks (bases, nucleosides, nucleotides; Section 42.5) and then more complex systems (single, double, and quadruple strands; Section 42.6). As photon emission is strongly related to photon absorption, at least in the reported work, we also discuss the absorption spectra and the Franck–Condon excited states (Section 42.4).

Detecting very weak fluorescence signals with UV excitation is not a trivial task. Therefore, we describe experimental methods specially related to this type of measurements (Section 42.2). Finally, in the case of DNA strands, particular cautions are required due to their increased fragility versus UV radiation and the plasticity of their structure. This renders comparison of data obtained by various groups using different experimental conditions quite delicate and the definition of commonly accepted protocols is an urgent need (Section 42.3).

42.2 Experimental Methods and Setups

42.2.1 Steady-State Fluorescence Spectra

The following procedure was followed in order to record fluorescence spectra of DNA components over a large spectral domain and make a refined comparison of the emission spectra of various systems.⁵

Fluorescence spectra were recorded with a SPEX Fluorolog-2 spectrofluorimeter equipped with a 450 W arc xenon lamp. The calibration of emission monochromator was verified using a Hg low-pressure standard lamp whereas that of the excitation monochromator was confirmed by observing the scattered excitation light from water. The emission correction factor was performed by means of deuterium and tungsten lamps of standard irradiance and checked via the standard fluorescence spectrum of quinine sulfate.⁶

For fluorescence measurements, 1 cm × 1 cm and 0.2 cm × 1 cm quartz cells (QZS) were used for dilute and concentrated solutions, respectively. For dilute solutions ($<5 \times 10^{-5}$ M; 1 cm × 1 cm cells), the signal of solvent (in most cases the Raman line of water) was not negligible compared to the fluorescence intensity. Therefore, its contribution was subtracted from the fluorescence spectra. Each spectrum was recorded several times: (1) without any filter at the emission side and using (2) a Schott WG320 or (3) a Schott GG385 filter. In all cases, a Schott UG5 filter was used on the excitation side. The three spectra were normalized at appropriate wavelengths and then joined. Such a procedure allowed us to eliminate the second order of the scattered excitation light from water, Raman scattering and also the second order of the main fluorescence peak.

Fluorescence quantum yields (ϕ_s) were determined using quinine sulfate dihydrate in 0.1 M HClO₄ ($\phi_s = 0.59$).⁶ As a control, the fluorescence quantum yield of 2,5-diphenyloxazole (PPO) in cyclohexane was determined and found to be 0.90 ± 0.02 , in perfect agreement with the most recent value reported in the literature (0.89).⁷

42.2.2 Time-Resolved Techniques

As mentioned in Section 42.1, time-resolved fluorescence studies of DNA constituents require femto-second resolution. Nevertheless, much longer-lived components are present in the fluorescence of DNA helices. In order to obtain a global picture, probing fluorescence over several decades of time is necessary. This can only be achieved by combination of different detection techniques.

Femtosecond time resolution is obtained by the use of femtosecond lasers together with optical gating detection: FU and optical Kerr gating (OKG). In FU, an intense laser (gate) pulse is mixed with the polarized fluorescence in a nonlinear optical crystal creating a sum-frequency light. The gate pulse defines a time window during which the fluorescence can be measured. By scanning the optical delay between the gating and excitation pulses, fluorescence intensity traces are recorded. The detection is performed by photon counting, favorable for high-repetition (MHz) laser sources,⁸ but also amplified kHz systems are used.^{9,10} In OKG, the polarized fluorescence is directed through a Kerr shutter consisting of two crossed polarizers between which a Kerr medium is positioned. Without a gating pulse, the fluorescence is extinguished by the Kerr shutter. However, when a highly intense laser pulse (gate) is focused into the Kerr medium, it induces a change of the fluorescence polarization, letting part of it to pass through to detection. An amplified kHz laser system is necessary in order to attain the gating pulse intensities needed.¹¹ Time-resolved fluorescence spectra of DNA were obtained by both FU¹²⁻¹⁷ and OKG.^{18,19}

Recent DNA fluorescence studies focusing on longer components relied on time-correlated single photon counting (TCSPC) using either femtosecond laser^{20,21} or synchrotron radiation.²²

The experimental setup developed in our laboratory for the time-resolved fluorescence measurements of DNA cited here gives the possibility to probe fluorescence over a large time domain from 100 fs to 100 ns using the same excitation source (267 nm, 120 fs). Two different detection techniques were used. On the one hand, FU detects emission associated with allowed electronic transitions with a resolution of ca. 100 fs after deconvolution. On the other hand, TCSPC probes emission from both bright and “dark” excited states with a time resolution of 10 ps after deconvolution.

We paid special attention to the determination of the fluorescence anisotropy. To this end, parallel $I_{\text{par}}(t)$ and perpendicular components $I_{\text{per}}(t)$ of the fluorescence signals were recorded by means of a half wave plate, positioned at the excitation side (FU) or by means of a Glan Thomson prism positioned at the detection side (TCSPC). Fluorescence decays $F(t)$ and fluorescence anisotropy decays $r(t)$ were determined as follows:

$$F(t) = I_{\text{par}}(t) + 2GI_{\text{per}}(t),$$

$$r(t) = \frac{I_{\text{par}}(t) - GI_{\text{per}}(t)}{I_{\text{par}}(t) + 2GI_{\text{per}}(t)}.$$

In the case of FU, the G factor was equal to 1, whereas in the case of TCSPC, it was determined by the tail-matching method using protonated guanosine (pH = 2.5).²³

42.3 Protocols for the Study of DNA Helices

Spectroscopic studies of DNA helices present specific difficulties, which are not encountered in the experiments carried out with monomeric chromophores.²⁴ Indeed, the close proximity of the bases within a helix favors photoreactions leading to dimeric products, such as cyclobutane dimers and (6-4) adducts.²⁵⁻²⁷ Moreover, base stacking increases their propensity to lose an electron upon photon absorption.²⁸⁻³⁰ Thus, laser pulses are likely to provoke two-photon ionization of both the aqueous solvent as well as of the DNA helices. The produced radicals³¹⁻³³ are very reactive and they lead to oxidation products, such as 6-hydroxy-5,6-dihydrocytosine or 8-oxo-7,8-dihydroguanine. Further reactions may be induced by the hydrated electrons, which can attack the studied nucleic acids.

The various photoproducts may affect fluorescence measurements in two ways. On the one hand, some of them emit light. This is typically the case of the (6-4) adducts whose fluorescence quantum yield is higher by two orders of magnitude than that of DNA components.³⁴ On the other hand, photoproduct formation within a helix may alter its conformation, which, in turn, may modify the electronic coupling. Consequently, excited-state relaxation of damaged duplexes should be different compared to that of the initial duplexes, which are the objects under study. For example, we found that accumulation of photoproducts in $(dA)_n \cdot (dT)_n$, shortens its fluorescence lifetime recorded by FU and increases that determined by TCSPC.²⁴

Analysis of the thymine dimers formed upon continuous irradiation at 267 nm of $(dA)_{20} \cdot (dT)_{20}$ using high-performance liquid chromatography coupled to mass spectrometry brought an important insight into the relation between spectral changes and photodamage.³⁵ It was demonstrated that changes in the steady-state absorption spectra result from two antagonistic effects: on the one hand, a decrease in the absorbance due to disappearance of the thymines which reacted and, on the other hand, an increase in the absorbance due to local denaturation of the adenines. Consequently, judging the amount of photodamage provoked by a laser experiment on the basis of absorption changes^{36,37} may be misleading. To be more specific, the formation of one cyclobutane dimer within $(dA)_{20} \cdot (dT)_{20}$ corresponds to a destruction of 5% of the bases of the duplex but leads to only 0.6% decrease in the absorption maximum.³⁵

In order to avoid contamination of the fluorescence signals with photons emitted from damaged helices, it is important to follow a few rules: keep the laser intensity as low as possible, use a sufficiently large ratio of molecules compared to that of the photons absorbed during the measurement and avoid local accumulation of photoproducts. In practice, FU experiments were performed using a flow cell allowing circulation of 20 mL of solution (ca. 2×10^{-3} M per base), the laser intensity at the surface of the sample being 2×10^8 W cm⁻². Much lower laser intensities (10^4 W cm⁻²) were used in TCSPC measurements, which gave the possibility to work with smaller volumes: 0.6 mL (ca. 2×10^{-4} M per base) in a moving cell. However, the ultimate test is to check if successive signals recorded with the same solution are reproducible. Experimental procedures similar to ours were also followed by Schwalb and Temps.³⁸

Besides the aforementioned cautions related to UV excitation of DNA helices, further problems are associated specifically with double strands. Polymers are produced biochemically, which insures efficient base pairing, whereas oligomers are prepared by annealing of the parent single strands. In the latter case, duplex formation depends both on the annealing conditions and on the base sequence. In particular, when repetitive simple base sequences are used, such as (dA)_n · (dT)_n or (dAdT)_n · (dAdT)_n, slipping between the two complementary strands is possible. The degree of hyperchromism observed upon melting of a duplex should be used as a quality test for base pairing.²⁴

42.4 Franck–Condon Excited States

42.4.1 Monomeric Chromophores

The absorption spectra of the nucleosides (dA: 2'-deoxyadenosine; dT: thymidine; dG: 2'-deoxyguanosine; dC: 2'-deoxycytidine), identical to those of the nucleotides (dAMP: 2'-deoxyadenosine 5'-monophosphate; TMP: thymidine 5'-monophosphate; dGMP: 2'-deoxyguanosine 5'-monophosphate; dCMP: 2'-deoxycytidine 5'-monophosphate) that constitute the monomeric DNA chromophores, are shown in [Figure 42.1](#). The cytosine and thymine derivatives belong to the pyrimidine family, while adenines and guanines are denoted as purines.

The lowest in energy absorption band of dA/dAMP and dG/dGMP corresponds to two close-lying electronic transitions. This is suggested by a shoulder present in the dG spectrum. In the case of the adenine derivatives, the existence of two transitions was evidenced experimentally by means of linear dichroism and magnetic circular dichroism.³⁹ These observations are corroborated by quantum chemistry calculations, which have shown the existence of two close-lying $\pi\pi^*$ states, denoted by L_a and L_b,^{40,41} in accordance with the Platt nomenclature.⁴² Even if their relative ordering in gas phase is under debate, we can assume that for chromophores in aqueous solution, the more polar L_a is the first excited state. For the pyrimidines, the L_a and L_b are much further apart, so the first absorption band corresponds essentially to only one strong $\pi\pi^*$ transition.

In addition to the spectra of the nucleosides corresponding to the four major bases, we also present in [Figure 42.1](#) that of 5-methylcytidine (5MedC). Methylation and demethylation at the five position of cytosine are natural processes playing an important biological role.⁴³ Methylated sites are strongly correlated with the occurrence of carcinogenic mutations.⁴⁴ The absorption spectrum of 5MedC is red-shifted with respect to that of dC.¹² This observation together with the fact that the intensity of the solar radiation reaching the earth increases with increasing wavelength could be a hint for the involvement of this rare base to the appearance of UV-induced DNA lesions.

42.4.2 DNA Helices

When going from monomeric chromophores to the DNA double strands, the absorption spectra are altered ([Figure 42.2](#)). The most striking change concerns the oscillator strength. The DNA hypochromism is used to characterize the stability of double strands via their melting curves, obtained by

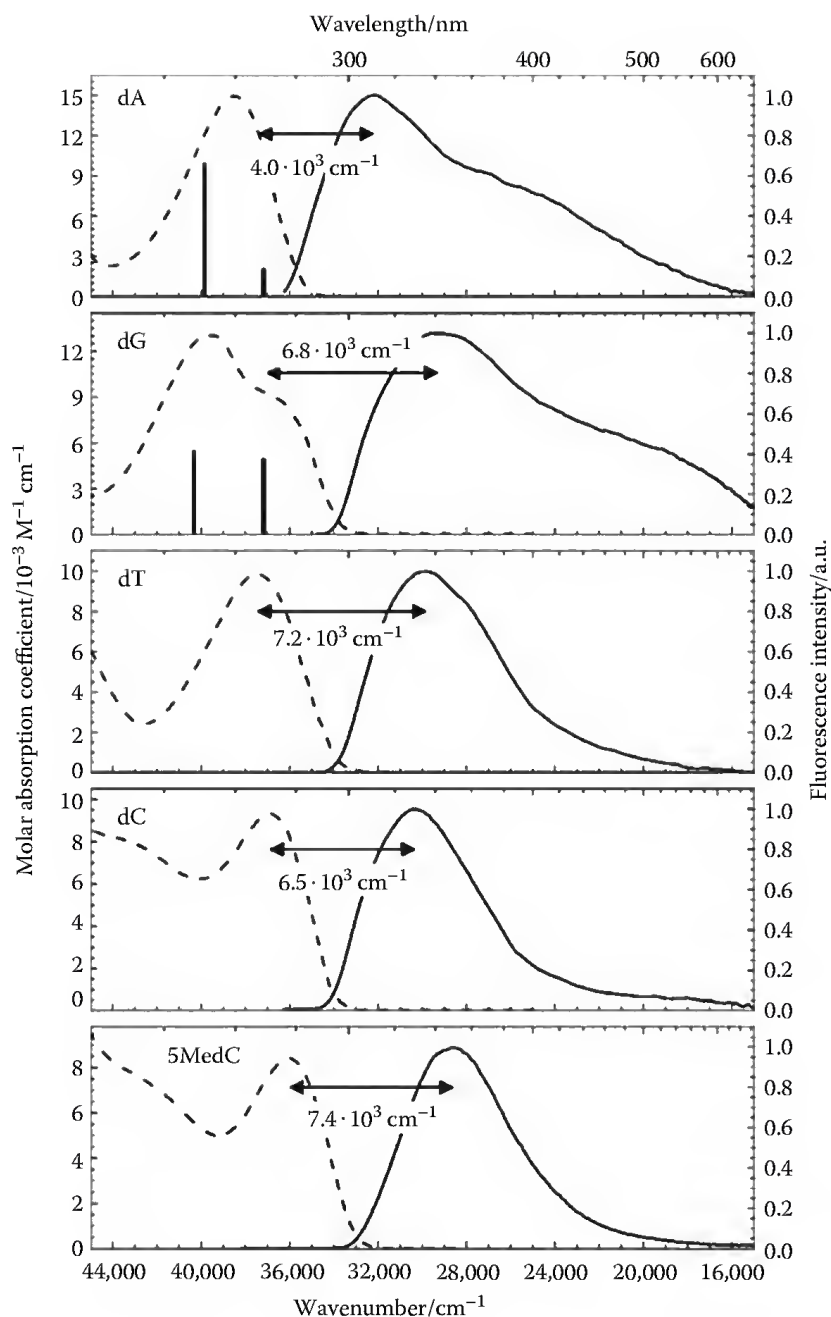

FIGURE 42.1 Steady-state absorption (dashed) and fluorescence (solid) spectra of dA, dG, dT, dC, and 5MedC in water. Arrows designate the Stokes shift. Vertical bars indicate the two lowest transitions of dA and dG; $\lambda_{\text{exc}} = 255 \text{ nm}$.

following the absorbance at 260 nm as a function of temperature. Despite the extensive application of this phenomenological property, the underlying modifications of the electronic transitions remained unclear until recently. The study of base pairs and dimers of base pairs by quantum chemistry methods shed light on this question attributing the DNA hypochromism to charge transfer transitions between different bases.^{45,46} It was also shown that simple coupling between bright and “dark” transitions may lead to the same effect.⁴⁷

It can be seen in [Figure 42.2](#) that the change in the molar absorption coefficient observed for the duplex with respect to an equimolar mixture of the constitutive nucleotides is not uniform over the

FIGURE 42.2 Comparison of the absorption spectra obtained for duplexes [D in solid lines: (a) poly(dGdC)·poly(dGdC); (b) poly(dA)·poly(dT); (c) poly(dAdT)·poly(dAdT)] and an equimolar mixture of the constitutive nucleotides (M in dashed lines). The shaded area in the lower part corresponds to $(D - M)/M$. The molar absorption coefficient is given per base.

whole spectrum and depends on the base sequence. Interestingly, an increase in the oscillator strength is observed at the red edge of the spectra of duplexes composed of homopolymeric adenine–thymine $(dA)_n \cdot (dT)_n$ and alternating guanine–cytosine $(dCdG)_n \cdot (dCdG)_n$ sequences. This is also known to occur in the case of four-stranded structures formed by self-association of guanines via Hoogsteen bonds (Figure 42.3) called G-quadruplexes.^{48–50}

In addition to orbital overlap interactions, another type of electronic interactions is also operative within double strands: coupling between dipolar transitions of the monomeric chromophores, which gives rise to Frenkel excitons. According to the exciton theory, the excited states of a multichromophoric system are linear combinations of the excited states localized on each monomeric constituent.^{51,52} The calculated properties of the eigenstates highly depend on the way that the exciton matrix is constructed. Recent calculations performed in this frame for duplexes composed of 10 base pairs marked a significant progress with respect to older studies.^{53,54} The diagonal terms of the Hamiltonian matrix (dipolar coupling) were calculated using atomic transition charges derived from quantum chemistry data⁵⁵ and taking into account various conformations determined by molecular dynamics simulations.^{56–58} These theoretical studies showed that, even in the presence of conformational disorder, the dipolar coupling alone is capable of inducing delocalization of the excitation over several bases. The number of coherently coupled bases in a given eigenstate k can be calculated by the participation ratio $PR = 1/L_k$,^{59,60} where L_k is given by

$$L_k = \sum_{\text{monomer } m} \left[\sum_{\text{states } i} (C_{k,m}^i)^2 \right].$$

The sum within the square brackets represents the contribution to the eigenstate $\langle k \rangle$ of different electronic states (i) belonging to the same monomer (m). The participation ratio was determined for two limiting cases (Figure 42.4). First, in the absence of spectral broadening, considering that each electronic transition of the monomeric chromophores is a delta function. Then, spectral broadening was taken into account. As the homogeneous width is not known, diagonal disorder was represented by the inhomogeneous width derived from decomposition of the experimental spectra in solution (Figure 42.1)

FIGURE 42.3 Schematic representation of (a) guanine–cytosine and adenine–thymine Watson–Crick base pairs and (b) a tetrad where guanines are linked via Hoogsteen hydrogen bonds and stabilized by a metal cation (gray circle).

FIGURE 42.4 Average participation ratios calculated for the 30 eigenstates of $(dCdG)_5 \cdot (dCdG)_5$ within the frame of the exciton theory. Two extreme cases are shown: the diagonal terms are represented either by delta functions (gray) or by Gaussian curves whose width corresponds to the inhomogeneous width of the experimental absorption spectra of nucleotides in aqueous solution (black).

using lognormal functions.⁵⁵ Even in the latter case, where the diagonal disorder is overestimated, many of the excited states, in particular those located near the absorption maximum, remain delocalized over several bases.^{57,58} The same theoretical studies showed that delocalization of the excitation does not induce large spectral shifts with respect to the spectra of noninteracting monomers.^{57,58} Burin et al.⁶² showed that the dipolar coupling within DNA hairpins composed of adenine–thymine pairs can be deduced from their absorption spectra.⁶²

Finally, theoretical calculations performed by quantum chemical methods for smaller systems than those studied by the exciton theory, also reported delocalization of the $\pi\pi^*$ transitions over two or more bases as well as mixing among $\pi\pi^*$ and charge transfer excitons.^{63–67}

42.5 Fluorescence of Monomeric Chromophores

42.5.1 Steady-State Measurements

Few studies have been consecrated to the steady-state fluorescence properties of the natural DNA bases in recent years. In 2002, we published refined room-temperature fluorescence spectra of the eight natural DNA nucleosides and nucleotides in water.⁵ Those of dA, dG, dT, dC, and 5MedC in water are shown in Figure 42.1, and the corresponding peak positions are given in Table 42.1. In contrast to the spectra published up to 2000, which were restricted to the near UV and blue region, the spectra in Figure 42.1 are extended further into the visible.

We determined the quantum yields using the fluorescence spectra recorded over the whole visible spectral region and compared their values with earlier ones.⁵ The fluorescence quantum yield values thus obtained were systematically higher than earlier ones and are given in Table 42.1.

Covalent substitutions have strong effects on the fluorescence properties. This is shown in a striking manner by methylation of the various bases. For 5MedC, the fluorescence peak value was found to be shifted by 14 nm to the red and the fluorescence quantum yield increased by a factor of six compared to dC.¹² The effect of methylation, as well as other substitutions, was also reported in a systematic study of various uracils in reference.⁶⁸ Uracil (Ura) itself has the lowest fluorescence quantum yield of all DNA/RNA bases.

TABLE 42.1 Fluorescence Maxima (λ_{fl}) and Quantum Yields (ϕ) of Monomeric Chromophores in Aqueous Solution

Compound	λ_{fl} (nm) ^a	$\phi \times 10^4$	τ_0	References
dA	307	0.86 ± 0.15		5
dAMP	306	0.68 ± 0.10	0.24 ± 0.01	5
dG	334	0.97 ± 0.08		5
dGMP	334	1.09 ± 0.10	0.15 ± 0.04	5
Thy	329	1.02	≈ 0.4	68
dT	330	1.32 ± 0.07		5
TMP	330	1.54 ± 0.11	0.36 ± 0.01	5
dC	328	0.89 ± 0.10		5
dCMP	328	1.15 ± 0.06	0.34 ± 0.01	5
5MedC	342	5.6 ± 0.1		12
Ura	312	0.35	≈ 0.4	68
5FUra	335	2.21	≈ 0.4	68

Thy, Ura, 5FUra, 5MedC refer to the Thymine, Uracil, 5-fluorouracil and 5-methylcytidine, respectively; dX and XMP/dXMP refer to 2'-deoxynucleosides and 2'-deoxynucleotides respectively, where X corresponds to the first letter of the name of the base.

^a Error: ± 1 nm.

For 5-methyluracil (thymine), the quantum yield increases by a factor of 3 and for 5-fluorouracil (5FUra), it increases by another factor of two. Furthermore, the maxima of the emission spectra are correlated with the quantum yields; for uracil, it is blueshifted with regard to thymine, while for 5FUra it is redshifted. This indicates that the emitting state is deactivated faster than its energetic relaxation.⁶⁸

42.5.2 Time-Resolved Measurements

42.5.2.1 Natural DNA Bases

Since 2000, numerous ultrafast spectroscopic studies in solution have contributed largely to characterize the fluorescence decays of the DNA monomeric chromophores. These studies have established that the excited-state decays are globally subpicosecond, even though there are differences from one system to another. In the large majority of cases, the decays have been measured close to the fluorescence maximum, that is, 330 nm in spite of the fact that, as mentioned earlier, the steady-state fluorescence extends well into the visible region. Visible wavelengths have only been probed in a few cases, showing that the fluorescence decays are ultrafast all over the spectral domain.

Peon and Zewail⁹ were the first to publish femtosecond fluorescence measurements of DNA/RNA nucleosides and nucleotides in room-temperature water solution using FU.⁹ They reported that all fluorescence decays are subpicosecond and monoexponential. The latter fact that was later revised.⁶⁹

We have, in a series of papers, refined the study of fluorescence from DNA monomeric constituents using femtosecond FU.^{5,8,17,68,70,71} A general feature for all molecules is that the fluorescence decay is strongly nonexponential. This is exemplified in Figure 42.5, where the fluorescence decay of TMP at 330 nm is shown over 7 ps, covering three decades in intensity. Also shown in this figure are the resulting curves from fitting with mono- and bi-exponential model functions.

Normalized fluorescence decays for the four mononucleotides at 330 nm are shown in Figure 42.6. In these experiments the apparatus function was 325 fs full width at half maximum (fwhm).

Regarding the two pyrimidine chromophores, there are only small variations between the fluorescence decays of the base, the nucleoside, and the nucleotide.^{5,18,68,70,71} The nonexponential decays are all dominated by an ultrafast component, between 150 and 300 fs and a slower one of ca. 1 ps having much lower amplitude (Table 42.2). In their broadband femtosecond Kerr-gate study of thymidine, Kwok et al.¹⁸ evoked the existence of a “doorway” state facilitating excited-state deactivation. This “doorway” state should mainly be $^1n\pi^*$ but mix with the close-lying $^1\pi\pi^*$ states.

FIGURE 42.5 Fluorescence decay of TMP recorded by FU at 330 nm. Also shown the apparatus function (gray) and the fits with mono- and bi-exponential functions.

FIGURE 42.6 Fluorescence decays of (a) dCMP (circles) and TMP (triangles) and (b) dAMP (triangles) and dGMP (circles) recorded by FU at 330 nm.

The fluorescence decay of adenine is characterized by an exceptionally long component of about 8 ps and a faster one of about 0.2 ps.^{5,8,72} The long component was assigned to the 7H tautomer, while the fast component was assigned to the canonical 9H tautomer. The simultaneous presence of two tautomers has only been observed in the case of adenine but not for dA and dAMP. The latter exist only in their 9H form and displays much faster fluorescence decays. Temps and coworkers studied adenine and adenosine by FU using a tunable excitation source.⁷² For the 9H-adenine tautomer, they found the decays to vary significantly with the excitation wavelength. This was explained by the opening of an additional nonradiative decay channel with decreasing excitation wavelength, possibly involving a near-lying $n\pi^*$ state. For adenosine, on the other hand, they found a monoexponential decay for all excitation wavelengths. Kwok et al.¹¹ studied the adenosine fluorescence by a broadband femtosecond Kerr-gated technique. Analysis of the fluorescence decays gave two components with lifetimes of ~ 0.13 and ~ 0.45 ps, which were associated these with the L_b and L_a $^1\pi\pi^*$ excited states, respectively. The 0.13 ps time constant was proposed to correspond to the $L_b - L_a$ internal conversion. This is in line with an interpretation based on the Strickler–Berg equation, suggesting that both $^1\pi\pi^*$ excited states contribute to the fluorescence of these chromophores.⁷³ However, the very low initial value (0.25) and the lack of any rapid decay of fluorescence anisotropy⁵ clearly show that the $L_b - L_a$ relaxation is too fast ($\ll 100$ fs) for L_b to contribute to the emission of dA/dAMP. This is corroborated by the fact that the steady-state emission spectra are independent of the excitation wavelength.⁵

Regarding the guanine chromophore, there are only data for the nucleoside and the nucleotide since guanine itself is not soluble enough in water. As their steady-state fluorescence spectra are by far the broadest, extending beyond 700 nm,⁵ we performed an extensive study of the dGMP fluorescence at various emission wavelengths.¹⁷ The fluorescence decays were found to depend strongly on the wavelength, indicating important spectral shifts (Figure 42.7). Incompatible with solvation dynamics, a global analysis revealed that the spectral evolution can be explained by an ultrafast redshift and broadening, in accordance with a recent theoretical study.⁷⁴ As in the case of dAMP, dGMP emission originates only from the first excited state.

The nonexponentiality of the fluorescence decays was rationalized as arising from two different “regions” of the potential energy surface of the first $\pi\pi^*$ state.^{68,74} The fast component should then correspond to the Franck–Condon region, while the longer one should be correlated with a “relaxed” geometry along the reaction coordinate toward a conical intersection (CI).

On Table 42.2, we have assembled fitted time constants from recent measurements of fluorescence decays at 330 nm of the four DNA bases and their nucleosides and nucleotides.

FIGURE 42.7 Fluorescence decays of dGMP recorded by FU at 330 (squares), 450 (circles), and 600 nm (triangles).

42.5.2.2 Role of Substituents

In addition to the natural DNA bases mentioned earlier, the fluorescence of various substituted bases has been studied by ultrafast spectroscopy. The objective was to elucidate conformational and electronic changes occurring during excited-state relaxation in close connection with theoretical studies. Among the possible substitutions, the most important one is without doubt methylation, which also occurs naturally. For example, thymine is just the 5-methylated form of the RNA base uracil.

The average fluorescence lifetime of 5MedC is about one order of magnitude longer than that of dC¹² (Figure 42.8b). Contrary to dC, the fluorescence decays of 5MedC depend strongly on the wavelength, indicating important spectral shifts.

We have paid special attention to the fluorescence of uracil and its derivatives.^{68,75–77} The effect of methylation, halogenation as well as that of other substituents on the first excited $\pi\pi^*$ and $n\pi^*$ singlet states were investigated by combining femtosecond fluorescence spectroscopy and quantum chemistry calculations.⁷⁸ The analysis relied on time-dependent density functional theory (TD-DFT) calculations, described in the following. Uracil itself has the fastest fluorescence decay observed for any nucleic acid. It is shorter than the time resolution (100 fs) of the FU setup. In contrast to methylation at the five position, methylation of uracil at positions 1, 3, and 6 does not induce any observable change on the fluorescence decays.⁷⁸ An example is given in Figure 42.8a, where the fluorescence decays of uracil and thymine are compared. These results, obtained with femtosecond resolution, contrast with those obtained for a “blocked” uracil (5,6-trimethylenuracil) by a TCSPC study combined with quantum chemistry calculations^{79,80} indicating that the six substituent is also involved in the internal conversion mechanism. According to these studies, the five and six substituents flip out of the molecular plane in opposite directions forming a biradical state.

Focusing on the five substituent, it was found that the fluorescence lifetime depends on its chemical nature.⁷⁸ The longest lifetime was observed for 5FUra. A particular behavior was observed in the case of the amino group.⁸¹ While amino substitution on the six position has no effect at all, amino substitution on the five position (5-aminouracil, 5AUra) causes a drastic increase in lifetime. The fluorescence decays of 5AUra depend strongly on the emission wavelength.

As noted in the preceding subsection, the adenine chromophore has the shortest fluorescence lifetime of the natural DNA constituents. However, slight structural changes may have enormous consequences on the electronic structure and thus the fluorescence properties. A striking example is provided by 2-aminopurine, which contrary to adenine (6-aminopurine) is highly fluorescent with a lifetime of

about 12 ns.^{82,83} Being a structural analog to adenine, it can replace the latter in stacked structures and form Watson–Crick base pairs with thymine allowing incorporation in the DNA double helix. Zewail and coworkers studied 2-aminopurine in water and in ethanol by FU, focusing on the early time evolution.⁶⁹ They observed important dynamical spectral shifts assigned to solvation dynamics.

Schwalb and Temps^{84,85} have published detailed FU studies of DMAdenine. This molecule presents dual fluorescence, covering the whole visible region. A global analysis of fluorescence decays between 290 and 650 nm enabled the authors to distinguish five different time constants from below 100 fs to 62 ps.

On Table 42.3, we have assembled fluorescence decays of substituted DNA bases.

42.5.2.3 Solvent Effects

Until recently, the solvent effects on the excited-state dynamics of DNA and its constituents were described as quite modest.³ This statement was based on the fact that the excited state decays actually faster than the solvent response. This may be true for “slower” solvents such as alcohols, but for water,

the solvation dynamics is actually too fast for the time resolution available with existing experimental setups. For many modified bases, on the other hand, important spectral shifts have been observed. However, the role of the solvent is not limited to its dynamical response. It can also influence the energetic ordering of the excited states, and thus the intramolecular dynamics.

We studied solvent effects on the fluorescence properties of chosen uracils.^{75–77,86} An example is given in Figure 42.9, where the fluorescence decays of 5FUra in acetonitrile, methanol, and water are compared. The fastest decays are observed in acetonitrile and the slowest in aqueous solution, while those observed in alcohols are intermediate.

In a FU study of isolated guanosine–cytosine base pairs in chloroform solution after 283 nm excitation, Schwab and Temps⁸⁷ also gave lifetimes of the individual chromophores. Since these “nucleosides” were modified with a tert-butyldimethylsilyl group instead of the deoxyribose group, some caution has to be made when comparing with aqueous solution data. The measured decays are dominated by a subpicosecond component followed by a small amplitude longer component. The subpicosecond components, 0.67 ps for dC and 0.84 ps for dG are fairly close to the fluorescence lifetimes measured in water solution. The longer components were assigned to $n\pi^*$ state emission, since this state is less destabilized in chloroform than in aqueous solution, and thus may be on the same level as or below the directly excited $\pi\pi^*$

FIGURE 42.9 Fluorescence decays of 5Fura in acetonitrile (squares), methanol (circles), and water (triangles) recorded by FU at 330 nm.

state. In a subsequent study of DMAdenine,^{84,85} they found that the lifetime of the intermolecular excited charge transfer state is much longer for dioxane solutions (1.4 ns) than that in aqueous solutions (62 ps).

42.5.3 Nonradiative Deactivation Mechanism

The ultrafast fluorescence decays of the DNA bases are due to highly efficient nonradiative processes occurring in the first excited singlet state. The detailed understanding of these nonradiative relaxation processes constitutes a major challenge from a theoretical point of view, and an increasing number of quantum chemistry calculations have addressed this problem for uracil/thymine,^{68,78,80,88–96} cytosine,^{79,91,97–105} adenine,^{65,89,106–121} and guanine.^{74,122–132}

The picture emerging is that the ultrafast decay of the excited state is due to highly efficient conical intersection between the first singlet $\pi\pi^*$ state and the ground state. These conical intersection are related to important geometrical changes occurring in the fluorescent ${}^1\pi\pi^*$ state, but the actual geometries involved differ from one molecule to the other. Complicating the picture even more is the fact that fluorescence only probes the first excited ${}^1\pi\pi^*$ state, but the calculated deactivation processes often involve near-lying dark states of ${}^1n\pi^*$ character. Most theoretical work has been performed for molecules in vacuo, while this chapter focuses on fluorescence of solutions. Evidently, the relative energy ordering of the ${}^1\pi\pi^*$ and ${}^1n\pi^*$ states is very sensitive to the environment, wherefore it is not always possible to compare theory and experiment. In general, the ${}^1n\pi^*$ states are strongly destabilized in aqueous solution and contribute less to the excited-state dynamics. An instructive comparison, from a theoretical point of view, of the nonradiative processes involved in the excited-state deactivation for the five DNA/RNA bases has recently been given by Serrano-Andrés and Merchán.⁴¹

Finally, it should be mentioned that transient absorption experiments probing from the UV to the infrared (IR) spectral domains have provided complementary information on the excited-state relaxation.^{4,133–136}

42.6 Fluorescence of DNA Helices

The fluorescence properties change dramatically when we go from monomeric chromophores to multichromophoric systems. This is reflected in both the fluorescence decays and the fluorescence anisotropies. The latter were used to evidence transfer of the excitation energy among the bases of duplexes occurring

before conformational changes. Therefore, we first describe this aspect, taking place on the femtosecond timescale, and we continue with the fluorescence decays, which extend up to the nanosecond timescale.

42.6.1 Energy Transfer

We have seen in Section 42.4 that the electronic coupling is capable of inducing delocalization of the Frank–Condon excited states within DNA double helices. According to this model, each eigenstate has its own spatial characteristics determined by the electronic transitions of the bases participating to the eigenstate. In the studies performed in the frame of exciton theory,^{55–58} the eigenstate topography was given by the square of the coefficients ($C_{k,m}^i$). The latter depend on the conformation of the duplex, which determines the strength of the electronic coupling. As an example, Figure 42.10 shows the topography corresponding to one eigenstate of $(\text{dCdG})_5 \cdot (\text{dCdG})_5$ averaged over 100 conformations.⁵⁸ Different eigenstates have different topographies.^{56–58} Therefore, it is expected that population of an upper eigenstate and subsequent internal conversion will result in a transfer of the excitation energy within the helix, which is known as intraband scattering.

As the polarization of the electronic transitions associated with the various eigenstates of a duplex are also different, intraband scattering should lead to a loss of fluorescence anisotropy. But molecular motions may produce the same effect. Therefore, probing fluorescence anisotropy on early times, when molecular motions have not the time to occur, in particular for large systems, may provide information about energy transfer.

We determined the fluorescence anisotropy decays of DNA duplexes and G-quadruplexes using FU (Section 42.2) and compared them with the anisotropy decays corresponding to a stoichiometric mixture of noninteracting nucleotides.^{13–16,20} Table 42.4 shows some typical anisotropy values obtained from these experiments. We found that the fluorescence anisotropy of all the studied duplexes decays more rapidly than that of noninteracting chromophores whose size is much smaller. These results reveal that energy transfer takes indeed place within the helices on the subpicosecond time domain.

More important, the anisotropy values detected for double helices are lower than that of the nucleotide mixture already at zero time, which means that the onset of energy transfer occurs at times shorter

FIGURE 42.10 Topography of the eigenstate $\langle 10 \rangle$ determined for $(\text{dCdG})_5 \cdot (\text{dCdG})_5$. The coefficients ($C_{10,m}^i$) represent the contribution of the chromophore m in its i -th excited state to the eigenstate $\langle 10 \rangle$. The upper and lower parts of each histogram refer to chromophores located on each one of the strands. Average values obtained for 100 different conformations of the duplex in the absence of diagonal disorder.

	420	0.22	0.15	0.11	0.06

than the 100 fs, time resolution of our setup. Such an ultrafast energy transfer cannot take place via Förster transfer considering, in particular, the very large Stokes shift associated with the monomeric chromophores (Figure 42.1).

Ultrafast energy transfer takes also place in the case of self-associated guanines.⁵⁰ Figure 42.11 shows the anisotropy decay determined for self-associated triguanosine monophosphates, likely to form four-stranded structures⁴⁹ composed of only one type of chromophore. Their fluorescence anisotropy is already lower than that of dGMP at zero time. Moreover, at 1 ps, it dwindles down to 0.02 whereas that of the mononucleotides remains higher than 0.10.

Energy transfer, possibly assisted by conformational motions, may continue on longer timescales, until the whole population of the excited states relaxes to the ground state.

FIGURE 42.11 Fluorescence anisotropy determined for dGMP (circles) and self-associated triguanosine diphosphates (triangles) at 350 nm.

42.6.2 Fluorescence Decays

The fluorescence decays of DNA helices recorded by FU slow down upon increasing the emission wavelength. At least two time constants, whose values vary with the emission wavelength, are necessary in order to fit the decays with exponential functions. This is not surprising for such multichromophoric systems, knowing that even the fluorescence decays of the monomeric chromophores cannot be described by single exponentials (Section 42.5). Again here, the average lifetime $\langle\tau\rangle$ is used in order to evaluate the sequence effect on the fluorescence decays. Table 42.5 shows the $\langle\tau\rangle$ values determined for various model systems.

The lifetimes of the single strands containing only one type of base are all longer than those of the corresponding nucleotides. The most important lengthening is encountered in the case of adenine and, even more, of guanine strands. For these systems, the fluorescence decays slow down with increasing number of bases.³⁸ We recall that guanine single strands have the propensity to self-associate but so far only one system characterized by a well-defined quadruplex structure was studied. This is formed by association of four single strands d(TGGGT); its FU decay is presented in Figure 42.12 together with those of TMP and dGMP.⁵⁰

A noticeable size effect is also reported for homopolymeric duplexes composed of adenine–thymine pairs, the oligomer (dA)₂₀·(dT)₂₀ and the polymer poly(dA)·poly(dT) (ca. 2000 base pairs).¹³ Not only is the lifetime at the fluorescence maximum longer when going from the oligomer to the polymer, but the fluorescence anisotropy also decays faster indicating a more efficient energy transfer.

TABLE 42.5 Average Fluorescence Lifetimes $\langle\tau\rangle$ (in ps) Determined for Various DNA Strands from FU Measurements

FIGURE 42.12 Fluorescence decays of dGMP (dashed line), TMP (dotted line), and (TG₄T)₄ (solid line) recorded by FU at 360 nm.

Moreover, the maxima of the steady-state absorption and emission spectra shift to slightly higher energies. All these effects are the fingerprints of a collective behavior becoming more pronounced as structural disorder diminishes with increasing size. The size effect on the fluorescence decays of alternating adenine–thymine duplexes is less pronounced.¹⁴ However, even here the fluorescence anisotropy decays more rapidly for the polymer compared with the oligomer. For the latter, a combined broadband time-resolved fluorescence and transient absorption study suggested the existence of an intermediate weakly emitting species.¹⁹

Focusing on the polymeric duplexes, the FU decays exhibit a clear sequence effect.¹³⁷ The decays of poly(dA)·poly(dT), poly(dAdT)·poly(dAdT), and poly(dGdC)·poly(dGdC) are successively longer, equal, and shorter than those of an equimolar mixture of the constitutive nucleotides. An acceleration of the excited-state dynamics was also found upon formation of isolated Watson–Crick guanine–cytosine pairs dissolved in chloroform.⁸⁷ These data were correlated with theoretical calculations, which pointed out the role of interbase proton transfer.^{138–140}

The introduction of guanine–cytosine pairs in homopolymeric purine–pyrimidine oligomeric duplexes leads to a decrease of the FU lifetimes.³⁸ Nevertheless, when the guanine/adenine ratio increases, a more complex behavior is observed, assigned to important structural changes.

In contrast to the monomeric chromophores, fluorescence emission of DNA helices contains long-lived components. Already described in earlier studies,^{27,141} they have been revisited recently in combination of FU and TCSPC measurements. As in the case of FU, TCSPC signals exhibit strong wavelength and sequence dependence.^{15,21} This is also true for the double strand poly(dG5MedC)·poly(dG5MedC).²² For all the studied systems, fits of the fluorescence decays with multiexponential functions gave time constants amounting up to a few nanoseconds and contributing to the signal with weak amplitude.

Extended time-resolved investigations were carried out for the duplex poly(dA)·poly(dT). A nonlinear fitting/deconvolution procedure was performed by merging the data obtained by FU and TCSPC. Then, using the parameters derived from this global fit, the percentage of the emitted photons per decade of time was calculated for various wavelengths. Figure 42.13 shows the time distribution of the photons emitted at 330 and 420 nm up to 10 ns together with the steady-state fluorescence spectrum. We remark

FIGURE 42.13 Fluorescence spectrum of poly(dA)·poly(dT). The inset shows the percentage of emitted photons per decade of time at 330 and 420 nm, resulting from a combined fit of the fluorescence decays recorded by FU and TCSPC using multiexponential functions.

that near the emission maximum most of the photons are emitted between 1 and 10 ps whereas the red tail of the spectrum is dominated by photons emitted at times longer than 1 ns.

The identification of the various emitting states of DNA helices is an intricate problem. The time constants derived from the fits with multiexponential functions, used in order to quantify the fluorescence decays, are not necessarily associated with precise excited states. As mentioned previously, a large multitude of excited states may exist for a given DNA helix, governed by electronic coupling and associated with the various conformations: $\pi\pi^*$ states localized on a single base, Frenkel excitons delocalized over a few bases, charge transfer states, $n\pi^*$ states,^{134,142} as well as combinations among them. The situation becomes even trickier due to the excitation energy transfer processes. In this respect, it is important to stress that, when energy transfer takes place within a low-dimensional multichromophoric system, the time constants derived from fits with multiexponential functions do not have physical meaning.¹⁴³ However, the change of the fluorescence anisotropy decays as a function of the emission wavelength observed for the same excitation wavelength^{13,14} clearly shows the existence of a variety of bright emitting states.

The great complexity of the fluorescence decays and fluorescence anisotropy decays observed for DNA helices contrasts with the relative simplicity of the transient absorption signals. In the latter case, only two time constants, assigned to localized $\pi\pi^*$ excited states and intrastrand excimers^{4,36,37} were determined in most studies. Yet, the fingerprint of Frenkel excitons, living a few ps and depending of the size of the helix, was reported in a transient absorption study.¹⁴⁴

42.7 Concluding Remarks

We have described earlier how sophisticated spectroscopic measurements have been performed during the past few years for DNA components despite the extremely weak fluorescence quantum yields. By following specific and rigorous experimental protocols, these measurements have started to unravel the very complex mechanisms that govern the excited-state dynamics.

Evidently, the experimental work has to be supported by theoretical calculations. This is relatively easier for the monomeric chromophores, even if modeling solvent effects correctly is not an easy task and more efforts are still needed. Modeling excited-state relaxation gets much trickier in the case of model helices for which two different approaches have been followed so far. On the one hand, quantum chemical calculations were performed for small systems taking into account orbital overlap and solvent.^{65,66} On the other hand, calculations in the frame of the exciton theory, neglecting orbital overlap but studying larger systems.¹⁴⁵ Ideally, the combination of both methods is necessary and can be done properly only in close connection with the experiments.

Collecting detailed experimental data such as fluorescence decays, fluorescence anisotropy decays, and time-resolved fluorescence spectra recorded over several decades of time will be a decisive step. Needless to say this has not yet been realized for any DNA strand, but we are fairly optimistic that this is now within reach. Modification of various parameters such as the ionic strength, the size of the helix, or the base sequence, known to induce conformational changes, is expected to provide precious additional information. Finally, investigation of nucleosomes (DNA–histones complexes) will provide certainly a more biologically relevant picture. This poses many problems from experimental point of view and constitutes a real challenge. After submission of the present chapter, two important articles dealing with DNA fluorescence have been published. One of them describes the first photophysical study of UVA-induced fluorescence in DNA model helices¹⁴⁶ whereas the other reports on fluorescence of natural DNA.¹⁴⁷ Moreover, two perspectives, dedicated to monomeric DNA building blocks¹⁴⁸ and DNA helices,¹⁴⁹ have appeared.

43.1 Introduction

Action spectroscopy is a general approach toward identifying the receptor pigment(s) for a particular photobiological response or effect. The early identification of major chromophores, such as rhodopsin and chlorophyll, depended on comparison of the action spectra for vision and photosynthesis, respectively, with the absorption spectra of candidate pigments.

It is remarkable how few chromophore types with intrinsic photochemistry are employed in photobiological systems (Delbrück 1976; Lipson and Horwitz 1991). A basic list consists of the following: (a) retinal pigments (in rhodopsins), (b) tetrapyrroles (including chlorophylls and phycobiliproteins including phytochromes), (c) flavin and pterin accessory chromophores (in cryptochrome and phototropin pigments; these are blue-light receptors in plants and microorganisms and, in the case of cryptochromes, in animals too), (d) hypericin pigments (Song 2005), and (e) the *p*-coumaric acid chromophore of the photoactive yellow protein (PYP) of *Ectothiorhodospira halophila* (Meyer et al. 1987; Schlichting and Berendzen 1997).

This chapter focuses on analytical methods for measuring action spectra, with emphasis on those derived from fluence–response data. For a set of examples, the reader can consult studies of *Phycomyces*, not only of its phototropism (Ensminger et al. 1990; Galland and Lipson 1985a,b) but also of the light-growth response (Ensminger and Lipson 1991; Ensminger et al. 1991), carotene synthesis

(Bejarano et al. 1990), and differentiation (Corrochano et al. 1988), as well as studies of other blue-light systems (Baskin and Iino 1987; De Fabo et al. 1976; Galland and Senger 1988; Presti and Galland 1987; Schmid et al. 1987). The later studies on *Phycomyces* employed formal data analysis methods—including error analysis with error propagation (Baird 1994) in the curve fitting and parameter estimation—as summarized elsewhere (Lipson 1991), so that error bars could be assigned to the points in the action spectra derived from the fluence–response raw data points and their error bars.

For other representative action spectra, the reader is referred to the following chapters in this volume and to the major photobiology journals: *Photochemistry and Photobiology*, the *Journal of Photochemistry and Photobiology*, *B: Biology*, and *Photochemical and Photobiological Sciences*. There are also a number of review articles that give various perspectives on action spectroscopy (Coohill 1991, 1992; Foster 2001; Galland 1987; Hartmann 1983; Jagger 1967; Lipson 1991; Schäfer and Fukshansky 1984; Schäfer et al. 1983; Shropshire 1972). For practical advice on light sources and radiometry, the reader should consult standard photobiology texts (Björn 2008; Häder and Tevini 1987; Smith 1989).

43.2 Alternative Types of Action Spectra

The most elementary type of action spectrum consists of a graph of some response or effect as a function of wavelength, under conditions where the photon fluence is maintained constant at all wavelengths. This convenient approach, however, can be confounded by the frequent circumstance that the response may depend nonlinearly on the fluence (or fluence rate). For example, if at some wavelengths the response is in a saturation region, then the action spectrum will be “clipped” (*viz.* peaks flattened) at those wavelengths; similarly, other types of nonlinearities will produce other distortions. Accordingly, a preferred way of obtaining an action spectrum—provided that the experimenter is willing and able to apply the additional effort needed—is to derive it from fluence–response curves (sometimes called dose–response curves, by analogy with pharmacology). In this way, one obtains essentially a graph of *sensitivity*, rather than response, as a function of wavelength. Operationally, one determines for each wavelength the photon fluence required to achieve a standard response level and then plots the reciprocal of that photon fluence as a measure of sensitivity. The graph so obtained is sometimes called an “equal-response action spectrum,” which is not subject to the nonlinear distortions, and is therefore more likely to represent the absorption spectrum of the responsible chromophore (subject to various considerations specified in the following).

43.3 Photophysics

After a chromophore absorbs a photon, a number of alternative photophysical events may ensue. These can be represented graphically by a “Jablonski diagram” depicting transitions among the electronic, vibrational, and rotational states of the pigment molecule (Grossweiner 1989). Upon absorption of a photon, the molecule is promoted from the ground state (usually of singlet character and designated therefore as S_0) to an excited electronic state (also singlet and designated as S_1 , S_2 , etc.); the molecule generally becomes excited with respect to vibrational and rotational motions as well (the corresponding energy spacings among these states are progressively lower than those between electronic states). The molecule then de-excites rapidly by internal conversion and vibrational relaxation to the lowest excited singlet level S_1 before there is time for photochemistry to take place. Consequently, regardless of the wavelength of the incident photon that excited the molecule, the molecular excitation relaxes rapidly to the bottom vibrational levels based on S_1 . Then the relevant photochemistry proceeds either directly from S_1 or else—following intersystem crossing from the singlet to the triplet manifold—from the lowest triplet state T_1 provided that the excitation energy has not been dissipated in the meantime by internal conversion or fluorescence.

43.4 Illumination Units

Fluence–response curves are sometimes measured using broadband rather than monochromatic light because (a) higher fluence rates are achievable with broadband filters and (b) unless one is trying to study the wavelength dependence of a particular response or effect, it may be more representative of natural illumination conditions to use broadband light covering the range of sensitivity. For example, in studies of photogravitropism “threshold curves” of *Phycomyces* wild-type and mutant strains (Galland and Lipson 1985a,b, 1987), it is customary to employ broadband-blue illumination at fluence rates extending over a 10 decade range. With broadband illumination, the units pertain to *energy* fluence rather than *photon* fluence. The energy units are J m^{-2} for fluence and $\text{J m}^{-2} \text{s}^{-1}$ (or, equivalently, W m^{-2}) for fluence rate. In action spectroscopy, however, one must use monochromatic light (occasionally in *combination* with polychromatic background light; see chapter in this volume by T. Coohill). It is then preferable to use photon units: photons m^{-2} for fluence and photons $\text{m}^{-2} \text{s}^{-1}$ for fluence rate.

43.5 Conditions for Measurement and Interpretation of Action Spectra

The shape of an action spectrum may be distorted significantly from the absorption spectrum of the responsible pigment. To obviate such distortions, the experimenter should strive to satisfy the following conditions insofar as possible (Jagger 1967; Shropshire 1972):

1. The quantum efficiency (or quantum yield)—defined as the probability that a particular type of event of photobiological or photochemical interest occurs as the result of absorption of a photon—should be independent of wavelength.
2. The absorption spectrum of the receptor pigment should be the same whether measured *in vivo* or *in vitro*.
3. Screening or shading pigments, as well as scattering effects, should not cause significant wavelength-dependent distortion. Scattering is generally stronger at shorter wavelengths, but the trend is a gradual one and normally would not obscure the key features of an action spectrum; instead, scattering tends to superpose a sloping baseline, which can be largely eliminated, if desired, by use of a suitable scattering reference.
4. When an action spectrum is derived from fluence–response curves, the condition of reciprocity should be valid over the range of fluence rates and exposure times used. In other words, the response should depend on the *product* of fluence rate and exposure time but should not otherwise depend on either factor.
5. Light should not be totally absorbed by the sample for any wavelength under study. More specifically, an ample fraction of the incident light (a practical guideline is 50%) should reach the receptor pigment region under all conditions.

43.6 Reciprocity

For measurements employing continuous illumination, the stimulus strength is given by the fluence rate itself. With pulse illumination, however, the fluence can be adjusted by varying the exposure time (pulse width) and/or the fluence rate. Considering the kinetics of photochemical and subsequent dark reactions, it is preferable in most circumstances to maintain the exposure time constant and vary the fluence rate. In general, though, one should establish the range of validity of reciprocity between exposure time and fluence rate (see the preceding text).

43.7 Fundamental Derivations

For action spectroscopy with pulse illumination, assume that the response R can be expressed as a function of the product of four variables:

$$R = R(\phi\sigma_1 I_1 \Delta t), \quad (43.1)$$

where

ϕ is the quantum efficiency (or quantum yield)

σ_1 is the cross section (see the following) at wavelength λ_1

I_1 is the fluence rate (*Note:* the traditional symbol I stands for “intensity,” which is sometimes used informally in place of fluence rate; however, according to strict radiometric terminology, intensity is defined as the power per unit solid angle)

Δt is the exposure time (pulse duration)

The fluence is given by $F_1 = I_1 \Delta t$.

To derive an equal-response action spectrum from fluence–response curves, the first step is to specify a “criterion” response level. Then, for each wavelength, one determines the fluence (or fluence rate) needed to produce that standard response. Choices for the criterion response include (a) some fixed absolute level, (b) a percentage (typically 50%) of the maximum response level, which itself may depend on wavelength, (c) the maximum response (peak) level, for those instances where the response descends at high fluence after reaching a peak, or (d) the absolute threshold fluence rate (often extrapolated downward to the baseline from the linearly rising part of the fluence–response curve; note that an alternative approach that should be avoided would be to try to find the limiting fluence at which there just begins to be a perceptible response; the difficulty is that this measure is highly susceptible to experimental noise and subjective judgment); see the following for a further discussion of threshold measurements.

If both fluences F_{λ_1} and F_{λ_2} elicit the same response level—the criterion response—and if one assumes that Δt is the same in both experiments (or, if reciprocity applies, one can correct for the different values of Δt), then the argument of the function in Equation 43.1 is the same for both experiments at these two wavelengths, λ_1 and λ_2 . If the quantum efficiency ϕ is assumed to be the same at both wavelengths, then

$$\frac{\sigma_{\lambda_1}}{\sigma_{\lambda_2}} = \frac{F_{\lambda_2}}{F_{\lambda_1}}. \quad (43.2)$$

It is assumed implicitly that the fluence–response curves are monotonic or at least that the corresponding criterion response points on the curves are chosen (otherwise, if the fluence–response curve were, e.g., bell shaped, there would be two values of fluence with the same response value, and one could conceivably err by choosing noncorresponding points on curves for different wavelengths). From Equation 43.2, it is evident that the cross section at any wavelength λ is inversely proportional to the applied fluence that produces the criterion response at that wavelength or $\sigma_\lambda \propto F_\lambda^{-1}$.

If, instead, the response is measured as a function of fluence rate rather than fluence, then a derivation similar to that mentioned earlier, starting from the equation

$$R = R(\phi\sigma_1 I_1) \quad (43.3)$$

leads to the relation

$$\frac{\sigma_{\lambda_1}}{\sigma_{\lambda_2}} = \frac{I_{\lambda_2}}{I_{\lambda_1}} \quad (43.4)$$

or

$$\sigma_\lambda \propto I_\lambda^{-1}.$$

43.8 Relationship between Extinction Coefficient and Cross Section

The extinction coefficient ϵ is used in conventional spectrophotometry and measured in the traditional units of $\text{L mol}^{-1} \text{cm}^{-1}$. It can be related by a conversion factor to a quantity from physics, the absorption cross section (introduced in Section 43.7), in traditional units of cm^2 . The ratio between the fluence rate I transmitted through a spectrophotometric sample and the incident intensity I_0 can be derived from the following relations:

$$\frac{I}{I_0} = 10^{-\epsilon cl} = e^{-\sigma nl}, \quad (43.5)$$

where

c is the molar concentration of the pigment

ℓ is the internal path length through the cuvet (usually 1 cm)

σ is the absorption cross section

n is the pigment concentration in units of molecules per cm^3

The expression in the first exponent, ϵcl , represents the absorbance, A .

The extinction coefficient and the cross section are therefore interrelated by the following conversion formula:

$$\epsilon = 2.62 \times 10^{20} \sigma, \quad (43.6)$$

where

ϵ is in units of $\text{L mol}^{-1} \text{cm}^{-1}$

σ is in cm^2

As an example of applying this conversion formula, consider riboflavin (or other flavin), which has an extinction coefficient of $1.25 \times 10^4 \text{ L mol}^{-1} \text{cm}^{-1}$ (at $\sim 450 \text{ nm}$), then $\sigma = 4.8 \times 10^{-17} \text{ cm}^2$. This represents the effective target area the chromophore presents for absorption of light. As another example, rhodopsin, with an extinction of $4 \times 10^4 \text{ L mol}^{-1} \text{cm}^{-1}$ (at $\sim 500 \text{ nm}$), has $\sigma = 1.5 \times 10^{-16} \text{ cm}^2$.

43.9 Derivation of Action Spectrum from Fluence–Response Curves

Figure 43.1 shows a set of five idealized fluence–response curves. The following discussion will demonstrate how action spectra can be derived from such curves. The hypothetical response is presumed to be measured as a function of the photon fluence; alternatively, fluence rate could have been chosen as the independent variable. The fitting function of the form $ax/(x + b)$, where x stands for the fluence (or fluence rate), is plotted for the five wavelengths on both (a) logarithmic and (b) linear scales for x . In this example, wavelength λ_3 is the most effective one because the least amount of light is required to achieve the criterion response level, chosen here to be half of the maximum response. Conversely, λ_5 is the least effective. So, when this set of “data” is converted into an action spectrum, the ordinate representing the sensitivity, or effectiveness, will be high for λ_3 and low for λ_5 .

In the semilogarithmic plot (Figure 43.1a), the curves all have the same sigmoidal shape and differ only by lateral displacement. The symmetrical sigmoidal shape is a property of the hyperbolic saturation

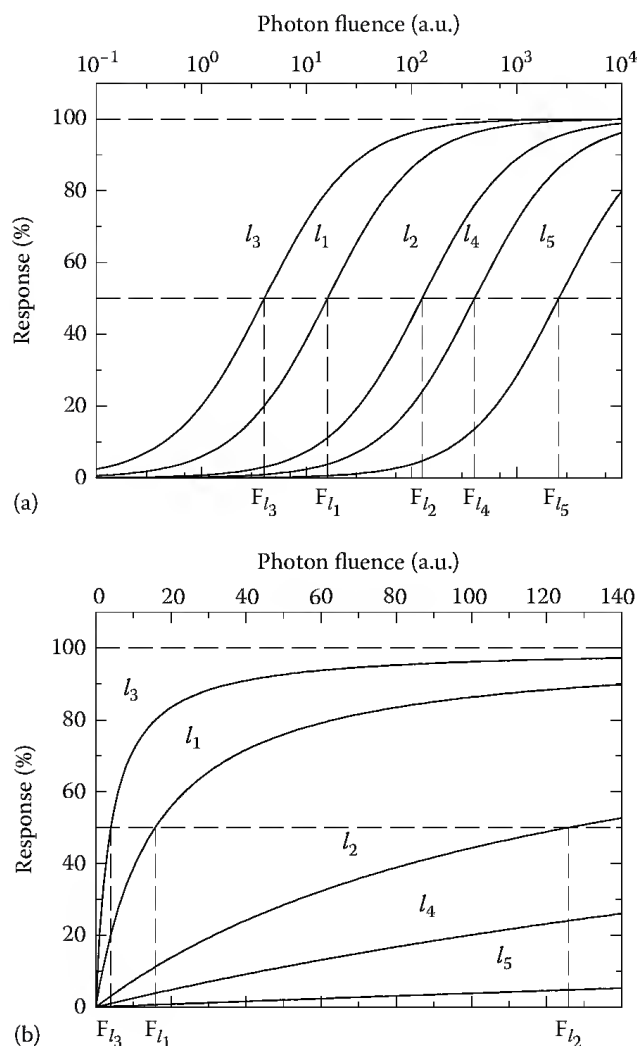

FIGURE 43.1 Generic fluence–response curves for five wavelengths (λ_1 through λ_5) shown on logarithmic (a) and linear (b) scales for photon fluence. The curves represent the hyperbolic saturation function of the form $ax/(x + b)$, where x is the fluence (also denoted in this chapter by the symbol F). On a semilogarithmic scale (a), the curves all have the same sigmoidal shape (see functions in rows 4 and 5 of Table 43.1). The fluence F needed to produce the standard criterion response (here chosen to be 50%) at each wavelength is shown by the vertical dashed lines. The designation of “arbitrary units” on the abscissa scales above each graph means that no importance should be given to the absolute numbers used in this example and, implicitly, that fluence rate could be used instead of fluence if continuous rather than pulse illumination were employed; the actual units of photon fluence would be mol m^{-2} . If photon fluence rate were used instead, the units would be $\text{mol m}^{-2} \text{s}^{-1}$.

function, which is frequently used to fit fluence–response curves and other types of stimulus–response relationships in sensory physiology (Naka and Rushton 1966; Williams and Gale 1978), in photochemical kinetics (Lipson and Presti 1980), and in other areas of biophysics and biology, including the well-known Michaelis–Menten enzyme kinetics.

The procedure for deriving the action spectrum (Figure 43.2) from these curves is straightforward. The action spectrum ordinate, often labeled as “relative quantum effectiveness” or just “effectiveness,” is simply the reciprocal of the fluence required to produce a criterion response (see Equations 43.2 and 43.4). Some authors choose instead to label the ordinate in “relative units,” for example, by normalizing several action spectra to the wavelength of maximal effectiveness of one of them. However, it is preferable to retain the proper physical units of $\text{m}^2 \text{mol}^{-1}$. If fluence rate–response curves are used instead as

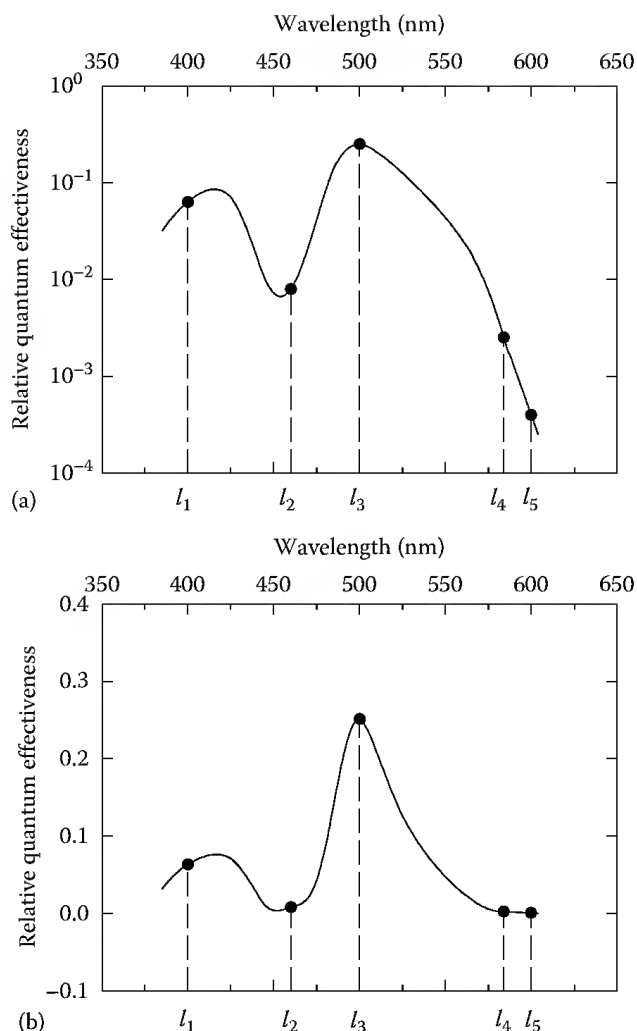

FIGURE 43.2 Five-point action spectrum derived from the fictitious fluence–response curves in Figure 43.1. The relative quantum effectiveness, shown on logarithmic (a) and linear (b) scales, is simply the reciprocal of the photon fluence F required at each wavelength to achieve the criterion response, as indicated in Figure 43.1.

the basis for the action spectra, then the corresponding reciprocal units for the “effectiveness” are $\text{m}^2 \text{s mol}^{-1}$. In the former case—based on fluence rather than fluence rate—the units of the action spectrum ordinate are reciprocal to the fluence units, which themselves are essentially m^{-2} (apart from dimensionless entities such as photons or moles of photons). Consequently, the action spectrum physical units are m^2 , indicating that some kind of area quantity is involved. This dimensionality corresponds specifically to that of a *cross section* (see relationship, given earlier, between extinction coefficient and cross section).

For a given application, one has to decide between plotting the action spectrum on a logarithmic or linear ordinate. In *Phycomyces*, with a sensitivity range exceeding 10 decades, it is particularly appropriate to plot such action spectra on a logarithmic ordinate (Galland and Lipson 1985a,b, 1987). This choice is advantageous for comparing action spectra with one another or with absorption spectra of putative receptor pigments. Spectra that differ only by a scale factor will have identical shape on a logarithmic scale (and will be displaced by the logarithm of the scale factor). Now, if such spectra were truly identical, apart from a scale factor, they could be forced to have the same shape on a linear scale too, simply by normalizing them at any wavelength of choice (thereby superposing the spectra completely). The practical problem, however, is that in the usual case when spectra are similar but not identical, choosing one wavelength or another for normalization will lead to different relative shapes.

Such ambiguity and subjectivity are avoided by doing the comparison on a logarithmic scale. On the other hand, though, using a linear ordinate scale has the advantage that it is the more familiar way of viewing absorption spectra, for example, the chart records from traditional spectrophotometers.

The abscissa of an action spectrum is usually presented as a wavelength scale. On the basis of quantum mechanical principles, it would be preferable to use an energy rather than a wavelength scale; the two are related reciprocally according to the relation $E = hc/\lambda$, where E is the energy of a photon of wavelength λ , h is Planck's constant, and c is the speed of light. When an action or absorption spectrum is plotted as a function of energy, the positions of peaks are linearly related to transitions between the energy levels corresponding to molecular states (as on a Jablonski diagram; see the preceding text). This is particularly worthwhile in the case of rhodopsin-type pigments in animals—as well as in halophilic bacteria and algae—because such pigments have spectra of standard shape except for lateral shifts in the energy of maximum absorption and vertical shifts in the absolute extinction or effectiveness. Nevertheless, most action and absorption spectra are plotted customarily on a wavelength scale for the abscissa, in keeping with the usual display from spectrophotometers.

43.10 Additional Fitting Functions

The hyperbolic saturation function of the form $ax/(x + b)$ often arises in biophysical and biochemical applications. It is more obvious that this represents a hyperbola, if it is written in a double-reciprocal form as in the Lineweaver–Burk transformation of the Michaelis–Menten enzyme kinetics that employs this type of function. Other contexts where this function appears are monomolecular photochemical kinetics (Lipson and Presti 1980) and visual physiology (Naka and Rushton 1966; Williams and Gale 1978). In the present context of action spectroscopy, x would stand for the fluence or, in some cases, the fluence rate. When $x = b$, the function is at the half-maximum level that is often chosen to be the criterion response. So, when one performs least squares fits using such a function, the parameter b is the estimate of the fluence needed for the criterion response, and the effectiveness (action spectrum ordinate) is just b^{-1} .

Table 43.1 gives several functional forms that are useful for fitting fluence–response curves. These are all based on the hyperbolic saturation function given earlier and shown in the top row of the table. In certain cases, fluence–response curves have a two-component (biphasic) structure. The first component reaches a plateau as in Figure 43.1, and then, at high fluence, a second component appears that may or may not approach saturation at the maximum available fluence. For such a two-component curve, if saturation is reached for the second component, then the function in the second row of Table 43.1 may apply, perhaps with the addition of exponents n (often attributable to cooperativity) for each component, as in the Hill function in the third row. Otherwise, if saturation is not reached at some or all wavelengths, then the function in the last row of Table 43.1 may be useful. The second and third terms of that function together have the shape of a hyperbola when plotted on a semilogarithmic scale (i.e., with abscissa $\log x$). Note that this hyperbola, with a (rising) slant asymptote at high fluence, is unrelated to the hyperbola functions (for linear axes) in the first and second rows.

The functions in Table 43.1 depend nonlinearly upon their parameters (unlike the case of a polynomial, e.g., where the coefficients are linear parameters). Therefore, it is appropriate to use nonlinear least squares data analysis methods. These are widely available and are specifically incorporated in graphical packages such as Origin® (OriginLab Corporation). For applications, like the present one of deriving action spectrum values from fluence–response curves, that require error-propagation methods, it is important to have the *variance–covariance matrix* of the parameter estimates obtained by least squares methods. This matrix is made available in Origin. For those preferring to develop their own data analysis programs, a valuable resource is the *Numerical Recipes* series of books and software (<http://www.nr.com>), which includes source code in Fortran, Pascal, C, and C++ programming languages for various numerical analysis problems including nonlinear regression (nonlinear least squares), applicable here.

TABLE 43.1 Representative Functions for Fluence–Response Curve Fits

Description	Function	References
Hyperbola	$\frac{ax}{x+b}$	Corrochano et al. (1988)

^a This function consists of a sum of two hyperbolas plus an optional constant, h . The coefficients a and c may be positive or negative for saturation components that rise or fall, respectively.

^b These two equivalent functions are derivable from the Hill function (e.g., familiar in the context of ligand binding for hemoglobin) in the third row, with the substitutions $u = \log x$ and $k = \log b$. They represent the sigmoidal shape taken on by the Hill function when plotted on a semilogarithmic scale, that is, plotted against $\log x$ instead of x . In the special case with $n = 1$, these sigmoidal functions are equivalent to the hyperbola function in the top row (see [Figure 43.1](#)). In general, the Hill exponent need not be an integer.

^c The last two terms together comprise a hyperbola when plotted on a *logarithmic* scale for x . Note that this usage of hyperbola is quite different from that in the top row function. The hyperbola here has a horizontal asymptote for small x and a slant asymptote with slope $2c$ for large x .

43.11 Null and Threshold Action Spectra

Another way to measure action spectra is to employ a balance or null method, in which the criterion response is zero, but without the need to work at absolute threshold levels. For example, two lights, one a fixed “reference” light and the other a variable “test” light could be applied, as appropriate, from opposite directions or in temporal alternation, in such a way that no net response occurs. Examples for action spectroscopy on *Phycomyces* are balance experiments on phototropism (Galland and Lipson 1985a,b) and null experiments on the light-growth response (Ensminger and Lipson 1991; Ensminger et al. 1991).

In general, when sigmoidal and other functions are fit to fluence–response curves for the purpose of action spectroscopy, there is another clear choice for criterion response besides the half-maximum (50%) level, namely, a “threshold” response level. However, as mentioned earlier, thresholds (defined as the highest fluence at which there is no apparent response) *per se* are difficult to measure because of signal-to-noise considerations at low response levels. A more practical measure of the threshold can be defined operationally as the fluence at which the tangent line at the inflection point (or midpoint) intersects the baseline. This level is generally somewhat higher than the actual threshold, but it has the advantages of being much better defined and easier to measure. For a fluence–response curve, or component thereof, described by the Hill function (third row of [Table 43.1](#)), the operational threshold fluence is smaller than the midpoint fluence by a factor of $e^{-2/n}$. In the special case when $n = 1$ (top two rows of [Table 43.1](#)), the factor is just e^{-2} . On a \log_{10} scale, this threshold fluence is displaced to the left of the midpoint fluence by $0.869/n$ “log units.”

43.12 Conclusion

This chapter on action spectroscopy, which has given some practical methodology for obtaining action spectra from fluence–response data, has not delved into action spectroscopy for photochromic receptors, such as phytochrome, a complex topic dealt with in many of the references on action spectroscopy cited in the introduction. Photochromic systems, and others with significant kinetic complexity, call for a mathematical approach termed “analytical action spectroscopy” by Hartmann (1983). Beyond the key recommendation of basing action spectra on fluence–response curves, readers are encouraged to apply formal data analysis techniques, including error analysis, for analyzing experimental results in action spectroscopy research. Details on such methods are available elsewhere (Lipson 1991).

44.1 Introduction to Ultraviolet Radiation

Ultraviolet (UV) radiation is the portion of the electromagnetic spectrum that extends from the lower wavelength limit of human vision (usually defined as 380–400 nm) to wavelengths as short as about 10 nm, where it overlaps the x-ray region. In the natural environment, the shortest wavelength of sunlight that can be routinely measured at the earth's surface is about 290 nm, largely due to the absorption properties of ozone and other atmospheric gases. So, the only environmentally relevant UV region is from 290 to 380 nm. However, artificial UV sources such as certain fluorescent lamps, mercury and xenon arcs, and lasers are readily available and extend the possibility of exposure of biological specimens to UV down to wavelengths of about 190 nm. Below 190 nm, air (oxygen) and water begin to absorb UV heavily, making it difficult to expose biological samples except under extreme conditions (e.g., in a vacuum). Hence, UV photobiology is concerned mainly with the effects on biological processes due to exposure to photons in the wavelength range of 190–380 nm.¹

44.2 Division of the UV Region for Photobiological Studies

44.2.1 Vacuum UV (10–190 nm)

Photons in the “vacuum” UV (VUV) are heavily absorbed by water and oxygen (in air), both of which become essentially transparent (more than 50% transmission, for a 1 cm path length) to UV at wavelength above 190 nm. Because of this limited penetration, VUV damage to cells is usually confined to a narrow region (a few micrometers) near the cell surface. The energies of single photons in this region are

above 6.5 eV, sufficient to ionize many biomolecules. Since the biological effects due to ionizing photons are different from those due to nonionizing photons, the VUV often causes different types of cellular and molecular damage. Thus, VUV effects can be qualitatively different from those of other UV regions.

44.2.2 UV-C (190–290 nm)

The shorter-wavelength end of the UV-C (190 nm) is the wavelength region where air and water become transparent. The longer-wavelength limit (290 nm) is the shortest solar UV wavelength easily measured at the earth's surface. Thus, all of the UV-C is environmentally irrelevant. However, research in the UV-C range was central in elucidating many important features of cell functioning. DNA, the genetic material, has a peak absorption near 260 nm that falls by a factor of 6 by 290 nm. This fact, combined with the readily available 254 nm "germicidal" UV fluorescent source, allowed for simple experimental molecular manipulation of DNA, and UV-C photobiology was central in establishing the then-new field of molecular biology.

44.2.3 UV-B (290–320 nm)

The shorter-wavelength limit (290 nm) of the UV-B region can be defined as the shortest UV wavelength routinely measurable at the earth's surface where it is about 1 million-fold less prevalent than 320 nm radiation. The longer-wavelength limit (320 nm) is where ozone and other atmospheric components begin to (more than 50%) attenuate sunlight appreciably. This absorption prevents much of the significant DNA damage that would result if no ozone layer existed. DNA absorption rapidly decreases by more than four orders of magnitude from 290 to 320 nm.² Nevertheless, absorption of UV-B photons by DNA contributes to a wide variety of bioeffects. The UV-B, which constitutes less than 0.3% of the total sunlight spectrum, is responsible for most of the damage inflicted on organisms by sunlight.

44.2.4 UV-A (320–380 nm)

The shorter-wavelength limit of the UV-A (320 nm) can be defined as that wavelength at which ozone becomes transparent. The longer-wavelength limit (380 nm) is where human vision begins and the UV ends. The UV-A region is also biologically effective and causes cellular death, mutation, and DNA damage, although the primary chromophores for these effects may be non-DNA sensitizers that are chemically matched to the photon energy and act as intermediates in relaying the absorbed energy to DNA.³ UV-A exposures from sunlight are considerable, constituting about 8% of the total sunlight spectrum.

44.2.5 Terrestrial Solar UV (290–380 nm)

This region is easily defined as the wavelength bracket that is the limit of human vision (380 nm) at the long-wavelength end and the effective limit of the solar UV reaching the earth's surface at the short wavelength (290 nm) end. This is the environmentally relevant UV region and is, of course, just the UV-B plus the UV-A.

44.3 Absorption of UV by Cells

The responses of biological samples to UV can be greatly affected by their absorption properties. Beginning at the cellular level, it can be seen in [Table 44.1](#) that 200 nm UV-C, for example, is absorbed only slightly by viruses (about 30%), more so by bacterial cells (about 70%), and entirely by mammalian cells (more than 90%). This absorption is due mainly to the presence of endogenous molecules that absorb heavily in the UV-C. At longer wavelengths, cell absorption decreases. The absorption of two important biomolecules, the genetic material DNA and protein, is compared in [Figure 44.1](#). Both molecules begin

TABLE 44.1 Percent Transmission to the Center of Selected Cells and Viruses in the UV

Biological Sample	Diameter (μm)	Wavelength (nm)			
		200	250	300	350
Bacteriophage (T2)	0.1	74	86	100	100
Herpes simplex virus	0.15	66	80	100	100
Bacterial cell	1	33	78	98	100
Yeast cell	5	1.6	69	97	100
Mammalian cell (spherical)	20	10 ^a	20	91	96
Mammalian tissue (100 μm thick)	—	—	10 ^b	39	66

Note: All values are approximate. Values at λ above 300 nm can vary widely due to the presence of endogenous chromophores (Coohill, 1984).

^a See also Coohill (1984).

^b See also Coohill (1990).

FIGURE 44.1 The absorption spectra of DNA and protein (bovine serum albumin). Both curves are for a 1% solution and 1 cm path length.

to absorb appreciably in the UV-B and substantially in the UV-C. On a weight-by-weight comparison, DNA absorbs about 20-fold as much 260 nm radiation as does protein. Therefore, the absorption of even homogenates of mammalian cells is similar in the wavelength range of 220–290 nm to that of DNA. The absorbance (a logarithmic function) of such homogenates is seven times higher at 240 nm compared to 300 nm. As the UV wavelength decreases below 220 nm, both proteins and nucleic acids contribute greatly to the total cellular absorption. At wavelengths below 190 nm, water and oxygen absorption prevails. In addition to these macromolecules, some cells contain certain pigments that can alter cellular absorption significantly, even at the longest UV wavelengths. Also, cellular particles and organelles can absorb and scatter UV radiation and, at some wavelengths, shield the center of the cell from a significant portion of the incident beam. Such cytoplasmic screening can alter measured bioeffects to a large degree, especially in the UV-C, and must be considered when cellular exposure is attempted.⁴ Such concerns are important because biological cells and tissues will absorb radiation in a wavelength-dependent

manner and alter the exposure of the target accordingly. Therefore, the absorption properties of cells are not merely a summation of the individual absorptions of their component molecules.

44.4 Absorption by Tissue

Much of the direct absorption of UV by tissues such as human skin can be accounted for by the presence of endogenous pigments, especially melanin, hemoglobin, carotenes, and keratin, and exogenous pigments and drugs. Because skin is such a heterogeneous material, UV can be reflected, absorbed, scattered, and rescattered. This means that the direct component of the UV beam is augmented by additions from photons scattered and reflected back into the beam pathway. Hence, at any tissue depth, the sum of the total UV exposure is just the direct plus the diffuse. At wavelengths below 300 nm, absorption by tissue rapidly increases, making all but the first few cell layers of the skin essentially opaque to radiation below about 290 nm.

44.5 Action Spectroscopy

44.5.1 Differences in Effect with Wavelength

An action spectrum (AS) is simply defined as the measurement of a biological effect as a function of wavelength. Crude AS was first used in the nineteenth century to help identify chlorophyll as the chromophore most responsible for the growth of plants. In this century, more sophisticated methods refined the analysis of AS so that it is now possible, in some instances, to make a reasonable determination of the molecule that is likely to contain the chromophore(s) responsible for the response being studied (see [Chapter 43](#)). It is this latter usage that was among the first methods that pointed to DNA as the genetic material. This was possible because small unicellular organisms, such as bacteria, had relatively high transmission rates for UV and thus meet the rather stringent criteria⁵ for a reliable analysis called an analytical action spectrum (AAS). An AAS can only be claimed if the AS corresponds closely to the absorption spectrum of the suspected molecule.

44.5.1.1 UV-C (190–290 nm) Action Spectra

Because some molecules absorb heavily in the UV, certain bioresponses are highly dependent on the wavelengths to which the cell is exposed. In 1930, Gates⁶ ([Figure 44.2](#)) reported that the AS for bacterial cell death closely followed the absorption of nucleic acid, not proteins, which was then widely believed to be the genetic material. In retrospect, this was the first clear evidence that DNA was the genetic material. It should be remembered that an AS could not distinguish between DNA and RNA as the target molecules since both have similar absorption spectra. However, an AS for a photoproduct exclusive to DNA, such as the thymine dimer, can. Although AS utilizing small cells is somewhat simple, it is difficult to extend these studies to larger (e.g., mammalian) cells because of the substantial absorption of UV by large cells and tissues ([Table 44.1](#)). Two other AS's in the UV-C for cell death, one for mammalian tissue and one for individual mammalian cells, are shown in [Figure 44.2](#).⁵ Experiments utilizing hanging-drop mammalian tissue samples failed to produce an AS with the fine structure of those studies that utilized bacteria because the tissue was essentially opaque to radiation near the peak of DNA absorption (260 nm). Thus, the target molecule (DNA) was shielded to an extent such that the shape of the AS did not parallel the absorption spectrum of the target. The advent of single-cell mammalian culture techniques and the unique flattened geometry that mammalian cells assume when in monolayer culture allowed these studies to begin. Thus, AS for killing of cultured mammalian cells reported data similar to those with bacteria, but the peak was shifted to about 270 nm. This discrepancy can be accounted for by looking at the absorption properties of single mammalian cells and considering, as is the case in bacteria, that the likely target molecule for cell killing is also DNA that resides in the nucleus. This means that the UV beam has to traverse half of the cell on average to strike its target. In bacteria, this

FIGURE 44.2 UV action spectra for the killing of bacteria, mammalian cells, and mammalian tissue. Also represented is the absorption spectrum for DNA. Note that the fine structure inherent in the AAS for bacteria and mammalian cells is absent in the case of the essentially opaque mammalian tissue.

distance is small enough to allow one to neglect absorption effects; in mammalian cells, the absorption is substantial. An AS for the production of pyrimidine dimers caused by UV exposure to the DNA in mammalian cells matched the AS for cell death. Therefore, DNA alone was considered responsible for mammalian cell lethality in the 220–290 nm region.⁷ However, if a detailed knowledge of scattering and absorption events before the beam reaches the target is not known, or if the identification of the target is unsure, then any attempt to “correct” or interpret the data generated is suspect. In some cases, it may be useful to modify the incident beam such that the center of the cell, rather than the cell surface, always receives the same exposure.

Not all UV-C AS's follow DNA absorption. For example, the loss of saxitoxin binding to sodium channels in rodent cells, or sodium conduction loss in frog cells or lobster axons, or the UV-induced termination of beating by embryonic chick heart aggregates, all follow an AS similar to the absorption spectra of protein moieties.⁷ In addition, UV-C AS's for highly pigmented tissues (such as plants) show little correspondence to the absorption of any chromophore. The latter is due to the high degree of absorption of UV-C, which essentially rules out useful AAS in this region for cells and tissues that absorb most of the incident radiation before it can reach the target molecule(s). Thus, UV-C AS's are very useful for small or relatively transparent cell studies, but are of very limited use for multicellular or highly pigmented samples. But even if a chromophore cannot be identified, an AS still shows the effect of separate wavelengths on a biological response, and as such is of some use in predicting the results due

to exposure. Studies of human skin exposure to UV-C (e.g., skin cancer or erythema) show on average, an essentially flat response in the UV-C, or in some cases a lessening of effect at shorter wavelengths, that is almost certainly due to limited penetration of the UV beam.

44.5.1.2 UV-B and UV-A (290–380 nm) Action Spectra

It was widely thought that experimental work in the UV-C and UV-B (wavelength range of 190–320 nm) could be extrapolated to predict photobiological responses in the UV-A (320–380 nm). This is not the case, and UV-A AS's are much more complex than had been predicted.³ Here, even events such as cell mutation, which surely involve the genetic material, can be affected at fluences that appear to be below those necessary to affect DNA in these wavelength regions. Details of the divergence of several AS's for human cell photoresponses from the DNA absorption spectrum as the curves shift to longer wavelengths in the UV-A are given in Figure 44.3. In the UV-C, cell killing and mutagenesis follow the absorption spectrum of DNA, and carcinogenesis shows a decrease in effect at shorter wavelengths. The UV-B is a transition region from the highly damaging UV-C to the less damaging UV-A. In the UV-A, all of the biological parameters are affected at levels that are not fully explainable by the absorption properties of DNA. The absolute absorption of moieties in the DNA molecule itself is difficult to measure at wavelengths above 320 nm because of scattering and contamination by extraneous chromophores.² It is thought that if the absorption is not intrinsic to DNA, then an intermediate molecule may be involved that absorbs the incident UV-A photon and transfers the effect to DNA.

The motivation for focusing on studies of the effects of UV-A, UV-B, and the solar UV wavelength region is provided by three observations. First, many cells and tissues are more transparent to terrestrial solar UV than to UV-C, especially in the UV-A; thus, this region should be more amenable to AS analysis.

FIGURE 44.3 UV action spectra for human cell killing and mutagenesis and carcinogenic AS for mouse skin.

Second, research has suggested that the nature of the primary and secondary chromophores, photoproducts, and mechanisms for cellular response to solar UV appear in some cases to be very different from those elucidated for wavelengths shorter than about 300 nm. For example, in contrast to their marked sensitivity to UV-C, certain photosensitive human cell lines, such as xeroderma pigmentosum (XP) cells, exhibit the same sensitivity to UV-A as normal cells.⁸ Third, solar UV impacts a large number of important bioresponses, such as skin cancer, plant growth, cellular survival, and mutagenesis. Research in this area should reveal ultimately the nature of biological responses to a portion of the radiation present in a normal environmental setting.^{9,10}

44.6 Carcinogenesis/Erythema/Vitamin D

The role of solar UV in human skin cancer has been long established. Squamous and basal cell carcinomas are believed to be the result of chronic UV exposure. The expression of these cancers is highly dependent on skin type and individual predisposition. The carcinogenic data in Figure 44.3 are mainly a composite from the analysis of De Gruijl and van der Leun¹¹ and incorporate 12 separate studies utilizing mice. This AS shows major effects in the UV-C and UV-B, and falls off rapidly in the UV-A. But, there is about 35× more UV-A than UV-B in sunlight; therefore, the contribution of UV-A to carcinogenesis is significant. As shown, however, the major cause of UV-induced cancer is the UV-B component of sunlight.

An AS similar, but not identical to the AS for carcinogenesis, is that generated for the production of previtamin D₃ in human skin.¹² Both action spectra peak in the UV-B, but previtamin D₃ synthesis decreases by two orders of magnitude going from 320 to 330 nm (entering the UV-A), whereas the carcinogenic or human erythema AS shows significant contributions in the UV-A. An analysis of the problems inherent in weighting these AS's to sunlight exposure is given by Pope et al.¹³

44.7 Polychromatic Action Spectra

Some scientists, perhaps realizing the futility of attempting to construct monochromatic AAS using multicellular organisms, have reported AS that employ polychromatic sources.¹⁴ These studies vary from irradiating the affected system with additional single wavelengths that are added to an ambient background, or generating a set of data using polychromatic sources that employ cutoff filters at successively shorter wavelength. The polychromatic system is complex and tends to obscure individual chromophores, but it is the closest experimental setup to natural field conditions. A major advantage of using polychromatic radiation in the development of polychromatic action spectra (PAS) is that interactions of biological responses to different wavelengths (usually unknown) are empirically incorporated into the composite spectrum. In addition, highly pigmented tissues, such as those of plants, have a large variety of chromophores that interact to give a total effect. Here, PAS can give a composite view of the organism's response even for such complex parameters as "generalized plant response"¹⁵ and many other field measurements.

In this regard, PAS play a central role in assessing the effects on the biosphere, and especially on plants, of the increase of solar UV-B irradiance at the Earth's surface caused by the depletion of the stratospheric ozone layer.¹⁶

Notwithstanding the complexity of experiments under natural radiation, various spectral studies have been performed either removing increasingly larger portions of the solar UV spectrum by means of different combinations of long-pass filters,¹⁷⁻¹⁹ or supplementing UV radiation by means of appropriate fluorescent lamps.^{20,21} Quite recently, a sophisticated irradiation system has been described, which uses both filters and supplementary UV lamps and can provide computer-controlled modulated changes in any radiation band between about 250 and 730 nm.²²⁻²⁴

Also sun simulators (also known as phytotrons) are very promising tools to overcome the difficulties of outdoor studies.²⁵⁻²⁷ The employment of a wide range of modern lamp types and different filter

combinations allow obtaining the spectral quality and the intensity of natural global radiation and the appropriate shaping of the short-wave cutoff. Moreover, the appropriate irradiation conditions and climatic factors can be reproduced at any time, and disturbing agents can be excluded.^{28,29}

Sutherland³⁰ describes mathematical procedures for calculating the biological effects from exposing samples to polychromatic (especially UV) radiation. His analysis includes a variety of fluence response functions and presents an approach for predicting total effect and analyzing subtle differences between classical AS analysis and biological weighting functions.

Two different approaches have been proposed for extracting an AS from experimental data obtained with polychromatic exposures in which UV irradiance is varied by means of filter combinations with progressively decreasing cutoff wavelength. Differential action spectroscopy (DAS) takes into account the spectral bands given by the difference in irradiance of two filter combinations with successive cutoff wavelength. Assuming that different spectral bands supplement one another in producing the observed effect, it is possible to estimate the weighted contribution of each band by dividing the differences in response to the treatment by the corresponding differential irradiances. Finally, the AS is derived by plotting the weighted effects as a function of the average wavelength of the corresponding band. As UV action spectra tend to exponentially increase with decreasing wavelength, the main limit of this method is given by the potentially large variability of the response in the range of each differential band, which could significantly alter the shape of the resulting AS.³¹ This limit, however, is present also for monochromatic action spectroscopy, when using currently available interference filters. The differential method can be improved by using several irradiance levels for each differential band, thus reducing statistical errors and allowing a more correct shaping of the AS.¹⁶

If DAS reduces the problem to the monochromatic situation, the other approach proposed by Rundel³¹ is a deconvolution technique in which it is assumed that the AS is an analytical continuous function $\epsilon(\lambda)$ and the predicted system response R_i to the i th irradiation regime $E_i(\lambda, t)$ can be expressed as depending on the biologically active irradiance integrated over the irradiation time:

$$R_i = F \left[\iint_{t, \lambda} \epsilon(\lambda) E_i(\lambda, t) d\lambda dt \right].$$

Once a functional form for $\epsilon(\lambda)$ has been chosen in dependence of a given number of parameters, the latter can be determined by means of iterative calculations to minimize the differences between each R_i and the corresponding measured response. The limit of this method is that the *a priori* choice of both the form of $\epsilon(\lambda)$ and the functional relationship F between response and exposure is critical for the correct determination of the AS. However, the use of multivariate statistical analysis (such as, e.g., principal component analysis) allows obtaining more detailed biological weighting functions.^{32,33}

44.8 Effectiveness Spectra

It is also possible to estimate the damage to a biological system by exposure to UV by combining an AS for a given effect with a known ambient exposure.¹⁵ These are called effectiveness spectra (ES's) and give at least a first approximation for the effects of UV on the studied system. One such ES is shown in Figure 44.4, which charts the AS for generalized plant damage¹⁵ and the ambient solar UV. The product of these two curves is the solar plant damage ES. From this chart, one can see that the UV-B region is the most damaging, with a peak at about 308 nm. Although solar intensity increases by a factor of 10 from 310 to 330 nm, the biological response decreases more rapidly over the same wavelength range so that the overall effect is less.

Cullen and his coworkers,³⁴ using spectrally resolved model calculations of water column photosynthesis (and its inhibition by UV), have been able to generate simple mathematical functions that allow researchers to add in environmentally relevant variables and generate results that predict total yield that match field measurements.

FIGURE 44.4 An AS for generalized plant damage, the terrestrial solar UV intensity spectrum, and a solar plant damage ES obtained by combining the previous two spectra.

44.9 Constraints

Finally, it should be pointed out that even if all the constraints necessary to produce a detailed AS are adhered to, experimental variables usually limit the reliability of any AS. These variables include, but are not limited to (1) the spectral purity of the radiation source (including the bandwidth of any “monochromate radiation”); (2) the accuracy of the dosimetry measurements; (3) the presence of endogenous or exogenous “nonparticipating” chromophores; (4) the ambient (even microenvironmental) condition; (5) the time in the life cycle (cellular) or growth cycle (developmental) of the exposed organism; (7) the geometry of the cell or tissue when irradiated; (8) the availability of proper nutrients; (9) water stress in plant studies; and (10) numerous other extraneous conditions.

45.1 Introduction

The first scientific documentation that sunlight or visible light can be detrimental for cells and more complex biological systems was provided by Marcacci in the late nineteenth century [1]; this investigator reported that the fermentation of plant alkaloids and amphibian eggs is drastically impaired under exposure to UV/visible light. Shortly thereafter, Raab [2], a medical student working in the laboratory of Prof. H. von Tappeiner in Munich, demonstrated that the presence of some exogenously added visible-light-absorbing compounds, for example, acridine orange, was necessary for sunlight to promote the death of paramecia. In a second paper, von Tappeiner [3] associated this property with fluorescence, postulating that the necrotic effects were consequent to the transfer of energy from the light-activated chemical compounds to other sites in their close surroundings. These photoactivatable substances were defined as photosensitizers. The overall scenario was completed by the observation [4] that the presence of oxygen is often a necessary requisite for photosensitization to occur. The combined effect of the three elements, namely, light, photosensitizer, and oxygen, has been termed “photodynamic action” [5]. Finally, von Tappeiner in collaboration with a dermatologist named Jesionek showed that the photodynamic processes could be quite useful in medicine by using topically applied eosin and visible light to positively treat skin tumors [6]. This finding prompted a wealth of studies aimed at defining the pharmacokinetic properties of photosensitizing agents *in vivo* and devising suitable strategies for promoting the selective or preferential localization of the photosensitizer in specific diseased tissues. The results thus obtained eventually paved the way to the development of the so-called photodynamic therapy (PDT) for several pathologies, including solid tumors, actinic keratosis, atheromas, rheumatoid arthritis, infectious diseases of microbial origin, sterilization of blood products, age-related macular degeneration, and a variety of skin diseases [7,8]. At the same time, photodynamic processes are now showing very promising features for addressing important problems connected with the protection of the environment and the preservation of biodiversity [9,10].

At present, it is generally recognized that a large number of near-UV or visible-light-absorbing dyes belonging to different categories of organic compounds exhibit interesting photosensitizing properties, whose control can lead to different types of damaging or beneficial effects on biological systems, including living organisms [11]. A particularly prominent role is played by porphyrins and their natural or synthetically prepared tetrapyrrolic analogues, including chlorophylls, porphycenes, purpurins, phthalocyanines, and naphthalocyanines. Porphyrins absorb essentially all the wavelengths included in the sun emission spectrum; hence, they are especially important for applications in natural environments where the sun represents the source of the photochemically useful light wavelengths. Historically, the first porphyrin to be isolated was hematoporphyrin, which was extracted from dried blood by treatment with concentrated sulfuric acid followed by solubilization with ethanol [12]. The name hematoporphyrin was assigned by Hoppe-Seyler in 1871 [13], and this porphyrin was first used as a photosensitizer in humans by Meyer-Betz in 1913 [14], who injected himself with hematoporphyrin and subsequently suffered a prolonged pain and swelling in light-exposed skin areas. A derivative of hematoporphyrin, known under the commercial name of Photofrin, was initially used as a photosensitizer for the PDT of tumors [7], whereas hematoporphyrin itself was proposed as an environmentally friendly photoinsecticidal agent [15]. Moreover, the tetrapyrrolic core of porphyrins can be chemically modified at different levels, such as the coordination of metal ions at the center of the macrocycle and axial ligands in the fifth and/or sixth coordination positions of the ion, as well as the introduction of substituents in the peripheral positions of the pyrrole rings or the meso inter-ring carbon atoms. In this way, the physical and chemical properties of the porphyrin photosensitizer can be tailored to orientate the molecule toward predetermined sites of a cell or tissue [16].

A few photosensitizers are naturally present in plants and animals, that have consequently developed appropriate protection or repair mechanisms to counteract the potentially noxious action of the wavelengths present in the solar spectrum. Otherwise, the photosensitizing agent can be introduced into the organism accidentally (e.g., through the diet or the uptake of drugs) or on purpose. The main photophysical, photokinetic, and photochemical characteristics of these photosensitizers will be briefly reviewed in the following.

45.2 Photodynamic Sensitization of Biological Systems: Photophysical Aspects

Upon absorption of a UV or visible photon, a photosensitizer P can be promoted to a variety of electronically excited states. Such higher energy states involve two systems, which are represented by the singlet (1P) and the triplet (3P) manifold. In general, the efficiency of the photosensitizing action in fluid media is dependent on the photophysical properties of the lowest excited triplet state, which is reached via intersystem crossing from the initially formed excited singlet state. The 3P species is most often characterized by a lifetime in the microsecond to millisecond range; hence, it can play a major role in diffusion-controlled processes. The most effective photosensitizers are therefore those which give a long-lived triplet state with a high quantum yield. The primary photophysical and photochemical steps involved in photosensitized processes can be represented according to the scheme outlined in Figure 45.1.

In the figure, 0P and 3P indicate the ground state and the lowest triplet state of the photosensitizer, respectively; 0Sub and 3Sub represent the corresponding electronic states of a photosensitive substrate. R indicates a general reactant, 3O_2 and 1O_2 are ground-state oxygen (a triplet), $^1\Delta_g$ is singlet oxygen, O_2^- is the superoxide anion, and P_{ox} and Sub_{ox} are oxidized forms of the photosensitizer and the substrate.

As shown in Figure 45.1, the 3P species can undergo deactivation to the 0P species by radiative (luminescence) or nonradiative (largely thermal) modes or become involved in a photochemical reaction with oxygen or another constituent of the medium, accompanied by a loss of the absorption typical of

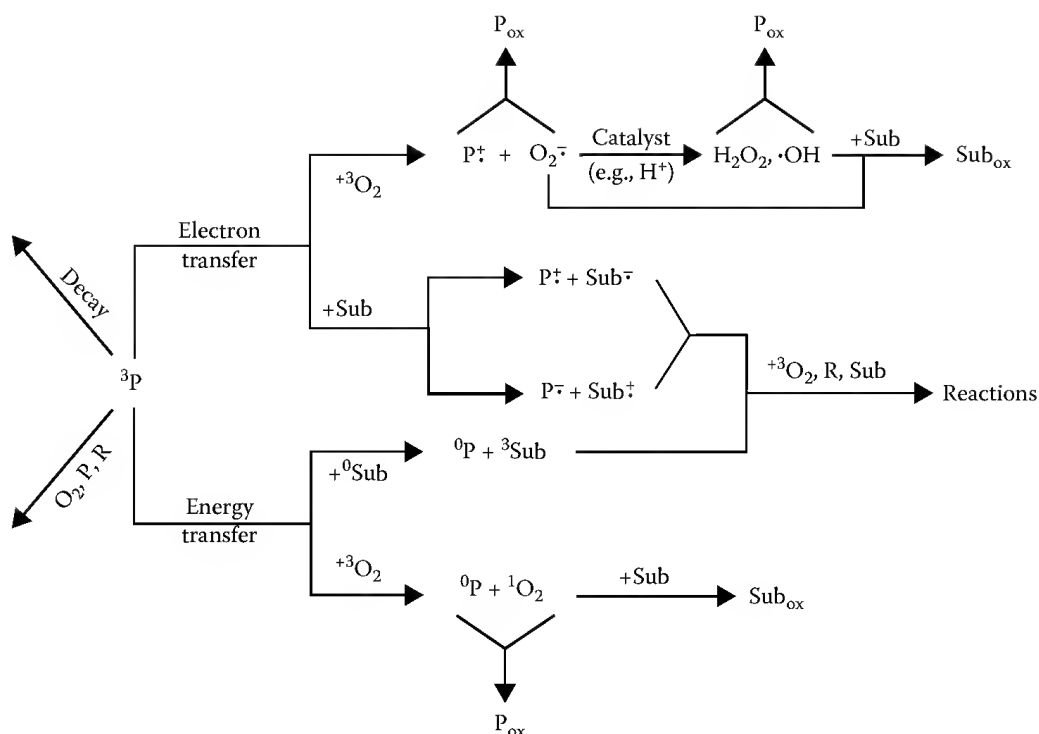

FIGURE 45.1 Schematic representation of the primary photophysical and photochemical steps typically involved in the photosensitized modification of biological substrates.

the photosensitizer in the visible spectral interval (“photobleaching”). For most photosensitizers, the quantum yield of photobleaching is around 10^{-4} to 10^{-5} . As regards the photosensitized modification of the substrate, two pathways are operative as follows:

1. *Electron transfer* between 3P and a suitable acceptor, resulting in the formation of semireduced and semioxidized radical-type species. This pathway is termed as *Type I mechanism*: the direction of the electron transfer step is obviously dependent on the value of the redox potential for the triplet photosensitizer and the substrate. The initially formed radical intermediates can then undergo further reactions with other substrates, solvent molecules, or oxygen. A particular case occurs when oxygen acts as the electron acceptor with the generation of the superoxide anion; the latter derivative has a relatively low level of reactivity; however, it can be often converted to very reactive and cytotoxic species, such as the hydroxyl radical and hydrogen peroxide. The production of free radicals in the Type I process less frequently involves the transfer of one hydrogen atom from a reducing substrate RH to the photosensitizer.
2. *Energy transfer* to any substrate whose triplet state lies at a lower level compared with the 3P species; this pathway is defined as a *Type II mechanism*. Most components of cells and tissues are not suitable acceptors of electronic energy from 3P , since their triplet states are too energetic. One notable exception is represented by oxygen; this almost ubiquitous component of biological systems can be readily promoted to its excited singlet state $^1\Delta_g$, whose energy level lies at only 22.5 kcal above the triplet ground state of molecular oxygen and which is endowed with a high reactivity and cytotoxicity. In actual fact, the $^1\Delta_g$ oxygen has an empty orbital, which imparts a high electrophilicity to this intermediate; moreover, its return to the ground state is forbidden by the selection rules; hence, singlet oxygen has a long lifetime (3–4 μs in aqueous media, several tens of microseconds in lipid environments), which allows this species to diffuse over appreciably long distances before being deactivated [17].

The Type I and Type II pathways occur competitively; the reaction rates for the interaction of the triplet photosensitizer with the substrate and oxygen can be described by the following equations:

$$v_{\text{sub}} = k_{\text{sub}}[\text{Sub}][^3\text{P}] \quad \text{and} \quad v_{\text{O}_2} = k_{\text{O}_2}[^3\text{O}_2][^3\text{P}]$$

The value of k_{O_2} for typical photosensitizing agents is approximately $2 \times 10^9 \text{ M}^{-1} \text{ s}^{-1}$, and $[^3\text{O}_2]$ is about 0.3 mM in aqueous solutions. Therefore, in aerated solutions, the substrate can compete efficiently with the triplet photosensitizer only if the product $k_{\text{sub}}[\text{Sub}]$ is at least $5 \times 10^5 \text{ s}^{-1}$. The competition between the Type I and Type II pathways could be significantly different in non-aqueous or inhomogeneous systems where the oxygen concentration generally increases while the local reactant concentrations and rate constants can be altered by the nature of the microenvironment.

On the other hand, the energy transfer reaction from ^3P to $^3\text{O}_2$ is much faster than the electron transfer; hence, the formation of singlet oxygen accounts for almost all the quenching steps of photosensitizer triplets by oxygen. The formation of the superoxide anion usually occurs on less than 1 in 100 deactivating collisions of oxygen with ^3P . Therefore, the singlet oxygen-involving pathway is of utmost importance for the photosensitized processes involving biological systems unless special situations obtain, as discussed in the following.

The intermediacy of singlet oxygen in photosensitized processes can be detected by a variety of techniques, out of which the most frequently used involve the following:

- Comparison of the photosensitized oxidation rates for a substrate in a given hydrogenated solvent and its deuterated analogue. It is well known that the lifetime of singlet oxygen is markedly longer in the deuterated medium (e.g., it is about 10-fold longer in D_2O as compared with H_2O), which must obviously favor a Type II, $^1\Delta_{\text{g}}$ oxygen-involving, mechanism.
- Direct spectroscopic determination of singlet oxygen through its luminescence emission at 1270 nm, namely, in the near-IR range.
- Use of specific acceptors, such as 9,10-dimethyl-anthracene (DMA), 2,5-dimethyl-furan (DMF), or 1,4-diazabicyclo[2,2,2]-octane (DABCO), which have the property to give 100% chemical quenching upon interaction with singlet oxygen.
- In some cases, the photooxidation products are at least partially different for Type I and Type II pathways; hence, the identification of such products can be a very helpful diagnostic tool for assessing the actual mechanism of the photoprocess (see Section 45.4).

Recently, the formation of singlet oxygen as a main intermediate of photosensitized processes has been detected also *in vivo* [18].

45.3 Kinetics of Photosensitized Reactions

The rate constants of the primary reactions, k_{I} and k_{II} , involved in the two processes are now well enough known, so that many of the factors which govern their competition can be stated definitely. The rate of the Type I process depends on the photosensitizer and the substrate and can vary over a rather wide range. Typical rates for a selected number of cell constituents are shown in Table 45.1. In general, triplet ketones and quinones are more powerful hydrogen abstractors than the common polycyclic organic dyes: for example, benzophenone abstracts hydrogen from a weak reductant, such as isopropanol, about 10^4 times more rapidly than does eosin. The scenario can change in the presence of powerful hydrogen or electron donors: thus, both eosin and benzophenone triplets react at similar rates with *N,N*-dimethylaniline. Notably, histidine differs from other amino acids, for the very poor tendency to undergo hydrogen/electron transfer with a very frequently used photosensitizer, such as methylene blue.

TABLE 45.1 Rate Constants ($\text{M}^{-1} \text{s}^{-1}$) for the Reaction of Different Triplet Photosensitizers with Selected Substrates

Substrate	Photosensitizer Triplet State		
	Benzophenone	Eosin	Methylene Blue
Aniline	4.8×10^9	1.4×10^9	0.8×10^9
<i>N,N</i> -Dimethyl-aniline	5.7×10^9	2.2×10^9	1.7×10^9
Isopropanol	1.8×10^6	ca. 10^2	n.a.
Tryptophan	n.a.	8.9×10^7	2.0×10^8
Methionine	8.8×10^8	1.0×10^7	3.5×10^7
Histidine	n.a.	2.7×10^5	3.3×10^6
Guanosine	5.6×10^8	1.1×10^9	2.4×10^9

n.a. = not available.

Riboflavin is an excellent promoter of Type I processes thanks to the presence of an internal hydrogen source in the poly-hydroxylated side chain, which predisposes it to complex radical reactions.

The types of molecular structures for the substrate that enhance the efficiency of a Type I process include those which are most readily oxidized, such as phenols and amines, or readily reduced, such as quinones. On the other hand, compounds belonging to the classes of olefins, polyenes, or aromatic compounds favor the occurrence of reaction pathways via singlet oxygen.

The rates of the Type II processes mainly depend on the oxygen concentration in the reaction medium, since the k_{II} rate constant with few exceptions falls in the $1\text{--}3 \times 10^9 \text{ M}^{-1} \text{s}^{-1}$ for a very large number of photosensitizing agents. Oxygen is known to be less soluble in water than in most organic solvents; therefore, the product $k_{\text{II}}[{}^3\text{O}_2]$ can be expected to be smaller in an air-saturated aqueous solution (ca. $5 \times 10^5 \text{ s}^{-1}$ as experimentally measured) than in oxygen-saturated organic solvents (ca. $3 \times 10^7 \text{ s}^{-1}$). As a consequence, depending on the type of photosensitizer and substrate, as well as on the nature of the reaction medium, the mechanism of the photosensitized oxidation may change from Type I to Type II and vice versa. In particular, the binding of the photosensitizer to the substrate, as it often occurs in biological systems, is likely to favor Type I mechanisms.

Lastly, it is important to emphasize the role of another competition in determining the fate of a photosensitization process, namely, that between the decay rate of singlet oxygen (k_d) and the rate at which singlet oxygen reacts with a substrate ($k_{\text{sub}}[\text{Sub}]$). In case $k_{\text{sub}}[\text{Sub}] \ll k_d$, the major result of a Type II pathway is simply the quenching of the triplet photosensitizer with no or very little chemical modification of the substrate. A very important example is provided by β -carotene and other carotenoids with a chain length involving at least 11 conjugated double bonds, whose triplet state is of sufficiently low energy to accept electronic energy from singlet oxygen. The k_{sub} for this interaction is higher than $10^{10} \text{ M}^{-1} \text{s}^{-1}$, and these considerations explain the very efficient photoprotective action of carotenoids in plants, as well as in humans affected by porphyria:

Rate constants controlling the reaction between singlet oxygen and selected substrates of biological interest are given in [Table 45.2](#).

TABLE 45.2 Rate Constants
($M^{-1} s^{-1}$) for the Reaction of Selected
Substrates with Singlet Oxygen

Substrate	Rate Constant
2,5-Dimethyl-furan	1.4×10^8
Tryptophan	4.5×10^7
Methionine	2.9×10^7
Histidine	1.3×10^8
Guanosine	4.7×10^8
2-Methyl-pentene	1.1×10^6
Cyclohexene	3.3×10^3

45.4 Initial Photooxidation Products of Photodynamic Processes

The electrophilic nature of the photoreactive intermediates generated upon electronic excitation of photosensitizers explains why the most sensitive targets of such photoprocesses are represented by electron-rich sites or functional groups.

Type I chemistry proceeds through radical intermediates, which may involve the promotion of chain reactions, which are often characterized by high overall quantum yields. Since such processes can involve substrates with a truly large typology of chemical structures, a broad variety of reactions can take place. In some cases, the products of the Type I photosensitized oxidations are identical with those which are produced by classical oxidative procedures: a typical example is represented by the benzophenone-photosensitized oxidation of secondary alcohols, which lead to the formation of ketones as the end products. Analogously, photooxidation of olefins at the level of the unsaturated carbon-carbon bonds by a Type I route yields a mixture of allylic hydroperoxides, peroxides, and epoxides.

More frequently, the photosensitized oxidation follows a specific reaction pathway: thus, the anthraquinone-photosensitized oxidation of tertiary amines proceeds via electron transfer from the nitrogen atom; a common result of this kind of process is represented by dealkylation: the photoinduced radical intermediates appear to react with oxygen with the generation of peroxides, whose subsequent decomposition promotes a breakdown to dealkylated products.

Interestingly, Type I photosensitization can result in the modification of substrates which are not sensitive to Type II photosensitization, thereby amplifying the scope of this photoprocess. Thus, quinone or ketone photosensitization can induce the decarboxylation of substituted carboxylic acids: again, this reaction is believed to involve electron transfer as the key step.

On the other hand, the reactions of singlet oxygen with biological targets have been studied in great detail, also in view of the aforementioned predominant role of such reactions in photosensitization of isolated biomolecules and cells or tissues. Five classes of singlet oxygen-involving reactions have been identified as follows:

1. *Oxidation of thiols and thioethers.* The usual product is represented by sulfoxides, which means that two thioether molecules are oxidized per each molecule of oxygen taken up, or sulfonic acids. A persulfoxide intermediate has been detected for this type of process.
2. *Oxidation of phenols.* Phenols are eventually converted to quinone-type products, even though hydroperoxide products can be also isolated if the photoprocess is carried out under mild conditions. It has also been observed that the quinones often undergo a spontaneous polymerization to yield melanin-type products.
3. *1,4 Addition to dienes and heterocycles.* This reaction is typical of many dienes, as well as of aromatic molecules and heterocycles, which are highly substituted by electron-donating moieties. In general, endoperoxides are initially formed, which are stable only at low temperatures; at room

TABLE 45.3 Effect of Photosensitization on the Nature of the Photooxidation Products of Selected Biological Substrates

Substrate	Type I	Type II
Tryptophan	Hydroxy-indoles	<i>N</i> -formyl-kynurenine
Histidine	Mixture of amino and carboxyl derivatives	Endoperoxides gradually hydrolyzed to ketone-type compounds
Methionine	Methional	Methionine sulfoxide
Cysteine	Cystine	Cystic acid
Guanosine	Dimeric polyketonic photoadducts	Endoperoxide/ketone derivatives
Cholesterol	7, α -Hydroperoxide	5, α -Hydroperoxide

temperature, the endoperoxides decompose and react with solvent molecules to yield stable peroxides or hydroperoxides.

4. *1,2 Addition to olefins*. Once again, this process occurs efficiently only in the presence of particularly electron-rich double bonds, for example, enamines or vinyl ethers. The photoproducts include fairly stable 1,2-dioxetanes; on mild warming, these cleave to carbonyl compounds, an event that is possibly characterized by the emission of light (chemiluminescence).
5. *Ene reaction with olefins*. Olefins with two or more alkyl substituents react with singlet oxygen to form allylic hydroperoxides. This photoprocess has been also observed for unsaturated fatty acids and steroids.

The different mechanisms which are involved in the Type I and Type II pathways often result in the formation of different end products. This circumstance can be taken advantage of for discriminating between the two mechanisms in a given system. This is exemplified in the case of the most highly photosensitive amino acids and cholesterol in [Table 45.3](#).

45.5 Photosensitization in Complex Biological Systems

Cells are intrinsically nonhomogeneous and highly compartmentalized systems and thus provide a great variety of microenvironments for photosensitizers and potential targets of a photoprocess. Since the photophysical parameters of a photosensitizer and the lifetimes/reactivity of the possible intermediate species are strongly dependent on the nature of their surroundings, it is often difficult to extrapolate information obtained from photosensitization studies in homogeneous solutions to cells. In particular, cell-associated photosensitizers are frequently bound noncovalently in different sites of cells, thereby altering their photochemical behavior. Further, the cell environment is dynamic; this requires that diffusion of the photosensitizer to different subcellular loci as a consequence of the endocellular modifications brought about in the initial stages of the photoprocess be taken into account in developing accurate descriptions of the mechanisms involved in photosensitization of cells. Therefore, relevant model systems mimicking specific cellular situations have been tested in order to obtain some clues as to how selected factors influence the course of a photoprocess in cells and tissues.

Such approaches are based on the tendency of several cell constituents, such as proteins, nucleic acids, and polysaccharides to form stable complexes with a variety of photosensitizers [19]. In many cases, such binding increases the photophysical properties of the photosensitizer, including the fluorescence emission quantum yield and the triplet lifetime. These effects, of obvious importance in cell photosensitization, result from the reduced probability of collisional deactivation for bound electronically excited photosensitizer molecules; thus, dyes located in internal regions of three-dimensionally folded macromolecules exhibit phosphorescent emission at room temperature. The incorporation of photosensitizing agents in polymeric matrices is often leading to an increased steady-state triplet population, as might be expected from the typical bathochromic shift of the absorption peak of bound photosensitizers and the consequent smaller singlet-triplet splitting.

TABLE 45.4 Effect of the Mode of Photosensitizer Binding on the Photoinduction of Free Radicals in Calf-Thymus DNA

Substrate	Mode of Binding	Absorption Maximum (nm)	Molar Extinction Coefficient ($M^{-1} \text{ cm}^{-1}$)	Radical Yield (a.u.)
Chloroquine	Intercalation	329	19,700	620
9-Amino-acridine	Intercalation	398	10,825	325
Proflavine	Intercalation	444	33,500	1000
Ethidium bromide	Intercalation	480	5600	160
Pyronine	Stacking	538	13,650	175
Thiopyronine	Stacking	564	46,960	450
Acridine red	Stacking	549	8320	98

Photosensitizer concentration: 0.50 mM; DNA concentration: 1.56 mM; solvent: aqueous 0.1 M NaCl; light source: high-pressure Hg lamp ($\lambda < 320 \text{ nm}$ removed by a cutoff filter)

The enhanced photoactivity of bound photosensitizers is particularly evident in the case of nucleic acids. Illumination of calf thymus DNA in the presence of intercalating and nonintercalating photosensitizing agents shows that, with comparable light absorption, binding increases the extent of photo-damage (Table 45.4). The efficiency of the photoprocess is favored by a tight and rigid environment for the photosensitizer as found in photooxidation studies with intercalated proflavine–DNA complexes: Supercoiled double-stranded DNA is approximately 10 times more photolabile than the corresponding double-stranded DNA [20].

The ground-state complexing of photosensitizers with macrobiomolecules can also influence the mechanism of the photoprocess, usually by enhancing the probability of a direct interaction between the triplet photosensitizer and the substrate through electron or hydrogen transfer. This is a consequence of the close spatial relationship between the bound photosensitizer and the photosensitive functional groups of the target. In some cases, the initially formed photosensitizer and substrate radicals can recombine with the formation of intramolecular cross-links in the macromolecule, dimeric substrate–substrate complexes, and covalent substrate–photosensitizer photoadducts [20].

Another class of model systems has been developed to address the problems connected with the abrupt phase changes and variations in medium polarity caused by the heterogeneous and compartmentalized structure typical of cells; this can appreciably affect the diffusibility and reactivity of the photogenerated oxidized agents inside cells. Toward this aim, aqueous dispersions of surfactant micelles and uni- or multi-lamellar liposomal vesicles are used to mimic biological assemblies that are characterized by the coexistence of hydrophobic and hydrophilic regions. This approach allows the availability of various combinations of photosensitizers and substrates solubilized in either the lipid or aqueous phase. As a result, several important advances as regards the mechanisms modulating the progress of photosensitized processes in complex biological systems have been achieved. The main conclusions can be summarized as follows:

- The observed high quantum yield of singlet oxygen generation inside micelles and liposomes and its rapid diffusion across phase boundaries support the hypothesis based on oxygen quenching of the fluorescence emitted by micellized aromatic compounds that oxygen diffuses through micelles in an essentially unrestricted fashion.
- In general, the reaction rate of singlet oxygen is at least as great with micelle- or liposome-incorporated targets as with the same substances in a homogeneous solution. Ionic micelles do not alter the lifetime of singlet oxygen appreciably, whereas neutral micelles (as prepared with Igepal CO-660 or Triton X) may reduce the singlet oxygen lifetime as a result of excitation transfer from its electronic levels to vibrational modes of the terminal hydroxyl groups of the surfactant.
- On the other hand, the reaction rate for a given pair of substrate–photosensitizer appears to depend on the micellar or liposomal outer charge. For example, the photooxidation of

1,3-diphenyl-isobenzofuran is most efficient when the substrate is embedded in anionic vesicles. With cationic photosensitizers, such as methylene blue, this may result from adsorption of the dye on the external shell of the micelle or liposome. Other factors which contribute to the modulation of the photosensitization rate are the dimension of the vesicle and the substrate distribution among the various endomicellar or endoliposomal districts, which could determine the accessibility of the target to the attacking agents.

- The outer charge also affects the rate and efficiency of electron transfer processes across the phase boundary. Thus, the forward e^- transfer step from a micellized donor to an external acceptor is usually favored in the presence of negatively charged sodium dodecyl sulfate (SDS) micelles as compared with homogeneous media: the negative charge of the micelle markedly decreases the rate of the back reaction. Conversely, the positive charge of cationic micelles (e.g., cetyltrimethylammonium bromide) or liposomes attracts the e^- toward the surface of the vesicle and extends the duration of the encounter, thus enhancing the overall efficiency of the photoprocess.
- Finally, it should be underlined that both singlet oxygen and electrons can diffuse from one micelle or vesicle through an aqueous medium and attack reactive targets localized in a different vesicle. The efficiency of the singlet oxygen-involving reaction is relatively little affected by both the external charge of the vesicle and the substrate accessibility, while the outer charge is of primary importance for the efficiency of electron-mediated photoprocesses.

45.6 Conclusions

On the basis of the discussions developed in the previous paragraph, it is apparent that the optimal utilization and fine control of a photosensitized process especially in *in vivo* systems require a carefully planned interplay among several different parameters, which can be operationally subdivided into physical–chemical, photophysical, photobiological, pharmacological, and phototherapeutic properties. An attempt at summarizing the main features which should characterize a biologically efficient photosensitizer is shown in [Table 45.5](#).

TABLE 45.5 Main Features of an Efficient Photodynamic Sensitizer

Property	Related Structural and Biological Features
<i>Physical–chemical</i>	
High chemical purity	Preferentially lack of structural isomers or stereoisomers
Large molar extinction coefficient in the red	Extensive conjugation of π electrons in the macrocycle
Low tendency to aggregation in aqueous media	Electrically charged peripheral substituents in the macrocycle
<i>Photophysical</i>	
Long triplet lifetime	
High yield of 1O_2 generation or electron transfer to substrates	Easy accessibility to oxygen or close proximity to substrates with suitable redox potential
<i>Pharmacological</i>	
Efficient and selective targeting of diseased tissue	Association with suitable delivery or targeting systems
Fast clearance from serum and healthy tissues	Affinity for serum proteins responsible for transport from peripheral tissues to liver
Low systemic toxicity	Lethal dose (LD-50) greater than ca. 100 mg/kg body weight
<i>Phototherapeutic</i>	
Preferential damage/necrosis of diseased tissue	Large concentration difference between lesional/perilesional districts and/or fast healing of any damaged healthy tissue
Lack of side effects	Particular attention to avoid generalized photosensitivity
Lack of mutagenic effects	No involvement of genetic material in the photoprocess

It is obvious from Table 45.5 that the photosensitized processes of biological systems are characterized by a high degree of complexity. Thus, it is understandable that this chapter is not intended to be an exhaustive review, but presents a framework of basic facts and principles essential to understanding the main phenomena, illustrating them with a few of the more interesting and instructive examples. A more detailed and in-depth description of the various aspects of this subject can be found in the reviews indicated at the end of the references, namely, Refs. [21–32].

46.1 Introduction

In addition to gravity, light is one of the most important external factors, not only for photosynthetic organisms, to control their movement and position in their habitat. For photosynthetic bacteria, algae, and higher plants, solar radiation is an indispensable source of energy. During evolution, a number of light-harvesting pigments have been developed for collecting solar energy, most of which are based on cyclic tetrapyrroles. In addition, a number of different accessory pigments are being utilized to augment the amount of light absorbed by funneling the energy to the reaction centers for photosynthesis.

The light intensity and wavelength distribution of solar radiation vary considerably in dependence of the habitat, the geographic position, the time of day, and the season. At low light intensities, photosynthesis is suboptimal and results in reduced growth and biomass production. At intensities below the light compensation point, the respiratory oxygen uptake exceeds the photosynthetic oxygen production and biomass production is negative. This light compensation point is reached after dawn and before dusk. For different plant species, it is found at different intensities; it is lower for shade plants than for high-light-adapted plants [1].

Plants are adapted to the availability of light in their habitat. Sun-exposed and shade plants are extreme examples for this process [2], and within the same plant, different leaves can be adapted to high- or low-irradiation regimes [3]. Plants in a forest under a canopy of trees may be exposed to less than 10% of the radiation impinging on the surface of the canopy, but may be shortly exposed to full sunlight during phases of sunflecks, when direct solar radiation finds a gap between the tree leaves. The photosynthetic machinery of the shade plants on the forest floor needs to adapt to these sudden changes in irradiation [4]. Likewise extreme is the light climate for macroalgae growing in the tidal zone on

a rocky shore. During low tide, the algae are exposed to the unfiltered solar radiation. Depending on whether they grow in rock pools or on rocks they may also have to tolerate desiccation and high-salt concentrations. At high tide, these macroalgae may be covered by up to several meters of water, which in the coastal zone can be very turbid and transmit little light. Since the occurrence of high and low tides changes from day to day, the algae need to adapt to a very variable light scenario [5,6].

Light plays a major role in the zonation of macroalgae, which selects light- [and ultraviolet (UV)] resistant species in surface locations and sensitive species deeper down in the water column [7]. Adaptation processes to widely changing light intensities include changes in pigmentation [8,9] and morphology [10] as well as changes in the physiological processes such as the photosynthetic electron transport chain [11–13].

Completely independent from utilization of solar energy for photosynthesis, light serves as an external factor for habitat selection. For this purpose, organisms have developed a host of photoreceptor molecules during evolution. Higher plants use light to direct growth into areas in their habitats with sufficient irradiation. On a short-term basis, they adapt to changing light conditions during the day by movement responses of their leaves.

Motile microorganisms heavily depend on light-directed behavior mechanisms to move to and stay at depths in the water column with optimal light conditions. Often flagellated cells swim toward the water surface guided by the light direction and/or the gravitational field of the earth [14,15]. However, the unfiltered solar radiation at the water surface may be excessive and their sensitive photosynthetic apparatus may be affected and even destroyed by visible and especially UV radiation [16]. When confronted with this situation, many motile photosynthetic—but also nonphotosynthetic—organisms reverse their direction of movement, for example, by switching to an orientation pattern away from the light direction [17]. The constant antagonism between upward oriented movement at low light intensities and downward directed movement at high intensities results in a dynamic habitat selection with optimal light conditions [18].

46.2 Photocontrol of Development and Movement in Higher Plants

After sessile plants have selected a habitat, they are confined to growth and movement of their leaves and branches to optimize light harvesting [19]. This is instrumented by long-term growth responses and photomorphogenesis as well as by short-term light-mediated movement responses.

46.2.1 Photomorphogenesis: Light Control of Growth and Morphology

Phytochromes constitute a small protein family (phyA–phyE) with a linear bilin chromophore linked by an S–H bond to a 126 kDa protein and are derived from prokaryotic ancestors in bacteria and cyanobacteria. These pigments show photochromicity: They absorb light in the red region of the spectrum (660 nm) and are converted to a far-red absorbing (730 nm) form and vice versa. The far-red absorbing form is assumed to be the physiologically active one. Hundreds of functions are known to be mediated by the phytochrome system. It controls seed germination by preventing germination of seeds exposed to light (dark germinators) or induces germination of seed in the presence of light (light germinators) [20]. Phytochromes regulate the hypocotyl length by inducing increased growth under low light conditions in order to allow plants to eventually reach areas of higher light intensities in their habitat [21,22]. A drastic example of this process is the extreme growth of etiolated, leafless shoots in darkness, which can be observed in germinating potatoes, beans, and many other plants (Figure 46.1). Phytochromes control size, shape, and number of leaves [23] and affect leaf thickness as well as stomata and chloroplast density [24,25], regulate flowering [26] by measuring the length of day and night (photoperiodism) [27], and control circadian rhythms, for example, of leaf position and pigment content [28,29].

FIGURE 46.1 Etiolated leafless bean plants that have grown in darkness (left) as compared to light-grown plants. (Photo D.-P. Häder.)

46.2.2 Light-Mediated Movement Responses in Higher Plants

In contrast to long-term developmental processes such as growth and flowering, photomovement of plant organs, such as branches, leaves, flowers, or fruits, occur within minutes or hours.

According to the classical definition, organs of sessile plants can respond to light by photonasty or phototropism [30,31]. Photonastic movements are induced by light quantity and quality but they are independent of the light direction; rather they follow a predefined pattern. Therefore, they are also described as nondirectional movement. For example, flower opening or stomata movements are guided by the existing morphology and are elicited by changes in the light quality or quantity. Other external factors that can elicit nastic movements are darkness (nyctinasty), chemicals (nyctinasty), for example, water (hydronasty), temperature (thermonasty), gravity (gravinasty), and mechanical stimuli such as touch (thigmonasty) or seismic stimuli (seismonasty). Usually, the intensity of the response depends on the stimulus strength. The movement is realized by changes in turgor or growth of specific plant tissues. This has been studied in the fast movements of leaves in *Mimosa* or *Dionaea*, which move by releasing the turgor in specific motor tissues [32,33]. Stomata open and close in response to the light level, but their movements are also triggered by the CO_2 concentration in the leaf and the water availability. This is controlled by the phytohormones auxin and abscisic acid. Photonasty in the prayer plant (*Maranta leuconeura*) is manifested by the downward movement of leaves induced by the increasing light intensity during sunrise. Some *Gentiana* species close their flowers after an even slight decrease in light intensity caused by a cloud. Night-flowering plants, in contrast, open their flowers following a decrease in intensity, such as *Silene nutans*, which is pollinated by night-active moths. Also leaves of some plants respond photonastically; for example, some *Phaseolus* and *Impatiens* species lower their leaves in darkness by an increased growth of cells at the upper surface. Leaves, which have stopped growing, respond photonastically by changes in the turgor or motor tissues, such as in the leaf base (pulvinus) of *Mimosa* species. Both phytochrome and blue-light-absorbing flavoproteins are involved in photonastic reactions.

Phototropism, in contrast to photonasty, is a movement of plant organs with respect to the light direction [34,35]. Shoots show positive phototropism and usually bend toward the light source

(positive phototropism) at low fluence rates. At higher irradiances, grass coleoptiles display negative phototropism (bending away from the light direction) [36,37], while many dicots stop bending in this intensity range. At even higher fluence rates, both monocots and dicots show again positive phototropism. Roots either do not respond phototropically or show negative phototropism [38,39]. Leaves orient themselves perpendicular or at other angles with respect to the light direction (plagio- or diaphototropism). A special case of leaf movement is suntracking in which the leaves follow the sun to harvest an optimal amount of light energy [40,41]. This can also be seen in some flowers; however, in contrast to common belief, mature sunflowers do not follow the sun, but, for whatever reason, face their flower heads toward the southeast, at least in the northern hemisphere.

In the absence of light, a shoot of a higher plant orients itself by negative gravitropism and grows upward (away from the center of the earth) [42,43]. This can be seen impressively in the stems of a forest growing on a steep slope. The trees are oriented upward and not perpendicular to the sloping surface. When a shoot of a higher plant bends toward a lateral light source, it will automatically be stimulated gravitropically and try to bend upward again. The vectorial product of both stimuli (light and gravity) results in a bending angle between vertical and horizontal. This phenomenon has been termed photogravitropism [44].

The photoreceptors for phototropism in shoots and leaves of higher plants are blue-light-absorbing phototropins [45,46]. They are characterized by a light, oxygen, or voltage (LOV) domain, which is the binding site for the flavin mononucleotide (FMN) chromophore [47]. However, their action can be modulated by phytochromes [48]. Phototropins are also responsible for the movement responses of chloroplasts within the photosynthetic tissues [49,50]. To make the story even more complicated, in addition to five phytochromes, at least two phototropins and at least two cryptochromes are found in higher plants; their roles as photoreceptors and their interactions are still under discussion [51].

Positive and negative phototropism has also been found in mosses and ferns [52,53]. In the latter group, even polarotropic reactions have been observed. Both protonemata and chloroplasts, for example, of *Adiantum* and *Pteris*, respond to and orient with respect to polarized light [54,55]. Even though not photosynthetic, several fungi show pronounced phototropic reactions. The mold *Phycomyces* has an extremely sensitive photoreceptor and reacts to $10^{-10} \text{ W m}^{-2}$ blue light [56,57]. The photoreceptor involved is still under discussion; pterins and flavins have been suggested as chromophoric group [58].

46.2.3 Effects of and Protection against Solar UV Radiation in Higher Plants

When exposed to high levels of solar irradiation, plants are simultaneously affected by solar UV radiation. Especially, the high-energetic photons within the UV-B band (280–315 nm) have been shown to affect the morphology of higher plants and mosses. In many species, increased UV radiation results in reduced leaf area and stem elongation [59,60]. Similar results have been found with artificial or supplementary UV-B radiation [61]. Even though UV-B radiation does not deeply penetrate into the soil, it has significant effects on root morphology and biomass production [62]. In other studies, reductions of fresh and dry weight as well as crop yield were found as a consequence of increased UV-B radiation [63]. Also germination [64], flower induction [65], and orientation with respect to light and gravity [66] are affected by increased UV-B radiation. However, there are marked differences between cultivars of the same species [67–69]. Therefore, it seems possible to select or breed UV-B resistant cultivars of crop plants to counter increased solar UV radiation. The manifold effects of increased solar UV-B radiation due to stratospheric ozone depletion, on higher plants, in conjunction with global climate change have been summarized [70,71].

Since species differ in their sensitivity toward short-wavelength radiation, an increase in solar UV-B radiation due to stratospheric ozone depletion can lead to changes in species distribution within terrestrial ecosystems [71]. Photosynthetic performance has been found to be affected in greenhouse studies with artificially increased UV-B radiation [72,73]; but it was rarely inhibited in field studies. Changes in the chemical composition of plant tissues have been often reported to be

induced by UV radiation. Some of the consequences are changes in herbivory, litter decomposition, and species composition of microbial communities [74].

Higher plants have developed a number of protective strategies against excessive solar UV radiation including the formation of epidermal hairs, cuticular waxes, and the synthesis of UV-absorbing substances [75,76]. In contrast to cyanobacteria, phytoplankton, macroalgae, and some animals, higher plants utilize flavonoids to reduce the penetration of solar UV. The synthesis of these substances, mostly in the epidermal layers, is induced by short-wavelength radiation [77–79]. Other defense strategies include the repair of UV-inflicted damage [80]. UV-B radiation causes the formation of cyclopurine dimers (CPD) such as those of adjacent thymine bases. These can be removed by the enzyme photolyase, which uses long-wavelength UV-A radiation or blue light as energy source to break the dimer bond. Other options include nucleotide excision repair (NER) [81].

46.2.4 Photoinhibition

The photosynthetic electron transport is prone to damage by excessive radiation. One way of protecting it is downregulation at the site of the D1 protein in photosystem (PS) II; both algae and higher plants use this mechanism, called photoinhibition [82–84]. When exposed to excessive solar radiation, the quantum yield of PS II decreases. This is due to a kink of the D1 protein by high-intensity visible or UV radiation [12,85]. Subsequently, the damaged protein is removed. Regeneration is brought about by resynthesis of the damaged and cleaved D1 protein in a fast turnover mechanism [86]. After short-term exposure, photoinhibition may be reversible within minutes or hours (dynamic photoinhibition), while long-term exposure may result in irreversible damage. With pulse amplitude modulated (PAM) fluorescence, several fluorescence parameters can be determined.

In this technique a red light-emitting diode (LED), produces short (microseconds) pulses that are repeated at a high frequency (e.g., 20kHz) and applied to a photosynthetic tissue by means of a glass fiber optics. A PIN diode detects the resulting fluorescence pulses via the same glass fiber. The actinic light is also applied to the leaf through the same glass fiber. In the beginning of an experiment, a weak red excitation light is provided to a dark adapted leaf, and a weak fluorescence radiation (F_0) is detected at this time all reaction centers are open (oxidized). Now a saturating pulse is applied, which reduces the photosynthetic electron transport chain and results in a peak of maximal fluorescence (F_m ; Figure 46.2). The difference between F_0 and F_m is denoted as F_v . From these parameters, the maximal quantum yield Y can be calculated [87]:

$$Y = \frac{F_m - F_0}{F_m} = \frac{F_v}{F_m}$$

After light adaptation of the leaf, a ground fluorescence higher than F_0 is found (F_t) and a saturating light pulse results in a lower maximal fluorescence ($F_{m'}$). From these parameters, the effective quantum yield can be calculated [88,89]:

$$Y' = \frac{F_{m'} - F_t}{F_{m'}} = \frac{F_{v'}}{F_{m'}}$$

The decrease of F_m to $F_{m'}$ is due to the nonphotochemical quenching (qN) calculated as

$$qN = 1 - \frac{F_{m'} - F_0}{F_m - F_0}$$

FIGURE 46.2 Parameters of PAM fluorescence. A weak red actinic light, which does not result in net photosynthesis, produces a weak fluorescence in a dark-adapted leaf (F_o). A saturating white light pulse induces F_m . After light adaptation, the ground fluorescence (F_t) is higher than F_o and the F_m after a saturating pulse ($F_{m'}$) is lower than F_m . From these parameters, qP and qN can be calculated.

while the difference between $F_{m'}$ and F_t is due to the photochemical quenching (qP) [90]

$$qP = \frac{F_{m'} - F_t}{F_{m'} - F_o'}$$

Simultaneous steady-state gas exchange measurements have proven the validity of this approach [91]. Modern versions of this technology include visualization of the quantum yield in an imaging PAM as well as multichannel chlorophyll fluorimeters [92,93].

Many plants show a typical midday decline in their photosynthetic yield around noon [94]. This pattern is believed to be mainly due to dynamic photoinhibition. Later in the afternoon, the photosynthetic yield increases again.

46.3 Habitat Selection in Microorganisms

Photosynthetic and nonphotosynthetic microorganisms are likewise affected by quality and quantity of solar radiation. Motile microorganisms use active propulsion to optimize their position in the water column. But even nonmotile microorganisms have been found to move up and down in the water column by changing their buoyancy in order to select a suitable habitat [95,96].

46.3.1 Orientation by Light

In addition to endogenous rhythms that govern vertical migration [97], motile microorganisms orient with respect to external factors to control their position in their habitat. Light and gravity are the major clues for orientation [98–100], but both flagellated and gliding microorganisms use chemical gradients (including organic molecules, dissolved oxygen or carbon dioxide) [101–103], temperature [104], the magnetic field of the earth [105,106], and even electric currents [107,108].

The reactions of microorganisms to quality and quantity of light, its direction, and spatial and temporal changes of light can be distinguished into several responses.

46.3.1.1 Photokinesis

Both prokaryotic and eukaryotic organisms show photokinetic reactions [109,110]. The term defines the locomotion velocity in dependence of the ambient irradiance [111]; it is independent of the direction of light. Not only photosynthetic microorganisms show this behavior, but also heterotrophic organisms such as the colorless *Astasia longa* [112]. In the flagellate *Euglena gracilis*, photokinesis saturates at low-intensity white light (about 300 lx) [113]. The photoreceptor for photokinesis absorbs in the blue light region but its chemical nature has not yet been identified [114].

46.3.1.2 Photophobic Responses or Photoshock Response

Engelmann [115] vividly described the behavior of photosynthetic bacteria, which reversed their swimming direction as if frightened when leaving the irradiated field under the microscope and entered a dark field. Phobic reactions at light/dark boundaries result in the accumulation of cells in dark or illuminated areas. This can be seen in, for example, flagellates, cyanobacteria, diatoms, and ciliates [116–118].

Photophobic responses are independent of the light direction and can also be elicited by a temporal change in light intensity. A sudden increase (step-up) or decrease (step-down) in the steady-state irradiance may cause a movement response, which may manifest itself as a sudden stop, a reversal of swimming or a tumble [119]. In the flagellate *Euglena*, step-down and step-up photophobic reactions occur at different irradiances [114]. The action spectra for both responses indicate the involvement of a blue light photoreceptor. Iseki et al. [120] have recently identified a novel photoreceptor [photoactivated adenylyl cyclase (PAC)], which belongs to the family of BLUF proteins and which they showed to be responsible for the step-down photophobic reaction, but interestingly not for the step-up response. BLUF proteins are also found in bacteria and cyanobacteria [121,122].

46.3.1.3 Phototaxis

Oriented movement with respect to the light direction is defined as phototaxis. Organisms move toward the light source (positive phototaxis), away from it (negative phototaxis), or at a given angle to the light direction (dia- or plagiophototaxis; Figure 46.3). Often the same organism shows positive phototaxis at low light intensities and a negative one at higher intensities. Most organisms use UV/blue light photoreceptors (300–550 nm). In addition to a light-absorbing pigment, the cells need an apparatus to identify the light direction. One option is to compare the readings from two or more receptors looking into different directions, the other is to scan the environment, for example, by rotation of the cell during forward locomotion [123]. Some ciliates have developed complicated cellular structures with a lens and a photosensitive layer of pigments, which resemble eyes in invertebrates even though the organisms are unicellular [124].

Phototaxis in the flagellate *Euglena* is mediated by the same PAC photoreceptor, which also governs step-down photophobic responses [125]. Other organisms use different classes of photoreceptors including cryptochromes, phototropins, phytochromes, and rhodopsins [126]. Several prokaryotic and eukaryotic organisms have been found to use photoactive yellow proteins (PYP), which contains a 4-hydroxycinnamate chromophore [127], chlorophylls, carotenoids, phycobilins, and pterins. Hypericin derivatives (e.g., blepharismine, stentorin) have been identified to mediate photoorientation of ciliates [128]. Phototaxis in cyanobacteria is currently intensively investigated. These organisms use a number of different photoreceptor pigments including bacterial phytochromes and BLUF proteins [129–131].

46.3.2 Defense Systems against Excessive Solar Radiation in Microorganisms

Vertical migration of motile phytoplankton organisms and protection in the shade of floating objects is an effective defense mechanism for motile microorganisms. Cyanobacteria were the earliest organisms with oxygenic photosynthesis [132]. They were responsible for releasing oxygen to the up-to-then anaerobic atmosphere. This was the prerequisite for the formation of the stratospheric ozone layer, which absorbs all of the solar UV-C and most of the detrimental UV-B radiation.

FIGURE 46.3 Circular histograms indicating positive (left) and negative phototaxis (right) of the flagellate *Euglena gracilis*. Light impinges from 0°. The length of the sectors indicate the percentage of cells moving in the respective direction.

Many organisms utilize protective pigments to absorb solar UV radiation before it can damage sensitive cellular targets. Since cyanobacteria evolved still under the influence of UV-C they have developed substances, which absorb in this wavelength range: scytonemins are yellow-brown lipid-soluble dimeric pigments (Figure 46.4), located in the extracellular sheath of certain cyanobacteria growing in extreme habitats such as on rocks or the bark of tropical trees exposed to intensive solar radiation [133,134]. In addition, these substances absorb in the UV-B and UV-A [135,136].

Other cyanobacteria, many eukaryotic phytoplankton and macroalgae produce mycosporine-like amino acids (MAAs), which are water-soluble substances [137,138] (Figure 46.4). These are characterized by a cyclohexenone or cyclohexenimine chromophore, which is conjugated with the nitrogen substituent of an amino acid (or its imino alcohol). They have absorption maxima ranging from 310 to 360 nm and an average molecular weight of around 300. Animals are believed not to synthesize MAAs but take them up with their food and use them likewise as UV protectants [138,139]. Up to now more than 20 different

FIGURE 46.4 Chemical structures of scytonemin (right) and the mycosporine-like amino acid shinorine (left).

MAAs are known, but their synthesis is still elusive. It is thought that they are synthesized within the shikimate pathway; currently molecular genetic methods and genome mining are employed to elucidate their biosynthesis [140]. Comparison of MAA-producing and nonproducing cyanobacteria, with sequenced genomes, identified a combination of genes involved in MAA synthesis. YP_324358 is predicted to code for a DHQ (3-dehydroquinate) synthase and YP_324357 for an O-methyltransferase; both were found only in the MAA-producing *Anabaena variabilis* PCC 7937 and missing in other (non-MAA producing) cyanobacteria. Phylogenetic analysis showed that these two genes were also transferred from a cyanobacterial donor to dinoflagellates and finally to metazoa by lateral gene transfer. All other investigated cyanobacteria, which possess these two genes, also had a second copy of the DHQ synthase gene.

In most cases, biosynthesis of MAAs is induced by UV-B radiation. The action spectrum for MAA synthesis induction in the cyanobacterium *Anabaena* shows a peak at 290 nm [141]. The UV-B-dependent induction of MAA synthesis in *Anabaena* sp., *Nostoc commune*, and *Scytonema* sp. promoted the synthesis of a single MAA, shinorine, containing both a glycine and a serine with an absorption maximum at 334 nm [142]. A polychromatic induction spectrum for MAAs in the dinoflagellate *Gyrodinium* showed a pronounced peak at 310 nm [143] and that for the chlorophyte *Prasiola stipitata* a maximum at 300 nm [144].

An alternative to preventing UV damage in the first place is the repair of DNA damage after it has occurred. Basically, three mechanisms are known to repair damages of the DNA. Photoenzymatic repair (PER) uses the enzyme DNA photolyase that breaks cyclobutane dimers in the presence of UV-A or blue light. NER starts with the recognition of damaged DNA and continues with the excision and resynthesis of the damaged strand by DNA polymerase. Recombinational repair (postreplication repair) repairs DNA damage that has not been recognized by the replication mechanism [145]. If not repaired, UV-induced DNA damage can result in mutations and death of the cells.

46.4 Ecological Consequences of the Photoenvironment

Both habitat selection of higher plants and movement of microorganisms to areas of suitable growth conditions is governed to a large extent by light. In addition to the availability of water and permissive temperatures, seed germination is often triggered by the presence of light (light germination, e.g., *Amaranthus retroflexus*, *Betula pubescens*, *Chenopodium album*, *Lactuca sativa*, and *Pinus sylvestris*), while in other plants seed germination is prevented by light (dark germination, e.g., *Brassica juncea*, *Cucumis sativus*, *Phacelia tanacetifolia*, and *Raphanus sativus*) [146]. After germination, the success of growth and development largely depends on the quality and quantity of solar radiation. Shade plants are inhibited by unfiltered solar radiation. In contrast, many trees, for example, in tropical and subtropical rain forests, start as seedlings and are sustained in an early developmental phase with limited growth until the falling of a large tree opens up a gap in the canopy. Only then, and this may be decades after germination, the young seedling quickly starts growing to reach the top level of the canopy [147]. Plant development in the shade under a canopy is governed by the red/far red ratio in the impinging radiation as shown by the work of Harry Smith [148,149].

Light also controls the timing of flowering. They do that by measuring the length of the day with great precision [150]. Some plants flower in short days, which need to be shorter than a species-specific critical day length (e.g., *Xanthium*, *Primula*, *Fragaria*); as a consequence, they flower in spring or autumn. Other plants flower in long days, longer than the critical day length (e.g., *Spinacea*, *Lactuca*), which therefore flower in summer. This is the reason why lettuce forms heads in spring, but elongates and flowers in summer, no matter when it has been planted. Still other plants flower independently of the day length (e.g., *Helianthus*, *Oryza*, *Pisum*, *Zea*). Since the day length varies with the geographical latitude, the same species flower earlier or later depending on the latitude. Biannual plants have an even more complex flowering control mechanism: in the first year they form a rosette, subsequently they require low temperatures (vernalization), and in the following year they shoot (stem elongation) and flower when the critical day length is reached (e.g., *Hyoscyamus*).

The movement responses of motile microorganisms in aquatic habitats result in the accumulation of populations in favorable light environments. Positive phototaxis leads the organisms toward the water surface. Often negative gravitaxis supports the upward movement [15]. Graviorientation has the advantage that it allows the organisms to orient themselves in darkness or in murky waters to move to the surface even without light guidance [151]. As indicated earlier, excessive solar visible and UV radiation at the water surface may damage the organisms. In response to this detrimental radiation, they often invert their direction of movement. This can be achieved by switching to negative phototaxis [152,153] or positive gravitaxis [154], by stopping movement and relying on sedimentation or by changes in buoyancy [155,156]. Often various responses operate antagonistically. In the flagellate *Euglena*, negative gravitaxis and negative phototaxis guide the cells in opposite directions. As a result, the population accumulates at a specific depth in the water column, which changes dynamically with changing irradiation and cloud cover. In this flagellate, the preferred depth is at an irradiance of 30 W m^{-2} , which is also the optimum for its photosynthesis [157].

While phototaxis has been found in several cyanobacteria, photophobic responses seem to be more important for habitat selection in these prokaryotes. At low light intensities, gliding cyanobacteria cross dark/light boundaries without responding, however, when leaving the light field they reverse the direction of their gliding motility; this behavior causes filamentous cyanobacteria (but also other gliding microorganisms such as *Dictyostelium* amoebae) to accumulate in light fields [158,159]. At higher fluence rates, the opposite behavior may occur. Again an antagonism between opposite behavioral responses allows the organisms to fine-tune their movement and select optimal light conditions.

Photokinesis seems not be as important for habitat selection even though a higher swimming speed in light compared to darkness causes the organism to spend less time in irradiated areas and more time in darkness [160,161]. This behavior has been discussed for the light-sensitive ciliate *Stentor*, which is easily killed by excessive solar radiation [162]. Other ciliates have been found to rely on phototaxis to escape excessive solar and especially UV radiation [163–165].

46.5 Excessive Light Stress

At low light intensities, growth and photosynthetic biomass production are suboptimal. On the other hand, exposure to excessive intensities is a stress factor for most photosynthetic organisms. One of the molecular mechanisms involved is the production of reactive oxygen species (ROS) [166,167]. Solar energy absorbed by the photosynthetic antenna pigments and passed to the reaction centers excites chlorophyll to one of several possible excited singlet states. Under normal conditions, this energy is utilized to initiate an electron transport involving several redox systems, which finally results in the production of ATP and $\text{NADPH} + \text{H}^+$. If under excessive radiation the electron transport chain is saturated, the chlorophyll molecule may convert to the first excited triplet state. The energy level of this is close to that of oxygen, which, in the ground state, is also in the triplet state. By transfer of the excitation energy to oxygen the latter reaches the singlet state $^1\text{O}_2$, which is rather short-lived but can destroy proteins, lipids, and other biomolecules in its vicinity. In the chloroplasts of photosynthetic organisms, this reaction is prevented as much as possible by assembling carotenoids in direct contact to the chlorophyll-binding proteins. By this construction, any excess energy is transferred to the carotenoids, which release the excitation energy as heat. Higher plants and some algae use the xanthophyll cycle to improve this protective mechanism [168,169].

In addition to singlet oxygen, other ROS may be generated including superoxide radicals ($\text{O}_2^{\cdot-}$), hydroxyl radicals (OH^{\cdot}), hydrogen peroxide (H_2O_2), and other radicals, all of which can destroy cellular organelles and biomolecules. Cellular responses are the synthesis of several enzymes [170–172], including catalase, superoxide dismutase, glutathione peroxidases, and peroxiredoxins. Furthermore, ascorbic acid, tocopherol, or glutathione are used to scavenge ROS [173].

Especially aromatic amino acids within the proteins absorb short-wavelength UV radiation. By this mechanism UV-B can break down proteins. In addition, it can bleach chromoproteins, such as

chlorophylls, carotenoids, and phycobilins, which are important accessory pigments of cyanobacteria, cryptophytes, and rhodophytes [174,175]. Other targets of solar UV radiation are DNA and RNA both in the nucleus and the plastids. As indicated above, UV-B mainly induces the formation of cyclobutane. UV-C radiation (<280 nm) results in the formation of 6-4 photoproducts, pyrimidine hydrates, and DNA-protein cross links. But solar radiation with wavelengths below ~290 nm does not reach the earth's surface due to the absorption by stratospheric ozone [176].

47.1 Introduction

47.1.1 Discovery and Biological Context of the Photoactive Yellow Protein

In 1985, several ferredoxins and other chromophoric proteins from the halophilic phototrophic bacterium *Ectothiorhodospira halophila* were isolated by T. E. Meyer in Tucson, Az.¹ One of the “other chromophoric proteins” he identified in this screen was yellow and was named “photoactive yellow protein” (PYP) in a subsequent study.² *E. halophila* was reclassified in 1996 to its current name *Halorhodospira halophila*.³ *H. halophila* is a unicellular prokaryote, or more specifically, a phototrophic purple spirillum that deposits sulfur extracellularly. It was first isolated and classified from salt-encrusted mud taken from the shores of Summer Lake, Lake County, Oregon.^{4,5} Later, it was also isolated from the extremely saline lakes of the Wadi el Natrun in Egypt.⁶ Both locations are salt lakes, and indeed, *H. halophila* only thrives in extremely salty environments.

As a phototrophic organism, *H. halophila* exploits the free energy available from sunlight to survive. However, like most organisms, *H. halophila* is not immune to the effects of UV radiation. It is therefore essential for the organism to find a place to live where there is enough light to grow, but where the amount of UV radiation is at a minimum. Like most phototrophic organisms, *H. halophila* has mechanisms to perceive the available light climate. It is not only attracted by (infra)red (i.e., photosynthetic)

light, but it also has a blue-light response system which steers it away from potentially harmful places, rich in blue light. This blue-light repellent response has a wavelength dependence that fits the absorption spectrum of the PYP.⁷ This observation provides evidence that PYP is the light sensor in the blue-light response of *H. halophila*. Further evidence for this function of PYP in *H. halophila* may be provided via genetic techniques. However, the application of these techniques in extremophilic prokaryotes like *H. halophila* is not well developed, which may be the reason why genetic proof for the function of PYP is not yet available.

Interestingly, the function of PYP is similar to that of the sensory rhodopsins, and in particular to sensory rhodopsin II, which is also a sensor for a negative tactile response to blue light (in *Halobacterium salinarum*, an archaebacterium that can also be found in salt lakes). The family of the rhodopsins is a large family. Its members are found in all kingdoms of life, from unicellular organisms to complex ones such as *Homo sapiens sapiens*. It is the most extensively studied family of photoactive proteins available. Its best known members are the visual rhodopsins, which allow *Homo sapiens sapiens* to see, and bacteriorhodopsin, which is a light-activated proton pump found in *Halobacterium salinarum*. Sensory rhodopsins are close relatives to bacteriorhodopsin and can be found in the latter organism too. In fact, the most notable difference between bacteriorhodopsin and the sensory rhodopsins is their function. Bacteriorhodopsin provides the cell with means of harvesting light energy, whereas the sensory rhodopsins are light detectors that make sure the organisms can find a niche in the environment in which bacteriorhodopsin can do its work safely and efficiently. Striking similarities between PYP and the sensory rhodopsins were already noted after the first characterization of PYP.² There is, however, one major difference with the sensory rhodopsins that has boosted the study of PYP: It is highly water soluble, whereas the rhodopsins, being membrane proteins, are not. As we shall see later, PYP and the sensory rhodopsins turned out to belong to two structurally very different families of proteins, which are only similar in function. For more information on the rhodopsins, the reader is referred to several excellent reviews on this topic.^{8–12}

47.1.2 Xanthopsins: The Family of PYPs

H. halophila is not the only organism in which a PYP has been discovered. The family of PYPs has been named the Xanthopsin family.¹³ Other Xanthopsins have been detected and biochemically characterized in *Rhodothalassium salexigens* (synonymous to *Rhodospirillum salexigens*),¹⁴ *Halochromatium salexigens* (synonymous to *Chromatium salexigens*),¹⁵ *Rhodobacter sphaeroides*,¹³ *Rhodobacter capsulatus*,¹⁶ *Rhodospirillum centenum*,¹⁷ *Idiomarina loihiensis*,¹⁷ *Thermochromatium tepidum*,¹⁷ *Stigmatella aurantiaca*,¹⁸ *Rhodopseudomonas palustris*,¹⁸ *Burkholderia phytofirmans*,¹⁸ and *Salinibacter ruber*.¹⁸ From DNA sequence information, more PYPs are predicted to exist in *Methylobacterium* sp., *Allochromatium vinosum*, *Leptospira biflexa*, *Gemmatimonas aurantiaca*, *Haliangium ochraceum*, *Sorangium cellulosum*, *Acidithiobacillus caldus*, *Leptothrix cholodnii*, *Magnetospirillum gryphiswaldense*, *Curvibacter* (a putative symbiont of *Hydra magnipapillata*), and *Spirosoma linguale*. All corresponding reading frames have significant similarity ($<10^{-8}$) to PYP from *H. halophila* and contain at least two of the strongly conserved key residues: Tyr42, Glu46, and Cys69 (Figure 47.1).¹⁹ All of these organisms are from the domain of the Bacteria, while most are Proteobacteria. *Salinibacter ruber* belongs to the subgroup of Bacteroidetes and *L. biflexa* is from the subgroup of Spirochetes. In the phylogenetic tree shown in Figure 47.2, the PYPs of these latter two organisms group together. Another member of the Bacteroidetes with a PYP is *S. linguale*, which however has only 30% identity with the Xanthopsin from *S. ruber*. The last non-Proteobacterium is *G. aurantiaca*, which is a member of the Gemmatimonadetes.

The length of all known Xanthopsins (domains) varies between 123 and 162 residues, which implies that this domain shows very few deletions or insertions (see Figures 47.1 and 47.2). Four of these Xanthopsins are the N-terminal domain of a multidomain protein. Significantly, these four PYP domains—from *Rhodospirillum centenum*, *T. tepidum*, *A. vinosum*, and *Methylobacterium* sp.—also cluster in the phylogenetic tree of the Xanthopsins (Figure 47.2). Also the Xanthopsin from *G. aurantiaca*, with a length

FIGURE 47.1 Sequence alignment of the Xanthopsins. An alignment of all currently known Xanthopsins is presented, where the following abbreviations stand for the organism in which the Xanthopsin was found with the strains in parentheses: Hha1, *H. halophila* (DSM 244/SL1); Hha3, *H. halophila* (DSM 244/SL1); Hsa, *H. salexigens*; Ilo, *I. loihiensis*; Rsa, *R. salexigens*; Hha2, *H. halophila* (DSM 244/SL1); Rsp1, *Rhodobacter sphaeroides* (strain ATCC 17023/2.4.1/NCIB 8253/DSM 158/ATCC 17029/ATH 2.4.9); Rsp2, *Rhodobacter sphaeroides* (KD131/KCTC 12085); Rca, *Rhodobacter capsulatus*; Mgr, *M. gryphiswaldense*; Sru, *Salinibacter ruber* (DSM 13855); Lbi, *L. biflexa* (Patoc 1/ATCC 23582/Paris/Ames); Bph, *B. phytofirmans* (DSM 17436/PsJN); Lch, *L. cholodnii* (ATCC 51168/LMG 8142/SP-6); Cur, *Curvibacter* (putative symbiont of *Hydra magnipapillata*); Hoc, *Haliangium ochraceum* (DSM 14365/JCM 11303/SMP-2); Sli, *Spirosoma linguale*; Aca, *A. caldus* (ATCC 51756); Sau1, *S. aurantiaca* (DW4/3-1); Rce, *Rhodospirillum centenum* (ATCC 51521/SW); Tte, *T. tepidum*; Avi, *A. vinosum* (DSM 180); Msp, *Methylobacterium* sp. (4–46); Rpa, *Rhodopseudomonas palustris* (BisB5); Gau, *G. aurantiaca* (T-27/DSM 14586/JCM 11422/NBRC 100505); Sau2, *S. aurantiaca* (DW4/3-1); Sce, *Sorangium cellulosum* (So ce56). Two slightly different Xanthopsins with one amino acid different are found in different *Rhodobacter sphaeroides* strains. In *H. halophila* and *S. aurantiaca*, two different Xanthopsins are found in the same organism. This figure was prepared with Jalview²⁰ (<http://www.jalview.org/>) using information obtained from alignment performed with ClustalW²¹ (<http://www.ebi.ac.uk/Tools/msa/clustalw2/>).

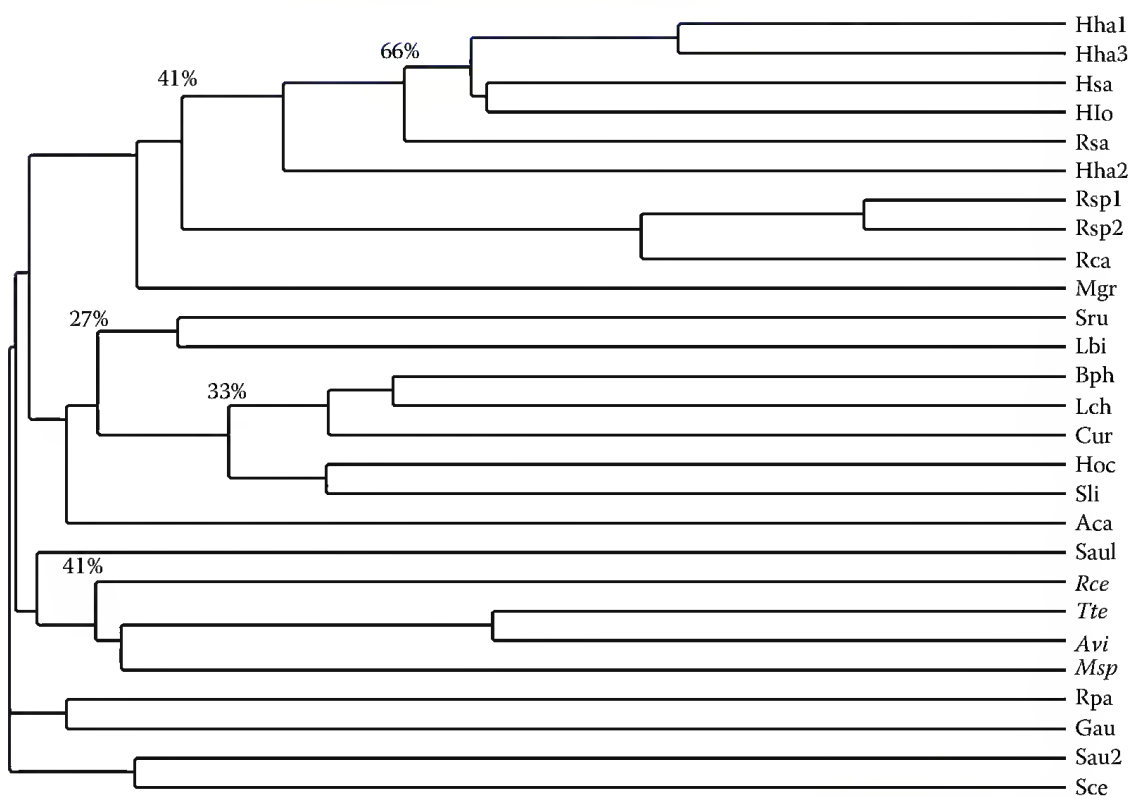

FIGURE 47.2 Phylogenetic tree of the 27 Xanthopsins from the alignment shown in Figure 47.1. The Xanthopsins from multidomain proteins are indicated in italics. Several percentages are placed for the lowest pair-wise identity for the set of PYP in that branch.

of 162 amino acids, may have a separate output domain, for example, in the form of a helix-turn-helix domain. Bioinformatics analysis of the secondary structure of this domain, however, only clearly showed one helical stretch in the carboxy-terminal 40 amino acids.

The biological function of the Xanthopsins in the various organisms may differ quite significantly. In *H. halophila*, PYP induces a photophobic tactile response.⁷ For *Rhodobacter sphaeroides*, genetic evidence is available that indicates that the blue-light-induced photophobic tactile response in that organism is not mediated by the Xanthopsin present in that organism, provided no genetic redundancy exists.²² The Xanthopsin found in *Rhodospirillum centenum* regulates chalcone synthase gene expression.²³ The PYP domains from *Methylobacterium* sp. and in the Ppr protein from *Rhodospirillum centenum* are followed by a bacteriophytochrome domain and a histidine kinase domain. For Ppr, it has been observed that blue light causes changes in autokinase activity.²³ In *T. tepidum* and *A. vinosum*, a PYP is present that is also part of a multidomain protein, but here the PYP and bacteriophytochrome domain is followed by a GGDEF/EAL domain, which may suggest that these photoreceptors have a function in biofilm formation. The function of only a limited number of members of the Xanthopsin family has so far been elucidated. However, it is reasonable to suggest that the members within the different subgroups of Xanthopsins, distinguished based on sequence similarity (see Figure 47.2), have a similar function, while these functions may differ between the subgroups.

47.1.3 Photoactive Yellow Protein: The Prototypical PAS Domain

As described earlier, PYP is part of a family of proteins named Xanthopsins. Nevertheless, PYP also shows striking similarities with the much larger family of PAS domains. These PAS domains have been identified in proteins from all three kingdoms of life, that is, in the *Bacteria*, the *Archaea*, and the *Eucarya*. PAS is an acronym formed from the names of the proteins in which the PAS motive was first recognized²⁴: the *Drosophila* period clock protein (PER), the vertebrate aryl hydrocarbon receptor nuclear translocator (ARNT), and the *Drosophila* single-minded protein (SIM).

Proteins containing PAS domains are predominantly involved in signal transduction. Over 21,000 PAS domains have been identified that contain (a) PAS domain(s).²⁵ Most of these are receptors, signal transducers, or transcriptional regulators present in the cytoplasm. PAS domains are usually present in proteins with a multidomain architecture. Furthermore, a single protein can have multiple PAS domains; in fact, proteins have been identified containing up to six. In contrast, the entire PYP from *H. halophila* can be considered a single PAS domain. As it is the first protein from the PAS domain family for which the 3D structure was elucidated, it was proposed that PYP is the structural prototype of the PAS domain fold.²⁶

47.2 Structure

After an initial period of confusion, in which only the primary structure of PYP was solidly secured through gene sequencing,²⁷ the spatial structure of PYP was solved at a resolution of 1.40 Å with x-ray diffraction analysis in 1995 and deposited in the protein data bank (PDB).²⁸ Not much later, multi-dimensional NMR spectroscopy provided the structure of PYP in solution,²⁹ and the resolution in the structure of PYP was brought down to 0.82 Å.³⁰ Now, even a neutron diffraction-derived structure is available for PYP.³¹ During the past 20 years, structural information on PYP has been secured through studies on wild-type PYP, nine site-specific and deletion mutants, one PYP-like protein (i.e., Ppr), crystallized in four different space groups (P63, P65, P21, and H) in the temperature range from 85 K³² to ambient temperatures. Besides structures of the stable ground state of these proteins, of wild-type PYP, and the E46Q mutant thereof, also nine and four (mixtures of) intermediate states of these two proteins, respectively, populated through illumination of the respective proteins, have been deposited in the PDB (<http://www.pdb.org/>). This wealth of information has helped to acquire very detailed understanding, not only of the stable dark structure of PYP, but also of its functioning, in terms of the dynamical changes in its structure that are elicited by illumination. Part of this insight will be discussed in the following.

47.2.1 Secondary and Tertiary Structure of PYP

The protein backbone of PYP is folded in an α/β -fold, with a six-stranded antiparallel β -sheet as the central scaffold, flanked by five elements with α -helical secondary structure.²⁸ In addition, a short π -helix can be identified at the site where the chromophore is attached to the apo-protein.³³ The loops containing helices $\alpha 3$ and $\alpha 4$, and helix $\alpha 5$, fold on top of this central β -sheet to form the major hydrophobic core of the protein, which then forms a pocket in which the chromophore of PYP, *p*-coumaric acid³⁴ (or 4-hydroxy cinnamic acid), is incorporated. The N-terminus of the protein, which contains helices $\alpha 1$ and $\alpha 2$, folds at the back of the central β -sheet to form a second, smaller, hydrophobic core. This tertiary structure is shown more clearly in Figure 47.3 in two orientations: with the plane of the central β -sheet parallel and perpendicular to the plane of the paper, respectively. The latter view allows one to see how the different α -helical loops fold around the central β -sheet.

47.2.2 Xanthopsins Compared

From previous alignment with six Xanthopsins, the Xanthopsin family was divided into three subgroups, based on their primary structure. Subgroup I contains Xanthopsins found in *H. halophila*, *R. salexigens*, and *H. salexigens*. With the current alignment (Figure 47.1), the Xanthopsins from another *H. halophila* strain, a second PYP in *H. halophila* and *I. loihiensis*, are added to subgroup I. Previous subgroup II contains Xanthopsins found in *Rhodobacter sphaeroides* and *Rhodobacter capsulatus* and to this subgroup belongs also a PYP from another *R. sphaeroides* strain. The only member of subgroup III was the Xanthopsin found in *Rhodospirillum centenum*. This Xanthopsin has a low similarity with the Xanthopsins from subgroups I and II. From the currently known 27 Xanthopsins, 19 fall outside subgroups I and II. These Xanthopsins have less than 45% identity to PYP from *H. halophila*. Xanthopsin from *Rhodospirillum centenum* forms a subgroup with the three other Xanthopsins of multidomain proteins. A fourth subgroup can be made from Xanthopsins found in *B. phytofirmans*, *L. cholodnii*, *Curvibacter*, *Haliangium ochraceum*, and *Spirosoma linguale*. The rest of Xanthopsins are not divided into subgroups. The primary structures within subgroups I and II are very similar with identities around 75% in pair-wise alignments. Subgroups III and IV have identities around 42%. In a comparison of Xanthopsins from subgroup I or II with other Xanthopsins, the alignments become worse with identities around 30%. Several pair-wise comparisons of Xanthopsins have even poorer results with identities low as 14%. Beside the earlier mentioned functional important residues Tyr42, Glu46, and Cy69, the residues Gly29, Phe63, Ala67, and Pro68 are highly conserved.

Since the Xanthopsin subgroups were defined based on sequence similarity, these results should not be very surprising. However, by looking at subdomains of the sequence alignments, better insight is

FIGURE 47.3 Tertiary structure of the PYP. Two orientations of a ribbon representation of the PYP from *H. halophila* are presented. Panel (a) clearly shows the β -sheet with the chromophore in front of it. Panel (b) is a side view, of the orientation in panel (a), visualizing both sides of the β -sheet. The figure was prepared using the program MOLMOL³⁵ using the structure coordinate file deposited at the Protein Data Bank³⁶ (<http://www.pdb.org/>) with PDB ID: 2PHY.²⁸ The program POV-Ray³⁷ (<http://www.povray.org>) was used to render the images.

obtained on which domains make a Xanthopsin a Xanthopsin, and which domains are important for the function the Xanthopsin has in the organism it resides in. PYP was earlier proposed to be a prototype for the PAS domain. The family of PAS domains is very large and spans all three kingdoms of life. A PAS domain is not so much defined by its primary structure, but more by its secondary and tertiary structural elements. The PAS domain can be divided into four subdomains, the N-terminal cap, the PAS core, the helical connector, and the β -scaffold. In PYP from *H. halophila*, these subdomains comprise residues 1–28, 29–69, 70–87, and 88–125, respectively. Thus, the N-terminal cap contains helices $\alpha 1$ and $\alpha 2$; the PAS core contains the β -strands $\beta 1$, $\beta 2$, and $\beta 3$, and the helices $\alpha 3$ and $\alpha 4$; the helical connector contains helix $\alpha 5$; and the β -scaffold contains the β -strands $\beta 4$, $\beta 5$, and $\beta 6$. The residues that form the chromophore pocket are all contained within the PAS core and β -scaffold, which are sandwiched together.

The conservation in the Xanthopsin family is different for the four PAS subdomains. The similarity is high for the PAS core and low for the N-terminal cap. The edges of the PAS core, including residues 28–46 and 58–69, have the highest degrees of homology. However, the helical connector and the β -scaffold also have high similarity within the different Xanthopsin subgroups. Especially, the β -scaffold in subgroup I and the helical connector in subgroup III have high homology. This suggests that the PAS core is important for the general sensing function of the Xanthopsins, and the other subdomains determine the specific function of a particular Xanthopsin.

Most Xanthopsins are small single-domain proteins. Twenty-one of these single-domain Xanthopsins have length between 123 and 146 amino acids. Two other single-domain Xanthopsins from *Salinibacter ruber* and *G. aurantiaca* have longer lengths of 156 and 162 residues, respectively. PYP from *S. ruber* has a 31 residue N-terminal extension that appears to be important for dimerization.³⁷ Dimerization of PYP is only described in literature for the PYP from *S. ruber*. The PYP from *G. aurantiaca* has a 39 residue C-terminal extension. The primary structure of the extension suggests that it contains at least one α -helix. Indicating the C-terminal extension is involved in signal transduction.

There are more proteins similar to the Xanthopsin family than these 27. An unclassified Gammaproteobacteria (NOR5-3) contains a single protein of 115 residues with similarity 10^{-6} to PYP from *H. halophila*. Despite the low similarity with PYP, this protein contains the conserved residues Gly29, Tyr42, Glu46, Phe63, and Cys69, but not the two conserved residues Ala67 and Pro68. Therefore, the environment of the chromophore-binding place is different than in most Xanthopsins. Further, PYP-like domains are found in *Methylobacterium radiotolerans*, *Methylobacterium extorquens*, *Methylobacterium populi*, and *Methylobacterium chloromethanicum*. All these PYP-like domains are N-terminal domains of multidomain proteins and have similarity between 10^{-9} and 10^{-8} to PYP from *H. halophila*. However, these protein domains lack conserved residues Tyr42, Glu46, Ala67, and Cys69. These protein domains have a serine or glycine instead of Cys69. Therefore, it is not clear if these proteins function as photoreceptor without a cysteine for chromophore attachment. However, all these PYP-like domains contain the highly conserved Gly29, Phe63, and Pro68. In these multidomain proteins, the PYP-like domain is followed by a bacteriophytochrome domain and a histidine kinase domain. These are the same domains as the domains of the Ppr protein from *Rhodospirillum centenum* and the Xanthopsins domain-containing protein of *Methylobacterium* sp. This suggests a similar function for all these six proteins.

47.2.3 Chromophore and Its Binding Pocket

As amino acids do not significantly absorb visible light, functional activity of a photoreceptor protein depends on a covalently, or non-covalently, associated chromophore to the specific photoreceptor. The type of chromophore selected by evolution typically corresponds with the wavelength range in which the receptor protein is required to function.³⁸ Accordingly, the Xanthopsins use an aromatic chromophore, identified in *H. halophila* in 1994 as 4-hydroxy cinnamic acid, covalently linked to the apo-protein via a thiol ester bond to Cys69.^{34,39} This chromophore plays a crucial role in the functional activation of PYP

via its sensitivity to *trans/cis* (or *E/Z*) isomerization upon absorption of a photon from the visible part of the electromagnetic spectrum. This chromophore is embedded in the protein in a pocket lined by the following amino acids (in the order in which they appear in the sequence): Ile31, Tyr42, Glu46, Thr50, Arg52, Phe62, Val66, Ala67, Cys69, Thr70, Phe96, Asp97, Tyr98, Met100, Val120, and Val122. These amino acids completely bury the chromophore in the major hydrophobic core of the protein and prevent direct contact of the former with solvent.

In the dark state of PYP, the chromophore is deprotonated.^{39,40} The resulting negative charge of its phenolic oxygen is buried in the main hydrophobic core of the protein. This is possible only through stabilization of this negative charge by a dedicated hydrogen-bonding network.^{28,41} The phenolate anion, of which part of the charge is delocalized over the large π -orbital system of the chromophore, interacts with Glu46, Tyr42, and Thr50, such that O _{η} from Tyr42 and O _{$\epsilon,2$} from Glu46 form very short hydrogen bonds with the chromophore. O _{η} from Tyr42 in turn hydrogen-bonds with O _{$\gamma,1$} from Thr50; the latter amino acid, however, does not line the chromophore pocket. This hydrogen-bonding network is the main determinant of the spectral tuning of PYP.⁴¹

The recent neutron diffraction study of deuterated PYP³¹ has revealed further specific detail of this hydrogen-bonding network: From the position of the deuteron relative to the two pairs of oxygen atoms that form the two hydrogen bonds, it has been deduced that Tyr42 and Glu46 form a short-ionic- and low-barrier hydrogen bond with the phenolate oxygen of the chromophore, respectively. The special character of these hydrogen bonds was recently confirmed with solid-state NMR spectroscopy.⁴² The discovery of the special character of these hydrogen bonds is particularly relevant for computational analyses of the mechanism of photoactivation of PYP because the relative bond strength changes dramatically from a regular to a low-barrier hydrogen bond. The latter type of bond is also predicted to convey typical characteristics to the infrared spectrum of the protein,⁴³ which, however, have not been characterized yet. Nevertheless, the ultrafast changes in the infrared absorption of Glu46 are fully consistent with the results of the neutron diffraction experiment.

The structure of PYP in aqueous solution, determined via multidimensional NMR spectroscopy,²⁹ is very similar to the structure determined with x-ray and neutron diffraction. The elements of secondary structure identified in both of them are nearly identical, be it that they may start/end 1–2 residues earlier or later. Notably different are helix $\alpha 2$ and the π -helix, which are just below the cutoff for positive identification in the solution structure. Furthermore, there are three poorly defined regions in the solution structure, comprising residues 1–5, 17–23, and 113–117. This is caused by lack of structural constraints in the NMR dataset in those regions, which may be caused by high side-chain and/or backbone mobility.²⁹ In the crystal structure, these same regions have higher values for the B-factor, which expresses the mean-square fluctuations of atoms from their average position. Another difference is observed with respect to the position of Arg52: This residue is present in two conformations in the solution structure: One in which Arg52 is positioned 4 Å above the aromatic ring of the chromophore, and in the other, the guanidinium group of Arg52 is positioned about 4 Å above the aromatic ring of Tyr98,²⁹ which is suggestive of π -stacking.⁴⁴ These positions of both Arg52 and Tyr98 differ from those in the crystal structures. The position of Arg52 is particularly relevant because it has been proposed that it plays an important role in the primary photochemistry of PYP.⁴⁵ The results of site-directed mutagenesis, in combination with ultrafast UV/Vis spectroscopy, however, have failed to substantiate this proposal (A. Stahl et al., unpublished).

All this information available about the dark or ground state of PYP has formed a very fertile frame of reference for the interpretation of a large body of spectroscopic and biochemical data on a wide range of aspects of this photoreceptor protein. Nevertheless, its photosensory function requires that additional (transient) structural states exist. Such states have been identified and characterized; they will be discussed within the framework of the discussion of the photocycle of PYP in the following. However, in the characterization of these intermediates, it has turned out that there is a profound effect of the crystal lattice on the dynamics and extent of the structural transitions to which the PYP acquires access upon photoactivation.

47.2.4 Dynamical Changes in the Structure of PYP and the Confines of the Crystal Lattice

From an ensemble of structures, such as obtained with NMR spectroscopy or molecular dynamics simulations, it is possible to determine eigenvectors that describe the path along which the atoms of a protein may move.^{46,47} Using these eigenvectors, or “modes of flexibility,” it is possible to transform the solution structure into the crystal structure, indicating that the observed differences between the two structures are within the confines of the intrinsic flexibility of the protein. This is further corroborated by the fact that a transition of the structures of PYP, crystallized in the $P6_5$ and the $P6_3$ space group, respectively,²⁸ can also be performed within the confines of its intrinsic modes of flexibility.

Illumination of PYP crystals allows formation of transient intermediate states that spontaneously revert back into their stable ground state. While doing this, they may largely use the same “modes of flexibility,” and therefore, initially such intermediates formed in a crystal lattice⁴⁸ were thought to show considerable similarity to corresponding states formed in aqueous solution.^{49,50} Nevertheless, when PYP is activated in the latter type of medium, structural changes take place that go far beyond these modes. This conclusion was initially based on spectroscopic measurements that revealed that PYP shows non-Arrhenius type of kinetics and that this kinetics is strongly affected by the hydrophobicity of the medium.^{51,52} This interpretation subsequently has been confirmed by molecular dynamics simulations⁵³ and multidimensional solution NMR spectroscopy,⁵⁴ be it that the latter experiments are complicated by the very high degree of disorder of a large part of the polypeptide backbone of PYP when the protein resides in its signaling state. Only recently has it turned out possible to record well-resolved spectra of the signaling state of PYP with ¹⁵N, ¹³C-NMR spectroscopy in solution (H. Ippel et al., unpublished experiments).

To characterize the different photocycle pathways that PYP goes through upon photoactivation in a crystal lattice and in aqueous solution (both at room temperature), dedicated spectroscopic experiments were designed both with microcrystals and with crystals of a size suitable for diffraction studies.^{55,56} These experiments have revealed that the crystal lattice does not only accelerate the thermal recovery of the ground state of PYP approximately 10-fold; it also allows various branching pathways to make a significant contribution to this recovery.⁵⁶ These studies have clearly shown that the presence of a crystal lattice confines the extent to which the PYP backbone reversibly unfolds with respect to the degree of transient unfolding in solution.

In vivo, the PYP functions in the cytoplasm of *H. halophila*.⁵⁷ The freedom it experiences for dynamical alterations in its structure in this crowded bacterial cytoplasm is as yet unknown, but may be intermediate between that of an aqueous buffer and a crystalline lattice. Particularly, the precise nature of the interaction of PYP with downstream transducer proteins may tip the balance to either of these.

47.3 Photoactivity of the Xanthopsins

Photoactivity of the Xanthopsins expresses itself in the form of a photocycle. When a Xanthopsin in the ground state absorbs a photon of the proper wavelength, structural changes occur in the protein that lead to a signaling state that can be “read” by the organism it resides in. From the signaling state, the Xanthopsin spontaneously returns to its stable ground state. This self-regenerative cycle only requires the holoprotein to be in hydrated form and does not require the presence of a membrane, additional proteins, or cofactors, etc. Most Xanthopsin research is focused on this photocycle or a part of it. The best-studied Xanthopsin by far is PYP from *H. halophila*. Therefore, the photocycle of this protein will be discussed in detail in the following.

47.3.1 Basic Photocycle

Though models for the photocycle of the PYP have become more and more elaborate over the years, they still feature no more than the three basic intermediates that were initially described⁵¹ (see [Figure 47.4](#)): (1) the ground or dark-adapted state, pG, in which the chromophore is deprotonated and the

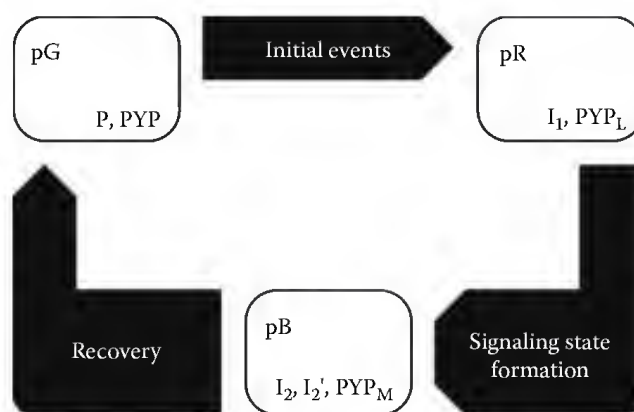

FIGURE 47.4 Basic photocycle model of PYP. Nomenclature used in this review is indicated in the top-left of the balloons. Alternative nomenclatures found in the literature are indicated bottom-right of the balloons.

isomerization state of the chromophore is *trans*; (2) pR, a spectrally red-shifted state (relative to pG), which is formed on a nanosecond timescale, in which the chromophore is still deprotonated but its configuration has changed to *cis*; and (3) pB, a spectrally blue-shifted state (relative to pG), which is formed on a microsecond timescale. This species is presumed to be the signaling state of the photoreceptor. It is stable enough to allow for a signal to be processed by the organism. In the pB state, the chromophore has become protonated while it retains the *cis* configuration. The holoprotein subsequently recovers to its ground state on the millisecond to second timescale.

These three major steps, isomerization, protonation change, and recovery, are also observed in the sensory rhodopsins, which have a similar cellular function as PYP, but are structurally very different. It is interesting to note that although the Xanthopsins and sensory rhodopsins have evolved separately, the photochemical mechanism they use to generate a signal from an absorbed photon is essentially the same.

47.3.2 Photocycle Interpretation

Over the years, several nomenclatures for the photocycle intermediates have been introduced. As the photocycle models become more and more complex, so does the nomenclature. Unfortunately, there is not a single nomenclature that is really able to handle all the new intermediates that meanwhile have been described. All the different nomenclatures contain the aforementioned three basic photocycle species and can therefore be compared using these three species as a reference (see Figure 47.4). Initially, these ground-, red-shifted, and blue-shifted states were called P, I₁, and I₂.⁵¹ In 1995, the names pG, pR, and pB were introduced by Hoff et al.⁵⁸ Yet another nomenclature⁵⁹ was introduced in 1996, in which these species are called PYP, PYP_L, and PYP_M, a nomenclature based upon the photocycle nomenclature of bacteriorhodopsin. To add to the confusion, in 2005 the use of the name I₂' instead of I₂⁶⁰ was proposed, while I₂ is used to indicate an intermediate introduced in 1996 as pB'.⁶¹ This nomenclature is becoming even more complicated by the use of various photocycle models that introduce “new” intermediates to describe results obtained under very specific reaction conditions.

Proteins are not static, but highly dynamic molecules. We therefore should see a photocycle intermediate as an ensemble of similar but individually different structures. The question is then of course what criterion is used to assign a structure to a specific intermediate ensemble. We have chosen to take the three main photocycle intermediates (pG, pR, and pB; see Figure 47.4) as anchor points. We then subdivided the ensembles representing the intermediates into sub-ensembles relevant to a specific analysis problem. Figure 47.5 shows an example for the pH dependence of the photocycle. Note that the intermediate ensembles are subdivided horizontally according to pH (left to right represents a change from low to high pH). In addition, several characteristics of interest (isomerization state, and

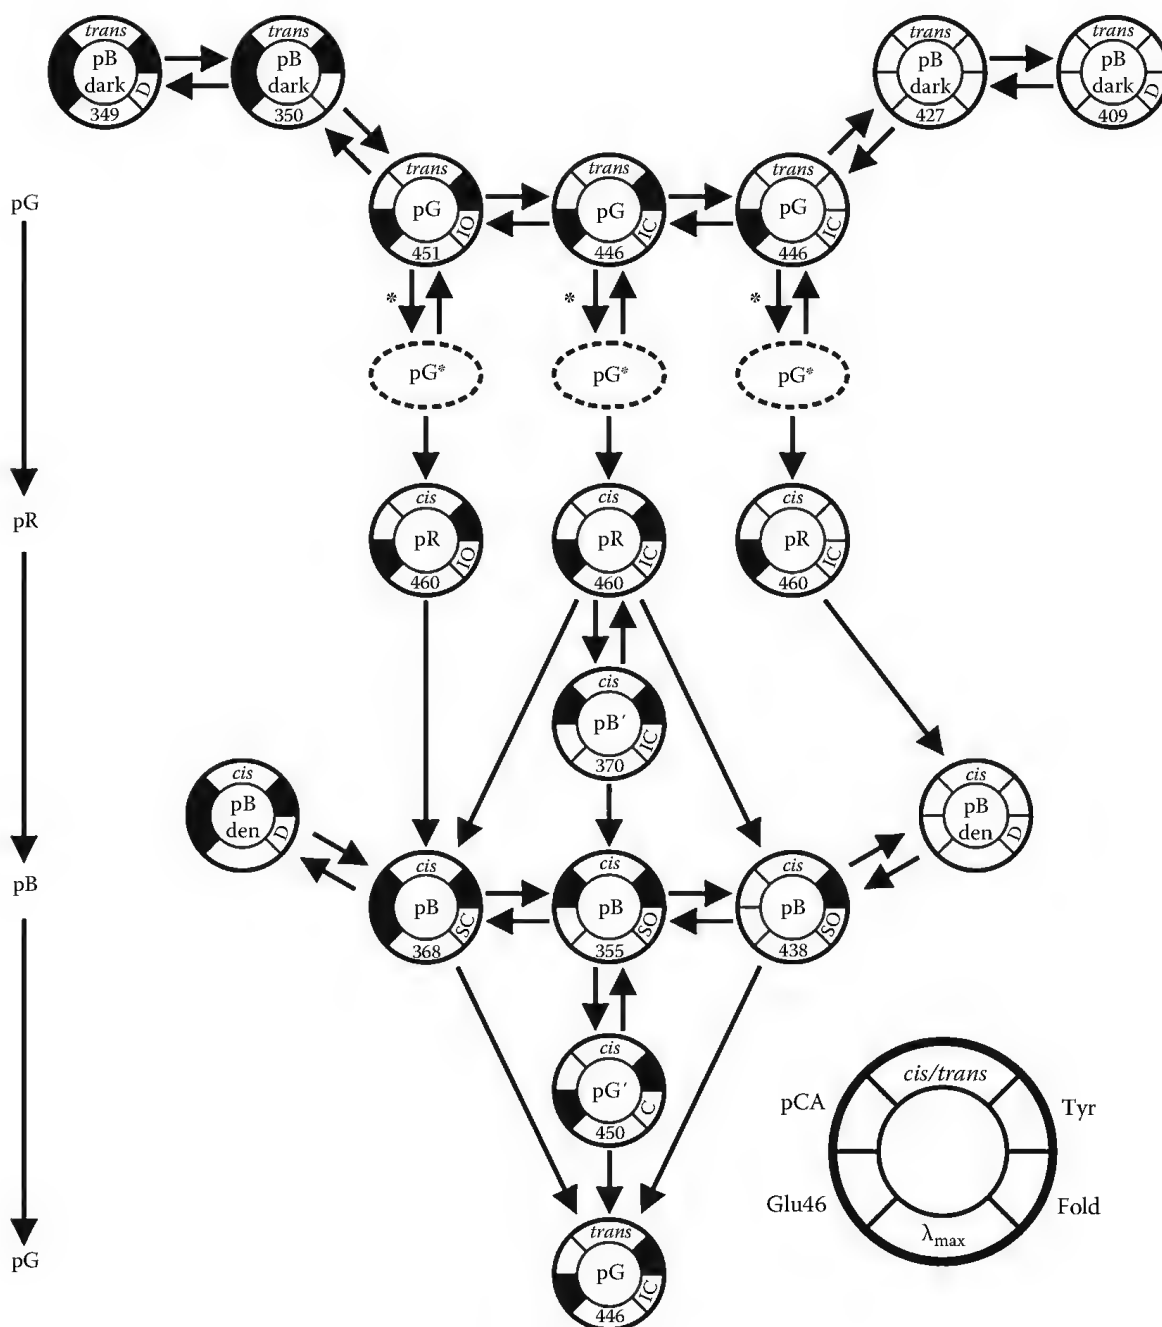

FIGURE 47.5 pH-dependent photocycle scheme for PYP. The scheme is an adaptation of the scheme presented in Ref. 62. The initial reactions are depicted in their most basic form, that is, light-induced formation of the excited state followed by formation of either pG or pR. Light-induced reactions are illustrated by a * next to the arrow. For each species in the scheme, several characteristics are depicted as indicated by the legend (bottom-right): *cis/trans*, the chromophore's isomerization state; pCA, Glu46, and Tyr, the protonation state of respectively the chromophore, of residue 46, and of tyrosine residues (black is protonated, white is deprotonated); Fold, the folding state of the protein; λ_{max}, the absorption maximum. Absorption maxima in italics are assumed. The following folding states are distinguished: IC and IO represent the closed and open form of the initial folding state of pG; SC and SO represent the closed and open form of the signaling state (pB); D represents an undefined denatured/unfolded state; C represents a hypothetical folded state that is able to catalyze chromophore isomerization.

protonation state of the chromophore and Glu46, folding state of the protein, and absorption maximum) are shown for each species. Of course, other characteristics may be chosen as well depending on the situation. A more detailed explanation of the pH dependence of the photocycle is given in the following. However, we would like to note two aspects of this photocycle: (1) There are five subspecies of pB indicated in the photocycle, with apparently quite different characteristics, such as the UV/Vis absorption maximum. Generally, one would try to think of different names for these species when depicted in a single figure. However, if one would have to describe them at a single pH, one would likely just use pB (or an equivalent from one of the other nomenclatures). (2) There is more than one route to step through the photocycle. The sample pH then will determine which route is the dominant route. Furthermore, depending on the physicochemical conditions of an experiment, one could construct additional routes when necessary. This partly explains the multitude of photocycle models for PYP that have been suggested in the literature.

47.3.3 Experimental Context

It is of crucial importance to take experimental context in consideration, when comparing different experiments. Four different experimental parameters are of basic importance: temperature, nature of the solvent, mesoscopic context (or phase), and illumination conditions. The first one, temperature, is obviously important in kinetic experiments. At very low (cryogenic) temperatures, certain photocycle species may be trapped,^{59,63} while others cannot be formed. The second one, the nature of the solvent, is also very important and is usually different between different experiments. Though pH is probably the most important solvent feature that has an effect on, for example, the kinetics of the photocycle,^{64,65} others such as hydrophobicity of the solvent,⁵¹ type and concentration of solutes present,^{50,51} and the nature of the solvent itself (e.g., water vs. deuterium oxide)⁶⁴ also can have their effect on the data. The third experimental parameter is the mesoscopic context or phase. In the crystalline phase (or lattice), no large structural change is observed in the protein upon formation of the signaling state, whereas when the protein is in solution such a significant overall structural change is observed.^{55,56} Furthermore, illumination conditions can also have pronounced effects on the data, particularly, the color and intensity of the light are important. The choice of wavelength can already have an effect on which photocycle species are formed.^{59,63} Also the duration of the excitation pulse can have an effect. Longer illumination allows the possibility of photoactivation of photocycle species other than the ground state⁶⁶ and may lead to hysteresis effects in the recovery (Gensch et al., unpublished). It should be kept in mind that in UV/Vis experiments the probe beam also contributes to illumination of the sample.

47.4 Photocycle of Photoactive Yellow Protein

The key element of the photocycle is the transition between the ground/dark state and the signaling state. In the signaling state, PYP interacts with a putative transducer protein to signal the cell that a blue photon has been absorbed. Therefore, this state needs to have a relatively long lifetime to allow for this communication. Since the interacting transducer protein has not been identified yet, all experiments have so far been performed with purified PYP itself. It is possible that certain characteristics of the signaling state will change when transducer protein is added. An example of the dramatic effect that a transducer protein can have on a photosensory protein can be observed in sensory rhodopsin I. Here, in the absence of the transducer protein, the sensor protein acts as a proton pump, while in the presence of the transducer protein the proton pump activity is lost.⁶⁷ Also, the pH dependence of the photocycle kinetics of sensory rhodopsin I changes upon removal of the transducer protein.⁶⁷ This does not imply that measurements on just the isolated photosensor are obsolete. On the contrary, any differences between the characteristics in the absence and the presence of the accompanying transducer may lead to a better understanding of how a signal might be transmitted.

47.4.1 pH-Dependence of the Photocycle

Before breaking down the photocycle into its elementary partial reactions, it is good to have a closer look at the pH-dependent aspects of the complete photocycle as illustrated in Figure 47.5. At first glance, this representation of the photocycle looks rather complicated. However, all species in a horizontal line have the same name (e.g., pG, pR, and pB) and the same basic structure (see Section 47.3.2). The point is that these species essentially are subspecies of the named species. It then depends on the pH which of these subspecies will dominate the mixture and the subspecies represent sub-ensembles of the main species. Depending on the absolute pH, the dominant route through the various (sub)species in the photocycle will vary. This to the point that some intermediates (like pB' and pG') may even be bypassed altogether under certain conditions. This explains some of the seemingly contradictory results that can be found in the literature.

The pH dependence of the photocycle in Figure 47.5 is illustrated via the equilibrium reactions between subspecies on a horizontal line, in which low to high pH is from left to right. Note that for any given pH, more than one subspecies may be present (dictated by the pKs involved) and consequently more than one route through the photocycle may be possible. The complexity that this introduces is in most cases not detected in the experimental data, which in most cases is (and should) to be analyzed with (highly) simplified models. This complexity can only be fully revealed if a series of measurements is analyzed in which specific conditions, such as pH, ionic strength, and temperature, are systematically varied. Regardless of the experiments, one might want to perform with PYP; this underlying complexity of its behavior should always be kept in mind, as the experimental conditions selected can have an important impact on results.

47.4.2 Initial Events

The initial photocycle events, studied in the science domain of biophysics, generally hold the key to important biological characteristics of a photosensory receptor, such as light sensitivity, and photocycle efficiency (or photocycle quantum yield). In its most basic form, the initial events can be depicted as the formation of a photon-induced excited state, which subsequently relaxes either back to the original dark state or to the first intermediate in the photocycle (see Figure 47.5). On the other hand, one can also try to describe all the different reactions in the initial photocycle step that leads to either formation of pR or pG. In both cases, the very first step, formation of an electronically excited state, is the same. Assuming that every absorbed photon results in the formation of an electronically excited state, an equation can be derived for the rate with which the excited state is formed (see Equation 47.1).⁶² In this equation, I_0 represents the light intensity (in $\text{mmol} \cdot \text{cm}^{-2} \cdot \text{s}^{-1}$) for a specific wavelength range; ϵ represents the molar extinction coefficient (in $\text{M}^{-1} \cdot \text{cm}^{-1}$) for the same specific wavelength range; l represents the light's path length (in cm) through the sample; $[R]$ represents the concentration of the photon-absorbing species (in M). Note that in most cases, Equation 47.1 can be approximated by Equation 47.2. One can use these formulas to simulate the light-dependent reaction(s) of photocycles:

$$k = \frac{I_0(1 - 10^{-\epsilon \cdot l \cdot [R]})}{l \cdot [R]}, \quad (47.1)$$

$$k \approx I_0 \epsilon \ln(10). \quad (47.2)$$

Trying to deduce what exactly happens after formation of the excited state of pG is a difficult exercise. This is evidenced by the very different models for the initial events in the PYP photocycle that have been published over the years. Furthermore, only very few experiments have been performed to analyze how much the experimental context influences these initial events.

Light absorption by the chromophore of PYP induces primary photochemistry that leads to its *cis* configuration within a few picoseconds, with a quantum yield of 0.35.^{68,69} The structural transition

underlying this E/Z isomerization can only be completed in a complex reaction in which also the hydrogen bond between the C=O group of the chromophore, and the nitrogen atom of the peptide bond between Pro68 and Cys69 is disrupted, to allow the C(9)=O group to rotate around the long axis of the chromophore to stabilize the isomerization of the C₇=C₈ ethylenic bond^{45,70} so that the first *cis* ground-state intermediate (GSI) I₀ can be formed.

During the past few years, it has become clear that in parallel, a transient GSI⁷¹ is formed, which may well also have an isomerized C₇=C₈ ethylenic bond but has its carbonyl group still hydrogen bonded to the nitrogen atom of the proteins' backbone.⁷² This GSI is also formed with a quantum yield of approximately one-third (the remaining one-third fraction decays through internal conversion) and then rapidly (i.e., with a half-life of 6 ps) thermally relaxes back to the stable GSI. The I₀ intermediate converts with near 100% efficiency into the I₁ state (also denoted pR₁) and subsequently to the pR₂ intermediate, through additional configurational relaxation of the *cis*-chromophore. Discovery of this transient GSI (5) has been relevant not only for the proper understanding of the primary photochemistry of PYP, but also has resolved several controversies on this aspect, for example, related to quantum yields.

Recently, we have shown (A. Rupenyan et al., unpublished experiments) that the formation of the GSI is due to a fraction of molecules in which the hydrogen bond between the C(9)=O group of the chromophore, and the nitrogen atom of the peptide bond between Pro68 and Cys69 is not disrupted during the initial stages after photoexcitation. Whether or not the chromophore in this GSI state has a true *cis* configuration, or (still) is in a distorted *trans* configuration, remains to be established.

Considering that formation of the electronically excited singlet state in PYP is accompanied by a very large charge redistribution, as was demonstrated with Stark spectroscopy,⁷³ and that for several organic dyes with a pronounced donor/acceptor asymmetry across the ethylenic bond light absorption leads to the formation of a so-called twisted-intramolecular charge transfer (TICT) state,⁷⁴ the relevance of single-bond rotation has been discussed for PYP. Independently, this issue was addressed in Quantum Mechanics/Molecular Mechanics (QM/MM) calculations on a model system that simulates the primary photochemistry in PYP.⁴⁵ Our most recent experiments suggest that such single-bond rotation indeed is relevant; however, most surprisingly, not as an alternative to double-bond isomerization, but rather to facilitate it (A. Stahl et al., manuscript in preparation).

After (spectroscopic) identification, the next important issue for any intermediate is its spatial structure. Consensus exists on the view that the protein part shows very little structural change during the first step of the photocycle and that even the aromatic ring of the chromophore stays more or less at the same position.^{75–77} The only way to facilitate isomerization of the chromophore under these conditions is by rotating the thiol ester carbonyl. This carbonyl flip can be interpreted as a double isomerization around the C₇=C₈ double bond and the C₉–S_γ single bond, that is, the chromophore configuration changes from C₇=C₈-*trans* C₉–S_γ-*cis* to C₇=C₈-*cis* C₉–S_γ-*trans*. This model was first introduced on the basis of low-temperature Fourier transform infrared spectroscopy (FTIR) spectroscopy⁶¹ and later confirmed.^{55,76,78}

The (free) energy content of PYP increases from 120 to 160 kJ·mol^{–1} upon formation of pR.^{68,79} This means that about half the energy of an absorbed photon is stored in the holoprotein at this point (a photon with a wavelength of 446 nm has an energy content of 268 kJ·mol^{–1}). This amount of energy should then be enough to drive the remainder of the photocycle. This also implies that half the energy of the absorbed photon is lost in, for example, thermal relaxations. FTIR analysis of the cryotrapped intermediates in the first step of the photocycle suggests that there is very little structural difference between these intermediates.⁷⁶ Thus, small movements induced by thermal relaxation may dictate the exact isomerization path of the chromophore.

47.4.3 Signaling State Formation

Much of the early work on the photocycle of PYP assumed a simple three-state photocycle model, that is, with the pG, pR, and pB state only. In these models, formation of the signaling state, that is, pB (from pR), has been described both as a kinetically biexponential and as a monoexponential event.

Actually, the first detailed analysis of the photocycle of PYP⁵⁰ postulated a photocycle containing an additional intermediate with similar spectral properties as pB, because of the observed biexponential kinetic character of pB formation. However, this model was refuted in a subsequent paper.⁵¹ Later, the intermediate pB' was introduced as an intermediate in the pR to pB photocycle step based on results obtained with FTIR spectroscopy.⁵⁵ A subsequent detailed laser-induced transient UV/Vis spectroscopic kinetic analysis of the photocycle confirmed the existence of this intermediate and showed it has spectroscopic properties very similar to those of pB.⁶⁴ Here, it was also revealed that the pB' intermediate is in equilibrium with pR, which explains the previously observed biexponential character of the pR to pB photocycle step.^{49,50}

47.4.3.1 Structural Relaxation of pR

After formation of pR, additional relaxation events occur in the protein.^{80,81} Through the use of the transient grating and pulsed-laser photoacoustic methods, it was shown that a microsecond dynamic component exists during the lifetime of pR. This indicates that after the structural changes in and immediately around the chromophore are completed, additional structural changes occur in the protein, further away from the chromophore. Thus, pR can be decomposed into the intermediates pR₁ and pR₂. Though the transition from pR₁ to pR₂ initially was claimed to be spectrally silent, the transition presumably was already observed earlier in UV/Vis data.⁴⁹ However, as this transition contributed only very little to the total UV/Vis signal, no confident assignment could be made in those experiments. In a more recent analysis of UV/Vis data,⁶⁴ reaction kinetics were obtained that fit the pR₁ to pR₂ transition, observed via transient grating. Though the obtained spectra for both pR intermediates are very similar, pR₁ seems to have a slightly higher extinction coefficient than pR₂, whereas the λ_{max} values are indistinguishable.

47.4.3.2 Protonation Change upon pB' Formation

One of the major events that have to occur in the transition from pR to pB is protonation of the chromophore. FTIR measurements have shown that deprotonation of Glu46 and protonation of the chromophore are a single event, which is followed by structural change of the protein.⁵⁵ This interpretation led to the introduction of the pB' intermediate, which then converts into the pB state. A photocycle model that included the pB' intermediate was then used to analyze UV/Vis data in a study on the kinetic deuterium isotope effect in the photocycle of PYP.⁶⁴ From these analyses, it was evident that pR and pB' exist in an equilibrium that shifts toward pB' upon going to the extremes of pH (both low and high pH). The observed kinetic Deuterium isotope effect is in line with a proton transfer from Glu46 to the chromophore for the whole pH range that was investigated (pH 5–11). However, for the return reaction, the situation is more complex. Here, formation of pR from pB' can occur via different routes, dependent on pH. The shift of the pR/pB' equilibrium toward pB', when going to the pH extremes, also explains the shift toward monoexponential behavior for the formation of pB at these latter pH values.

The UV/Vis spectroscopic properties of pB' and pB are rather similar,⁶⁴ which explains why the first experimental evidence for the existence of this intermediate was obtained via FTIR measurements. The pB' spectrum is most similar to the pB subspecies that dominates at low pH (see [Figure 47.5](#)). Incidentally, this is also the pB subspecies that shows the least structural change, and thus of all the pB subspecies presumably structurally resembles pB' the most. However, pB' typically transforms into either pR or the pB subspecies that dominates at medium pH. The latter has an absorption maximum blue shifted by 13 nm with respect to pB'.

47.4.3.3 Structural Change upon pB Formation

Another major event that occurs in the transition from pR to pB is structural change. From the strongly nonlinear Arrhenius kinetics of the pG recovery reaction,⁵² it was concluded that the signaling state of PYP is at—least partly—unfolded. In a mutant with the first 25 N-terminal amino acids removed,⁸² the deviation from normal Arrhenius behavior was largely gone. It therefore seems that the N-terminal

region of PYP is largely responsible for the large structural change upon formation of the signaling state. Several other methods, like, for example, CD, NMR, fluorescence, and FTIR spectroscopy have confirmed this partial unfolding.

Hydrogen-Deuterium exchange measurements in particular have contributed to the insight into the structural change that is at the basis of signaling state formation in PYP. Whereas a buried hydrogen atom may take days to exchange, an exposed hydrogen atom may be exchanged within seconds. PYP contains 235 potentially exchangeable hydrogen atoms, 42 of which are from (de)protonatable groups. In a study with electrospray ionization mass spectrometry,⁸³ it was shown that in the dark, less hydrogen atoms were exchanged for deuterium atoms compared to an experiment performed in the presence of light. Also, in apoPYP 29 potential exchange sites resist exchange, which can be interpreted as that 29 or less of the 42 (de)protonatable groups are deprotonated. Additionally, it may mean that apoPYP has a certain degree of structure, depending on the actual number of deprotonated groups. The light-induced hydrogen/deuterium exchange was independently confirmed using FTIR difference spectroscopy.⁸³ Though these experiments show that there is a difference between the ground and signaling state of PYP with respect to hydrogen/deuterium exchange protection, they do not pinpoint the areas of the protein responsible for the observed differences. However, it is possible to obtain more specific information with NMR spectroscopy.⁸⁴ Though it was only possible to obtain specific information for the backbone amide exchangeable hydrogen of 51 residues, 14 of these showed a significant change in protection (i.e., resistance against exchange) upon formation of the signaling state pB, that is, only two less than the number predicted by mass spectrometry, which was not limited to the backbone amide hydrogen atoms. The residues with the most significant loss in protection are Phe28, Glu46, and Thr70. The latter two are close to the chromophore, whereas Phe28 is close to Glu46. These results have been confirmed and extended by Brudler et al.⁸⁵

In a solution NMR study of the pB intermediate, it was shown that pB exhibits structural and dynamic disorder with respect to the ground state.⁸⁶ Interestingly, a subsequent NMR study of pB_{dark} formation⁸⁴ showed that pB_{dark} and the photocycle intermediate pB are very similar. It was also made clear that upon formation of pB_{dark}, the protein can be divided into three parts, a relatively stable core (residues 32–41, 80–94, and 113–122) and two areas that display large structural perturbation: the N-terminus (residues 6–18 and 26–29) and the area around the chromophore-binding site (residues 42–58, 69–78, and 95–100). As discussed earlier, the structural perturbations of the N-terminus are largely responsible for the observed non-Arrhenius behavior of the photocycle kinetics. Furthermore, the NMR data suggest that the pB intermediate is a mixture of structurally perturbed forms and a form structurally similar to the ground state, or more specifically, similar to the pB crystal structure.⁴⁸

The trigger for the major structural change upon formation of pB is the formation of a buried negative charge on Glu46 when it donates its proton to the chromophore.⁵⁵ After formation of pB', the buried negative charge, initially located on the chromophore, is centered on Glu46. On the chromophore, the negative charge can be effectively neutralized by delocalization of the charge and the hydrogen-bonding network of the chromophore. On Glu46, the buried negative charge cannot be effectively neutralized. This leads to a stress situation within the protein, which can be relieved via several routes. One is return to the pR state, reflecting the reversible nature of pB' formation (see earlier paragraphs). Other routes lead to the formation of pB. The extent of the structural change upon formation of the pB intermediate depends then on the route taken. One route to relieve the buried negative charge is to expose it to solvent, which requires structural change of the protein. Another route is to protonate the Glu46, but not via the chromophore since that would lead to the reformation of pR. Once Glu46 is protonated, the stress situation is relieved and a large structural change is no longer necessary. Since protonation changes play a key role, it is to be expected that these events are pH dependent. Thus, depending on the pH, one route may dominate over the other. In fact, a pH dependence of the extent of structural change has been observed to coincide with protonation of Glu46 (J. Hendriks and A. Xie et al., unpublished results). Of course, both routes to pB mentioned here assume that pB' is formed as an intermediate. It is also possible that a direct, or alternative, route from pR to pB exists. In such a route, Glu46 may stay protonated, that is, it does not donate a proton to the chromophore. The chromophore then becomes protonated only after

exposure to the solvent, or via another residue (e.g., Tyr42). Such a route would require little structural change of the protein and might be preferred in the crystal environment. All mentioned routes are possibilities, and depending on the conditions one particular route may dominate. The key factor in all these routes is what happens to the protonation state of both Glu46 and the chromophore. In fact, it has been shown that for the Glu46Gln mutant in solution, the structural change upon formation of pB is significantly less compared to the wild-type protein.⁵⁵ In this mutant residue, 46 no longer can donate a proton to the chromophore, and thus, no buried negative charge is formed on residue 46, and hence less driving force for structural change is generated. Though residue 46 plays an essential role in the amount of structural change that takes place, other residues may also have influence. For example, His108 also has influence on the extent of structural change as it has been shown that the mutant His108Phe also exhibits less structural change compared to the wild-type protein.⁸⁷

The pH dependence of structural change has also been shown to exist via transient probe binding,⁸⁸ showing less structural change at low pH. Together with experiments monitoring the pH-dependent net proton uptake/release of PYP during pB formation⁸⁹ and pH-dependent FTIR results (J. Hendriks and A. Xie et al., unpublished results), this leads to the conclusion that the pK_a of Glu46 in pB is 5.5, so that above pH 5.5 much more structural change occurs than below.

The structural change upon formation of pB is typically related to changes in the N-terminus. However, significant structural changes also occur on the other side of the central β -sheet, around the chromophore pocket. This was nicely demonstrated by NMR measurements on a mutant of PYP lacking the N-terminus.⁵⁴ Furthermore, these latter measurements showed that the N-terminus most likely is involved in stabilizing the helix containing residues Asn43 to Thr50 (helix α 3). These NMR results were independently corroborated via parallel tempering simulations initiated to simulate the formation of pB.⁵³ Further simulations showed the importance of helix α 3 for the successful recovery of the ground state.⁹⁰ These pioneering steps in trying to simulate events that take place on a millisecond timescale have since then been improved to the point that the mechanisms underlying the transition from pB' to pB can be deduced.⁹¹ Here, a salt-bridge between Asp20 and Lys55 appears to play an important role. As such, the effect of salt (or ionic strength) on the PYP photocycle may be linked to this salt-bridge.

47.4.4 Ground-State Recovery

Recovery of the ground state can be achieved either spontaneously in the dark or light induced via an accelerated path. In the latter, a photon absorbed by pB' and/or pB photoisomerizes the chromophore, thereby allowing a 1000-fold increase in the rate of recovery, with respect to the rate of recovery in the dark.⁹² The existence of this branching reaction can influence data in the presence of light that can be absorbed by any of the pB intermediates. This may allow recovery kinetics to appear faster than they really are in the absence of this light.⁹³ Such accelerated recovery with visible light can be exploited in the study of the very slow recovery variants, like M100A.

During the thermal recovery of the ground state of PYP, several events have to take place simultaneously. The chromophore has to reisomerize to the *trans* form; the protonation state of several residues and the chromophore have to be changed, and the protein needs to return to its original fold. Though these are seemingly distinct steps, until recently, they often were assumed to occur concertedly. However, it had already been suggested that prior to isomerization, the chromophore must first be deprotonated, and thus an intermediate must exist between pB and pG.⁹⁴ Confirmation of the existence of this intermediate was obtained in measurements of the kinetic deuterium isotope effect.⁶⁴ Here, it was shown that deprotonation of the chromophore occurs prior to its isomerization. Though deprotonation of the chromophore aids the reisomerization of the chromophore tremendously,⁹⁵ this reisomerization is still a rate-controlling step, in which the protein fold likely plays a crucial part. Only recently, the existence of such an intermediate was actually shown experimentally, in an extensive pH-dependent study on PYP recovery.⁶² The new intermediate was named pG' and appears to have a UV/Vis spectrum highly similar to pG, indicating that the chromophore is already deprotonated in this photocycle intermediate, as

suggested before. It also explains why pG' was not noticed before. The pG' intermediate is characterized by a deprotonated chromophore and a folding state that allows reisomerization of the chromophore. This latter characteristic is important, as this intermediate has an absorption spectrum that is similar to that of the ground state of PYP and not one that is similar to the pB intermediate at high pH, which also has a deprotonated chromophore but has its absorption maximum around 430 nm.^{64,89}

Several studies have been done to study refolding of PYP. In a study utilizing the denaturants urea and guanidinium ·HCl, refolding was studied in unfolded ground-state protein and in the unfolded signaling state.⁹⁶ The major difference between these two denatured forms of the protein is the isomerization state of the chromophore. Where refolding from the denatured ground state is a monoexponential event, refolding from the denatured signaling state is biexponential. Here, the fast component is identical to refolding from the denatured ground state, and the slow exponent has a rate similar to the photocycle ground-state recovery rate under similar conditions. This indicates that after the signaling state renatures, it recovers to the ground state through the regular photocycle pathway. Interestingly, extrapolation of the obtained refolding kinetics in the absence of denaturant shows close to a 1000-fold faster rate for refolding for the protein with the chromophore in the *trans* state compared to protein with the chromophore in the *cis* state. This is similar to the difference in rate observed between the ground-state recovery in the dark and photo activated ground-state recovery via the branching reaction.⁹²

Similar experiments with the acid denatured state of PYP were also performed,⁹⁷ and similar results were obtained. Refolding from the acid denatured state with the chromophore in the *trans* state, that is, pB_{dark}, is 3–5 orders of magnitude faster with the chromophore in the *cis* state. Interestingly, it was shown with temperature denaturation that in the acid denatured state, the chromophore is in the *cis* state, the protein is more stable than when the chromophore is in the *trans* state. Furthermore, it was shown that the acid denatured state with the chromophore in the *cis* state is very similar to the photocycle intermediate pB.

For a few mutants of PYP, a dramatic decrease in recovery rate has been observed, that is, Glu46Asp,⁹⁸ Met100Ala,⁹⁹ and Met100Leu.¹⁰⁰ This indicates that Glu46 and Met100 are important for facilitating recovery. Met100 is important for the reisomerization of the chromophore, as indicated by the dramatic increase in rate of recovery when the chromophore is photochemically reisomerized in the Met100Ala mutant.⁹⁹ In a recent study, it was argued that the electron-donating character of the residue at position 100 influences the rate of recovery through interaction with another residue, most likely Arg52.¹⁰¹ With the Glu46Asp mutant, such a dramatic increase in recovery rate was not observed upon photochemical reisomerization of the chromophore.⁹⁸ As such it is likely that Glu46 is important for refolding of the protein, though it may still be involved in dark reisomerization of the chromophore.

47.5 Future Perspective

Soon after its discovery, 26 years ago, PYP developed into a model system for biophysical research on protein structure and function. In retrospect, this development came quite rapidly after the initial confusion about its spatial structure. Its excellent physicochemical and photochemical stability, however, made it to an excellent tool with the introduction and calibration of new biophysical methodology, like various forms of ultrafast spectroscopy, time-resolved diffraction experiments, small-angle scattering, etc. Conversely, the application of this myriad of techniques has provided almost unprecedented insight into the dynamical and structural aspects of its function.

Nevertheless, these experiments are still ongoing and promise to provide even more intricate detail. A surprising aspect herein is that we know most of the initial and the final stages of the processes that underlie the functional photocycle of the protein. A key step in the central part of this cycle, the transfer of a proton from Glu46 to the chromophore, is still poorly understood with respect to its dynamics and the structure of the protein from which this transfer takes place in solution. Not even the extensive computational efforts, that have rationalized many aspects of the functioning of PYP, have provided this insight.

With respect to the biological aspects of functioning of PYP, little progress has been made beyond the initial studies of phototaxis in *E. halophila*. This is partly due to the difficulty of applying the methodology of molecular genetic to extremophilic bacteria. Nevertheless, an additional factor has been the rather restricted range of organisms in which a representative of the Xanthopsin family was discovered. In this light, the expansion of the Xanthopsin family as described in this review is very exciting. Furthermore, this recent expansion implies that the range of output domains to which PYP appears to be able to couple has increased to the extent that now also domain of unknown function (DUF) domains are included. This even more suggests that this photoreceptor family may have a role in biofilm formation.

Procedures for heterologous expression of the holoprotein form of PYP have been well-established. So far, applications of a Xanthopsin member in the exciting field of optogenetics have not yet been reported. But who knows what the future has in store.

48.1 Introduction

Since solar radiation that reaches earth's surface can be both beneficial and harmful to living organisms, the large majority of them have developed mechanisms to perceive it as a signal to get information on the surrounding environment and behavioral strategies to expose themselves to radiation intensities suitable for their survival.

Also many motile microorganisms, despite their reduced dimensions and the absence of a neural system, use radiation as an environmental clue and are able to accumulate in areas where light is favorable to their viability and to disperse from areas where it is harmful. These behaviors mainly evolved because of the necessity of optimizing photochemical energy production or avoiding photoinduced damage; however, some microorganisms show photooriented movement for different reasons, since radiation may also be correlated with the presence of preys (e.g., photosynthetic algae)¹ or predators² or favor the possibility of reproducing.³

48.1.1 Historical Perspective

Despite the fact that unicellular organisms were described for the first time in 1675 by Anton van Leeuwenhoek, it is not until the beginning of the nineteenth century that the first references to a motile response elicited by a luminous stimulus in microorganisms appears in the scientific literature. In his paper of 1817, Treviranus describes the behavior of the algae *Draparnaldia glomerata* and *Ulothrix subtilis* under illumination, noting that they accumulate in the shadowy region of the vessel and interpreting this behavior as a mean to avoid harmful light irradiances.⁴

In the following years and especially at the end of the century, several authors began to study the effect of light on the movement of filamentous algae and cyanobacteria, debating on the mechanisms of photoorientation in microorganisms.^{5,6} In those years, the foundations of the study of photomovement were laid, and it is interesting to note that many of the discussions initiated at that time have continued until few years ago, even if in a more modern way.

An important contribution to the study of photomovements was given by Engelmann, starting in 1879. Better known for his studies on the role of chlorophyll in photosynthesis, Engelmann was the first to describe the sudden change of motion of microorganisms when encountering a light-dark boundary (he named it “schreckbewegung,” i.e., “phobic motion”), to correctly explain the mechanism of accumulation in a light trap in terms of single cell behavior, and to perform the first experiments on the localization of light sensitivity in particular areas of the cell body.⁷

At the beginning of the twentieth century, Jennings includes light among the stimuli affecting the behavior of microorganisms and reports the findings of several authors on the phototile responses of unicellular organisms.⁸ His hypotheses and suggestions, like those on the mechanisms of reaction in *Euglena* sp. later supported by Mast who repeated his experiments, are the basis of the modern research on photomovements.⁹ The fact that the discoveries and ideas of Jennings were cited and considered fundamental for so many years is even more remarkable if we consider that all the experiments were carried out using an optical microscope with the aid of primitive techniques (e.g., he modulated the intensity of the actinic light by screening the light source with a hand).⁸

After these pioneer years, the study of photomovements benefited by a better control of the experimental conditions (such as temperature, salinity, and pH), by the collection of quantitative rather than qualitative data and by a more accurate description of the phenomena.

In 1977, an *ad hoc* Committee¹⁰ revised the terminology of behavioral responses of motile microorganisms and indicated three basic movement patterns following an external stimulation: phobic response, taxis, and kinesis. These patterns, with the prefix “photo” to denote the light stimulation, have a sign according to the effect triggered by the perception of the stimulus (Figure 48.1): step-up and step-down photophobic reactions follow an increase or a decrease in light intensity, respectively; phototaxis can be positive or negative if the cells move toward or away from the light source; photokinesis is either positive or negative if the cell speed increases or decreases after the onset of the light stimulus (see Chapter 46 for the definition of the terms). Positive phototaxis, step-down photophobic responses, and negative photokinesis cause photoaccumulation, whereas negative phototaxis, step-up photophobic responses, and positive photokinesis result in photodispersal.

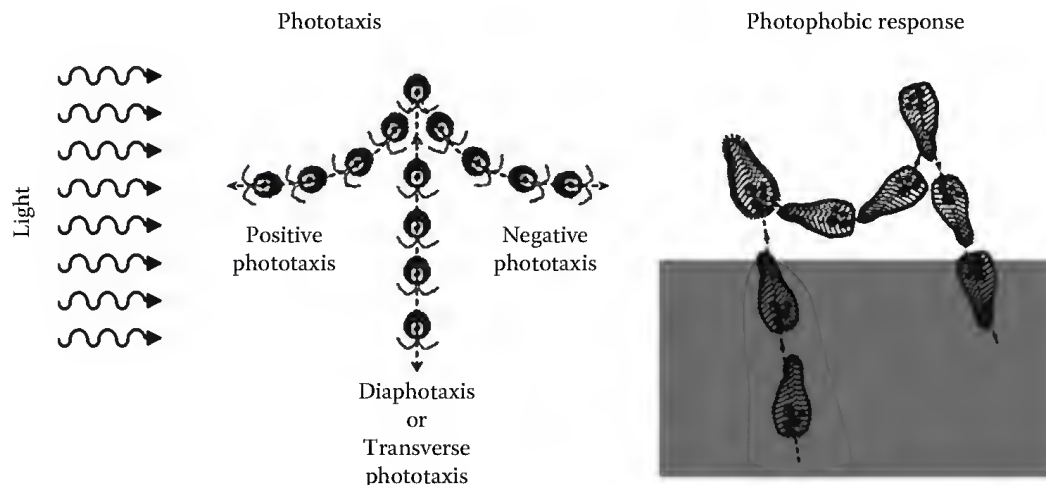

FIGURE 48.1 Schematic representation of the different types of phototaxis and of the step-up photophobic response.

Most eukaryotic microorganisms exhibit more than one of these photoresponses, which can be concurrent in producing photoaccumulation or photodispersal, or act separately depending on the level of light intensity and/or the presence of other signals from the environment.

48.2 Photoreceptor

While the eyes of metazoa share similar characteristics even when comparing organisms phylogenetically very distant, the photoreceptor apparatuses of different microorganisms show a significant richness in photoreceptive apparatuses, chromophores, and apoproteins.

Notwithstanding this high variability of structures and molecules, the flow from light perception to the motile reaction, that is the photoresponse, can be split into different stages characterized by similar features. In fact, the absorption of a photon induces molecular modifications of the photosensing chromophore that switches to the signaling state, which in turn activates the dark reaction of the transduction chain to eventually bring a signal to the motor apparatus. In the following, we will go through the different stages of the photomotile process, briefly discussing the main recent advancements and the still open questions in a few case examples.

48.2.1 Photoreceptor Organelles and Antennas

In many photosensitive eukaryotic microorganisms, the light perceiving apparatus is formed of two parts: the actual photosensing organelle, analogous to the metazoan retina, and other supramolecular structures (antennas) dedicated to modulate the signal reaching the photoreceptor molecules, either collecting and focalizing the light or screening it altogether.

The photosensing organelles are structures showing a wide range of complexity, from photoregulated channels embedded in a patch of the plasma membrane, such as in the case of the green alga *Chlamydomonas reinhardtii*¹¹ to the ordered 3D array of the paraxonemal body (PAB) of *Euglena gracilis*.¹² Some heterotrichous ciliates (like *Blepharisma japonicum*, *Stentor coeruleus*, and *Fabrea salina*) possess a high number of granules rich in pigment, diffused all over the cell body and arranged in rows below the plasma membrane; in the case of *B. japonicum*, electron microscopy showed an internal honeycomb-like structure.¹³ These ciliate pigments, strong photosensitizers, are thought to have both a photosensing and a defensive function, and the pigment granules are supposed to work as photoreceptor organelles^{13,14} and to be discharged as defensive barrage against predators if need be.¹⁵

Also the antennas modulating the light signal are rich in variety.^{16–19} In the slime mold, *Dictyostelium discoideum* light is focused on the distal side of the pluricellular slug by means of a lens effect of the roughly cylindrical surface of the body.²⁰ Slightly more complex is the stigma of *E. gracilis*, whose function is simply to screen the light reaching the photosensor: because of the helicoidal swimming of this microorganism, light reaching the PAB is alternatively switched on and off, thus allowing *E. gracilis* to detect light direction comparing its intensity in two different instants.²¹ In *C. reinhardtii* and in several dinoflagellates, the antenna, also known as eyespot, is constituted by one or more layers of globules containing carotenoids or melanoid pigments. Such layers are usually concave, and they work on one side as screening devices and on the other as reflectors, focusing the light on the photoreceptor organelle and possibly selecting the wavelength by means of a positive quarter-wave interference.¹⁶ Also light-refractive devices show a wide range of complexity from the watchglass organelle of the Ophryoglenidae ciliates¹⁷ up to the most elaborated eyespots found in Warnowiaceae dinoflagellates, a complex structure called ocelloid for its resemblance to a metazoan eye.^{22,23}

48.2.2 Chromophore

Microorganisms are an artificial wide assembly of unicellular organisms belonging to several phyletic groups; it is therefore not surprising that different taxonomic groups have evolved different strategies to be able to extract information from solar radiation, beginning from the chromophore used as the

prosthetic group of the photoreceptor complex. For example, in unicellular eukaryotes at the moment the identified chromophores for motile photoresponses include retinoids (e.g., in green algae), pterins (in euglenoids), flavins (in euglenoids and *Loxodida* ciliates), porphyrins (in slime molds), and dianthronic molecules (in *Heterotrichida* ciliates) (Figure 48.2).

Even if belonging to different chemical groups, natural chromophores usually share similar features. In fact, a chromophore is usually characterized by broad absorption bands with high molar extinction coefficients in order to be able to detect light over a large range of the solar spectrum; in alternative, an assembly of different chromophores, absorbing in contiguous spectral ranges, could be spatially arranged in molecular frameworks in order to maximize the collective interaction and in the end the spectral sensitivity.

The direct identification of the chromophore is in most cases difficult because it is often present in extremely low amount, and the photoreceptor organelle is very tricky to isolate and in some cases even hard to identify.

Action spectroscopy allows to establish a direct link between the observed photoresponse and the functional absorption of photons in order to formulate hypotheses on the nature of the chromophore; in fact, the structure of the action spectrum is expected to be corresponding to that of the chromophore absorption spectrum. However, the shape of the action spectrum may be affected by the presence

FIGURE 48.2 Determined molecular structures of chromophores for photomovements in eukaryotes.

either of screening pigments not involved in the photosensing process or of more than one chromophore absorbing in different spectral ranges and acting in parallel or in cascade (i.e., by means of energy transfer) (see Chapter 43).

Notwithstanding these limitations, in several cases, action spectroscopy proved to be a sufficiently sensitive technique. For example, Foster and Smyth, reinterpreting previous data by Nultsch et al.,²⁴ produced an action spectrum suggesting a rhodopsin-like photoreceptor for the phototactic response of the flagellated alga *C. reinhardtii*.¹⁶ Later, this hypothesis was confirmed using a blind mutant, which exhibits photoresponse only at very high fluence rates: incorporating analogues of the retinal chromophore into the mutant cells, it was shown, in fact, that the photoresponse was restored also at lower fluence rates and that the maxima of the action spectra were shifted consistently with the absorption maxima of the different incorporated retinoids.¹¹

Also in the case of the ciliate *B. japonicum*, several research groups identified by means of action spectroscopy the endogenous pigments blepharismine and oxyblepharismine (OxyBP) as the photosensing chromophores. This ciliate, when grown in dim light (less than about 30 W m^{-2}), is characterized by the fact that the endogenous red pigment blepharismine photoconverts to blue OxyBP and the absorption spectrum structure changes with a shift toward the red. However, OxyBP maintains the photosensing properties and the action spectra for step-up photophobic response of red and blue *B. japonicum* match blepharismine and OxyBP absorption spectra, respectively.^{25,26} Also the action spectrum for the membrane receptor potentials of red cells correlated with the absorption spectrum of blepharismine.²⁷

Also absorption and fluorescence microspectroscopy has been used to formulate hypothesis on the localization and the nature of the chromophore. For example, recent confocal microscopy measurements showed that in *B. japonicum*, the putative photoreceptor chromophore is located not only in the pigment granules, as thought before, but also in the cilia.²⁸ Moreover, by means of fluorescence lifetime imaging microscopy (FLIM), it has been found that the cilium chromophore shows a different fluorescence decay time pattern, thus allowing to formulate the hypothesis that it could be the functional photosensing chromophore, also due to its proximity to the motor apparatus. In the case of *E. gracilis*, the nature of the photoreceptor chromophore was a much debated issue also because *in vivo* microspectrofluorometry suggested that the PAB contains flavins,²⁹ whereas absorption studies on a single isolated PAB indicated the presence of rhodopsin.^{30,31}

Chemical, biochemical, and physicochemical approaches have been used in the attempt to isolate the chromophore alone or bound to its apoprotein, characterize its structural and functional properties, and investigate the following stages of the transduction chain. By means of anion-exchange and gel filtration chromatography on *E. gracilis* isolated PABs, Iseki and co-workers³² were able to separate a 400 kDa protein complex to which flavins were bound. Sodium dodecyl sulfate-polyacrylamide gel electrophoresis (SDS-PAGE) revealed that this protein complex is constituted by two pairs of similar subunits with different molecular mass (105 and 90 kDa) and therefore has a heterotetrameric structure. The presence of the 105 kDa subunit in the PAB was confirmed by means of immunostaining with the polyclonal antibody.

In the case of the hypericin-like endogenous pigments of the heterotrichous ciliates *S. coeruleus*,³³ *Maristentor dinoferus*,³⁴ and *B. japonicum* in its blue form,³⁵ high-performance liquid chromatography (HPLC) isolation and subsequent nuclear magnetic resonance (NMR) and mass spectrometry characterization highlighted differences in the molecular structure, which were not predictable from the absorption and fluorescence spectra.

Experiments with nonphotoresponsive mutants have been used to identify the chromophore, supplying the putative photoreceptor molecule to check whether the photoresponse is restored, and in general to study the phototransduction chain. In fact, one of the first evidences that the photoreceptor for phototaxis in *C. reinhardtii* is a rhodopsin-like molecule came from the observation that light-unresponsive mutants lacking carotenoids recovered orientation capability when incubated with retinal and other retinoids.¹¹

Nowadays, molecular biology is becoming one of the most powerful methods to study the different steps of the photoreception process, especially because the number of microorganism genomes completely

or partially determined is constantly increasing. The most used techniques in photomovement studies are gene sequencing of proteins characterized by biochemical methods and the subsequent search in DNA databanks of homologous sequences in other organisms; DNA and RNA inhibition by means of antisense DNA/RNA to block the expression of specific proteins; heterologous expression of selected proteins to study their functionality in host cell systems; DNA hybridization to build the phylogenetic tree and to study the evolution of the photosensing apparatus.

The antisense approach has been used to identify the photoreceptor proteins of *C. reinhardtii*. Although several opsin proteins are encoded in its DNA,³⁶ only two of them, channelrhodopsin 1 and 2, have been shown to be involved in phototile responses; reducing the content of one or the other channelrhodopsin, it was found that the light-generated flagellar currents are smaller, and consequently, a diminished photophobic response is observed.³⁷ These two channelrhodopsins and a rhodopsin from *Volvox carter* have also been heterologously expressed in *Xenopus* oocytes, HEK and PC12 cells to study their functions by means of electrophysiological techniques.³⁸

The amino acid sequence of the amino-terminal portion of the two subunits of the *E. gracilis* 400 kDa flavin-binding protein was determined and used to synthesize degenerate primers for the amplification of the cDNAs by polymerase chain reaction (PCR). The analysis of the products evidenced in both polypeptides the presence of two regions homologous to flavin-binding domains already sequenced in various microorganisms (AppA in *Rhodobacter sphaeroides*, F403 in *Escherichia coli*, Slr1694 in *Synechocystis* sp.) and two regions homologous to catalytic domains from class III adenylyl cyclases (*Treponema pallidum* and *Anabaena cylindrica* adenylyl cyclases). Fluorescence investigation of the heat-denatured protein complex seems to indicate that the chromophore is flavin adenine dinucleotide (FAD) not covalently bound, and it was proposed that each subunit binds two FAD molecules. In the PAB gel filtration chromatography, the adenylyl cyclase activity and fluorescence peaks were observed in the same fraction, and the activity in the light was 80-fold that measured in the dark, thus confirming the importance of photoactivation. The knockdown of the expression of the two subunits by means of RNA-mediated interference (RNAi) did not alter the vitality of the treated cells, but caused the PAB to diminish in size or disappear altogether and inhibited several responses to light, that is positive and negative phototaxis and step-up photophobic responses, but not step-down photophobic responses.³² In this regard, it is interesting to note that, whereas phototaxis, step-up photophobic response and photokinesis are induced by the absorption of one or more photons, the signal for the step-down photophobic response is a decrease of the number of photons absorbed by the photoreceptor. Therefore, it is reasonable to suppose that a different photoreceptor triggers the step-down photoresponse.

48.2.3 Chromophore Primary Reactions and the Surrounding Environment

After the absorption of a photon, the photosensing chromophore undergoes molecular changes which depend on its physico-chemical properties and lead to the primary event of the sensory transduction chain. For the different chromophores, the proposed primary events are photoisomerization (retinal), photoinduced charge transfer (flavins, stentorins, and blepharismins), and energy transfer (from pterins to flavins, as proposed in *E. gracilis*³⁹).

However, reliable hypothesis on the primary molecular event can be formulated only based on a deep knowledge of the surrounding microenvironment. In fact, the molecular pocket in which the chromophore is inserted affects the probability of radiationless and radiative transitions from the singlet and triplet excited states and the yields of charge and energy transfer processes from excited and metastable states.

As mentioned earlier, restoration of phototaxis by adding retinal analogues in blind mutants suggested retinal as photosensing chromophore of *C. reinhardtii*.¹¹ Like in animal vision, the photoperception of *C. reinhardtii* is based on the photoisomerization of retinal. However the molecular conformation of the chromophore and the molecular modifications it undergoes upon photon absorption are different in the

FIGURE 48.3 Comparison between retinal of microbial and metazoan photosensory receptors showing the molecular conformation before and after light absorption.

two cases. In fact, it has been demonstrated that in the green alga the photosensing chromophore is a microbial type *all-trans* retinal instead of a *11-cis* retinal and that the isomerization involves the double bond in position 13 rather than that in position 11 (Figure 48.3).⁴⁰

An OxyBP chromophore–protein complex has been extracted from the blue form of *B. japonicum*.^{13,41} Both blepharismine and OxyBP are strong photosensitizers; however, red cells undergo photodamage when irradiated with strong light, whereas blue cells are resistant under the same irradiation condition.⁴² The advantage of extracting from blue *B. japonicum* is that the complex is stable, contrary to what happens in the case of the red cells. The apoprotein has a molecular weight of about 200 kDa, is not water soluble, and not covalently bound to OxyBP, which is presumably inserted in a molecular pocket of the protein and free to rotate in all directions, even if about 10 times more slowly than in an ethanol solution due to a local higher microviscosity.⁴³

This photoreceptor complex [OxyBP-binding protein (OBIP)] has been widely studied in buffer solution by means of steady-state, transient absorption and time-resolved fluorescence spectroscopy in order to verify the hypothesized involvement of a fast electron transfer in the first steps of the phototransduction chain. The interpretation of the most recent experimental data suggests the presence of two independent classes of chromoproteins: a reactive species rOBIP, undergoing fast dynamics, and a nonreactive one nrOBIP, behaving like the free chromophore in solution with a nanosecond decay.^{44,45}

An important feature of rOBIP is the much faster kinetics of bound OxyBP compared to free OxyBP in dimethyl sulfoxide: in fact, OBIP displays a characteristic 675 nm absorption band occurring with a time constant of 0.54 ps and decaying with lifetimes of 3.7, 29, and 133 ps. This relaxation process could be interpreted as a reversible excited-state intermolecular electron transfer followed by electron recombination in the ground state. Brazard et al. hypothesized that OxyBP is involved in a hydrogen-bond interaction with a yet unknown electron acceptor within the apoprotein. However, these rOBIP dynamics seem too fast to generate any biologically useful signaling state, and it has been proposed that, rather than being the primary step of the transduction chain, it could be a fast efficient deactivation pathway of the OxyBP excited state, which could explain the resistance to photodamage showed by the blue cells. Therefore, the task of triggering the phototransduction chain remains for the moment assigned to the nrOBIP class of chromoprotein, hypothetically acting as a proton donor.⁴⁵

48.3 Dark Steps of the Transduction Chain

Once the chromophore has undergone the molecular changes that constitute the primary event, the output signal from the photoreceptor travels to the motor apparatus to elicit the final cellular response. Although not directly dependent on the photic stimulus, the phases of the phototransduction chain connecting the photoreceptor to the effector, usually called "dark steps," are nonetheless important to fully understand the photoresponse, because in general this part of the transduction chain is used to amplify and modulate the signal without increasing the noise, to control the interaction with other transduction pathways, and in general to extend dynamic ranges, improve the accuracy, prevent overloads as well as signal reduction and uncontrolled fluctuations.⁴⁶

The first models depicted the phototransduction chain to be made up of a small number of functional components spatially contiguous, with the photoreceptor directly influencing the state of ion channels, especially in the case of flagellated algae, where it was hypothesized that the vicinity of the photoreceptor to the motor apparatus, that is the flagella, was functional to the direct control of the photoreceptive protein on the nearby membrane channels. As a matter of fact, the more it has been studied, the more the transduction chain in unicellular eukaryotes has been found to involve secondary messengers and transduction pathways similar to those found in pluricellular organisms.

A typical example is given by the studies conducted on *E. gracilis*. Since its photoreceptor organelle exhibits a crystalline structure and a lattice-like morphology and it is strictly adjoining the emerging flagellum (hence the name PAB), it was hypothesized that a light-generated photoelectric signal, more precisely a long-range coherent displacement photocurrent, would propagate along the flagellar rod, finally causing flagella stiffening and therefore a change in swimming direction of the microorganism.⁴⁷ However, recent results of genetic analysis, demonstrating a photoactivated adenylyl cyclase activity of the flavin-carrying photoreceptor protein (see the preceding text), suggest that cAMP is somehow involved in the signaling pathway, as already shown for gravitaxis in the same microorganism.⁴⁸

Similar considerations can be done on *C. reinhardtii*, where the presence of the two channelrhodopsins had suggested a direct control of this light-activated proteins on the influx of mono- and divalent ions and, consequently, on the membrane potential.⁴⁹ However, the presence of guanine nucleotide-binding proteins (G proteins) in the eyespot could suggest a more complex transduction mechanism,⁵⁰ as proposed in the closely related green alga *Spermatozopsis similis*. In eyespot preparations from this microorganism not only the presence of heterotrimeric G proteins was confirmed, but also specific, reversible green light modulation of at least one G_q subunit was demonstrated. Moreover, light-sensitive GTPase activity was completely abolished by antisera directed against G_q and G_i subunits as well as by an antiserum directed against the rhodopsin of *C. reinhardtii*, whereas corresponding control sera had no significant effect. This clearly indicates that in *S. similis*, there is a close coupling of at least one of the putative G proteins to the photoreceptor for phototaxis.⁵¹

Also in the case of *S. coeruleus* and *B. japonicum*, initial studies suggested a quite simple mechanism of phototransduction: an intracellular increase of the concentration of protons released by the photoreceptor could induce the opening of membrane calcium channels, the depolarization of the membrane, and consequently the stop of the ciliary beating. More recent pharmacological and biochemical results enrich and complicate this simple model, suggesting the involvement of secondary messengers (cGMP and IP_3) similar to those operating in the visual processes of metazoa.⁵²

The fundamental role of G proteins has been demonstrated also in the photo- (and thermo-) transduction chain of the slime mold *D. discoideum*. This small soil amoeba (10–20 μ m diameter), when undergoing nutritional stress, becomes aggregation-competent and capable of responding chemotactically to a specific pheromone. As a consequence, a few hundred thousand amoebae aggregate together to form a multicellular mass, called pseudoplasmodium or slug.⁵³ Both unicellular and multicellular forms react to photic and thermal stimuli with extremely high sensitivity. The two senses share most of the transduction chain and help the slug to reach the surface, where light and the concomitant drop in humidity induce culmination, i.e., the fruiting body formation.⁵⁴

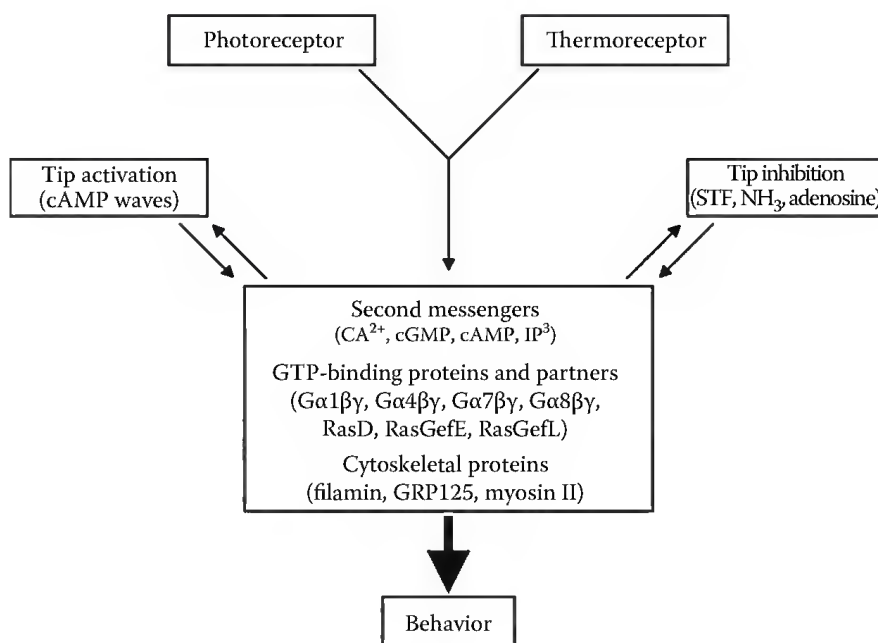

FIGURE 48.4 Simplified scheme of the known messenger molecules and proteins taking part in the transduction chain of *D. discoideum* slug phototaxis and thermotaxis. (Modified from Fisher, P.R. and Annesley, S.J., *Methods in Molecular Biology, Dictyostelium discoideum Protocols*, Eichinger, L. and Rivero, F., Eds., Vol. 346, Humana Press, New York, 2006, p. 137.)

The slug amoebae communicate among them by means of extracellular chemical signals, which are modulated by light and temperature gradients. The leading role in the slug is played by the anterior tip, which “chooses” the direction and is followed by the slug body. Slug turning is the result of the imbalance in the extracellular concentration of activating and inhibiting messengers produced by the slug tip: the activating signal is carried by cAMP waves, whereas the inhibiting signal is yet unknown (possibly one or more between NH_3 , adenosine, and a small unidentified substance called slug turning factor). Light perception is supposed to alter the pacemaker frequency associated with the cAMP waves, which in turn are detected by four cAMP receptors coupled to heterotrimeric G proteins. At least two of these G proteins are known to be essential for normal slug phototaxis (and thermotaxis).⁵⁴ By means of molecular biology techniques, it has been found that also other proteins are essential for a correct phototaxis: monomeric GTP-binding proteins of the RAt Sarcoma (RAS) family, cAMP 7-transmembrane domain receptors, protein kinases, and even cytoskeletal proteins, like filamin (actin-binding protein ABP-120 or gelation factor) and GRP125 (gelsolin-related protein of 125kDa), which are required to build a photoreceptor signaling protein complex, or myosin II (Figure 48.4). As a matter of fact, by genetic analysis it has been estimated that the number of genes that can be silenced without affecting cell viability and aggregation capacity, but are necessary for a correct photoorientation, is most probably around 20 and could be as high as 55.⁵⁵

48.4 Concluding Remarks

This chapter is mainly focused on the photosensing and transducing systems of the most studied phototile eukaryotic microorganisms, but not even in these few examples a full comprehension of the molecular machinery connecting the perception of the light stimulus to the motile response has been achieved. Many other microorganisms have been studied less intensively, and in these cases, the knowledge of the photosensory processes is even more fragmented and incomplete. However, the results of the last 30 years of research reveal the existence of a relatively wide variety of photoreceptor structures and transduction mechanisms for which it seems impossible to provide any unitary description.

Taking into account that light is not the only environmental signal influencing the motile behavior of microorganisms, which is also affected by chemical, thermal, mechanical, and gravitational stimuli, it is conceivable that some similarity exists between the various transduction pathways. Integrated studies of motile responses elicited by light in the presence of others of the aforementioned external signals might therefore offer clues for a deeper understanding of microbial sensory processes.

However, from the point of view of the photobiologist, the most interesting aspect is the primary mechanism of triggering the transduction chain by the chromophore–protein complex. Its knowledge should be the objective of future research, by unambiguously localizing the photoreceptor in the cell body, determining its structure, the kind of interaction between chromophore and apoprotein, and the first molecular events which initiate the transduction cascade.

In conclusion, further intensive and multidisciplinary studies, conducted on as many phototile microorganisms as possible, are needed to understand the different steps of the photoreaction both as an isolated process and in relation to other external and internal stimuli.

Dedication

49.1 Introduction

Rhodopsin molecules are photochemically reactive membrane-embedded proteins, with seven transmembrane α -helices which bind the chromophore retinal (vitamin A aldehyde).^{1,2} Rhodopsins are classified into two groups, microbial (type 1) and mammalian (type 2).³ Type 2 rhodopsins, such as visual pigments, are G-protein-coupled receptors (GPCRs) that are widespread in vertebrates and invertebrates.^{2,4,5} This chapter reviews type 1 rhodopsins functioning as light-driven ion transporters or photosensory receptors in microorganisms. They are widespread in the microbial world in prokaryotes (bacteria and archaea) and in eukaryotes (fungi and algae).^{3,6,7} A striking characteristic of these photoactive proteins is their wide range of seemingly dissimilar functions. Some are light-driven transporters, such as the proton pump bacteriorhodopsin (BR) and the chloride pump halorhodopsin (HR) (Figure 49.1).^{3,8} Others are light sensors, such as the phototaxis receptors sensory rhodopsins I and II (SRI and SRII).⁹ SRI and SRII relay signals by protein–protein interactions to integral membrane transducer proteins HtrI and HtrII, respectively, and SRI–HtrI and SRII–HtrII complexes control the flagellar motor rotation through kinases (Figure 49.1). The microbial rhodopsins have become a focus of interest, in part because of their importance to the general understanding of ion flux across membranes, and communication between integral membrane proteins, about which little is known.

BR was first identified in 1971 in the archaeon *Halobacterium salinarum* (also called *Halobacterium halobium*).¹⁰ Subsequently, HR, SRI, and SRII were independently discovered in *H. salinarum* before 1985.^{11–14} Those four archaeal rhodopsins have been well characterized over the past 40 years using various techniques from fields including photochemistry, biochemistry, and molecular biology.¹⁵ At this

FIGURE 49.1 Microbial rhodopsins in microorganisms and their functions.

time, thousands of investigations concerning the structure and functional mechanisms of BR have been reported, and therefore, BR is one of the best-understood membrane proteins and photoactive proteins.⁸ The proton gradient produced by BR is utilized by adenosine triphosphate (ATP) synthase, indicating that organisms having light-driven pumps can produce ATP under light illumination (Figure 49.1). It is well known that ATP is a multifunctional nucleotide, used in cells and organisms as a coenzyme, and is often called the molecular unit of currency of intracellular energy transfer. Since 2000, new types of microbial rhodopsins have been found in various microbes,¹⁵ including the light-gated cation channelrhodopsins I and II (ChR1 and ChR2) from *Chlamydomonas*,^{16–18} a light sensor *Anabaena* sensory rhodopsin (ASR) from algae,¹⁹ BR homologues from fungi and algae [*Leptosphaeria* rhodopsin (LR) and *Gloeobacter* rhodopsin (GR)],^{20,21} SRI homologues from eubacteria (*Salinibacter* sensory rhodopsin I: SrSRI),²² etc. In this review, the characteristics of new types of rhodopsins are also discussed.

49.2 Ion-Pumping Rhodopsins

49.2.1 BR and BR-Like Proton-Pumping Rhodopsins

In 1971, Oesterhelt and Stoekenius identified a visual rhodopsin-like membrane-embedded protein having retinal (vitamin A aldehyde; see Figure 49.2) as a chromophore in the archaeon *H. salinarum* (*halobium*).¹⁰ They named that protein BR. In the past four decades since then, BR has become a model for the simplest and most essential features necessary in an active proton transporter that is activated by a light stimulus. The mechanism of the proton pumping across the membrane is based on the stepwise reactions that accompany the photoisomerization from all-*trans* to 13-*cis* retinal upon formation of the K-photointermediate (Figure 49.2).⁸

A description of the transport mechanism, to a large extent at atomic resolution, has been elucidated due to the huge effort of many researchers on the spectroscopic, mutational, theoretical, and crystallographic aspects of the intermediates.^{23,24} The structure and structural changes of the protein and the

FIGURE 49.2 Retinal chromophore and its isomerization by light activation.

retinal in photointermediates are essential to understand the transport mechanism. However, in this chapter, they are only discussed in the context of the proton transfer reactions. The structure of BR is available from cryo-electron microscopy and x-ray diffraction at 1.55 Å resolution.^{24–27} The retinal chromophore is linked to a specific lysine residue (Lys216) via a protonated Schiff base (PSB) (**Figure 49.2**). The active center is composed of deprotonated Asp85, deprotonated Asp212, protonated Arg82, water molecules, and their hydrogen bonds (**Figure 49.3**). It should be noted that x-ray crystallography does not report the charged states of these groups, and they have mainly been revealed by vibrational spectroscopic studies.²⁸ As shown in **Figure 49.3**, the membrane normally is roughly in the vertical plane of the image, and the top and bottom regions correspond to the cytoplasmic (CP) and extracellular (EC) sides, respectively. D85N and D212N mutant proteins lack the proton-pumping activity.²⁹ In addition, water 402 (Wat402) of BR forms an unusually strong hydrogen bond with Asp85,³⁰ indicating the importance of the pentagonal cluster for active transport. Using comprehensive low-temperature Fourier transform infrared (FTIR) spectroscopy, Kandori and coworkers showed that strongly hydrogen-bonded water molecules (water O–D stretching vibration in D₂O at <2400 cm^{–1}) are found in the proton-pumping rhodopsins (including BR) but not in the nonproton-pumping rhodopsins.³¹ That suggests that a strongly hydrogen-bonded water molecule (Wat402) that bridges the Schiff base and its counterion Asp85 are essential for the proton-pumping function (**Figure 49.3**). The hydrogen bond becomes much weaker upon photoisomerization,³² suggesting that the specialized hydrogen bond between Wat402 and Asp85

FIGURE 49.3 X-ray structure of the Schiff base region in BR.

carries the energy needed for the proton-pumping function. Water molecules exist not only in soluble proteins, but also in membrane-embedded proteins, and they play important roles in the functions of those proteins. One of the roles of internal water molecules is to occupy the sites inside the protein that may be energetically unfavorable. Proteins that actively pump ions across membranes must translocate these ions through hydrophobic regions inside proteins. In particular, such water molecules must participate in hydrogen-bonding networks inside proteins that constitute an ion flux pathway. Therefore, internal water molecules may assist the transport of ions inside proteins by raising the dielectric constant.

BR absorbs light at around 570 nm, and this photoexcitation results in the sequential appearance of various photointermediates (K_{590} , L_{550} , M_{410} , N_{560} , and O_{640}), followed by a return to the unphoto-lyzed form of the protein (Figure 49.4).³³ The numbers in Figure 49.4 denote wavelengths (in nm) of the maximum absorption, λ_{max} . This linear cyclic series of photochemical reactions is referred to as the photocycle. A schematic representation of the BR photocycle is shown in Figure 49.4, with the cascade of proton movements. During the photocycle of BR, proton movement occurs through the following steps: (1) upon formation of the M-intermediate, the proton of the PSB is transferred to the nearby deprotonated Asp85. (2) The pKa values of Glu204, an initially protonated residue located at the EC surface, and Asp85 are coupled in such a way that when Asp85 becomes protonated, the proton of Glu204, or the cluster of water molecules, is released to the EC surface. This is accompanied by the outward helix titling of the CP end of the sixth α -helix (F-helix) at the M-intermediate. This structural change leads to an accessibility change of the Schiff base from Asp85 on the EC side toward Asp96, an initially protonated residue on the CP side. (3) The proton of Asp96 is transferred to the Schiff base upon formation of the N-intermediate. (4) the deprotonated Asp96 is protonated upon formation of the O-intermediate. (5) consequently, during the recovery from the O to the BR state, the proton of Asp85 is transferred to Glu204. Thus, the one-photon accumulation of the BR molecule drives the active proton transport across the membrane. The detailed conformational changes of the protein and retinal chromophore during the photocycle have been discussed at length in numerous review articles elsewhere.^{23,24,26–28,33,34}

So far, BR and related proteins capable of producing a chemiosmotic membrane potential in response to light have only been described in halophilic archaea. Recently, genome-sequencing projects, and environmental genomics, have revealed that proton-pumping rhodopsins also exist in eukarya and eubacteria.^{15,35,36} In 2000, a type of rhodopsin derived from eubacteria was discovered through genomic analysis in marine bacterioplankton and was named “proteorhodopsin (PR).”³⁷ The recombinant PR,

FIGURE 49.4 Proton movement during the photocycle in BR.

having retinal as a chromophore, showed active proton transport upon photoillumination, and exhibited a photocycle with intermediates and kinetics characteristic of BR. This implies that archaeal-like rhodopsins are broadly distributed among different taxa, including members of the domain Bacteria. This also indicates that a previously unsuspected mode of bacterially mediated light-driven energy production may commonly occur in oceanic surface waters worldwide.³⁸ In 2005, a fungal rhodopsin LR was cloned and heterologously expressed in *Phichia pastoris*.²⁰ LR turned out to be very similar to BR in its photochemical behavior. Interestingly, LR exhibits light-driven active proton transport and, consequently, LR is the first BR-like proton pump to be identified in a eukaryote. At present, microbial rhodopsins, *Acetabularia* rhodopsin (AR),³⁹ xanthorhodopsin (XR),⁴⁰ and GR²¹ have been found in the genomes of various microbes, and they also function as light-driven proton pumps. It should be noted that most amino acid residues important for the proton pumping in BR (Arg82, Asp85, Asp96, Glu194, Glu204, and Asp212) are also conserved in LR, AR, and GR. Thus, it is now clear that BR and related proteins are very common for large taxonomic groups, implying that light-driven proton transport is considerably important for various organisms.

49.2.2 Halorhodopsin

A light-driven inward chloride pump, HR, was discovered in the archaeon *H. salinarum* in 1980, 9 years after the discovery of BR.¹² In contrast to the extensive studies on BR, the molecular mechanism of HR is less well understood. Functionally, HR is the mirror image of BR: an anion rather than a cation is transported, and the translocation is in the EC→CP direction.^{41,42} In 1995, Sasaki et al. reported that replacement of Asp at position 85 to Thr converts BR from a proton to a chloride pump,⁴³ which implies that the essential features of the proton transport mechanism of BR are commonly conserved in the anion transport mechanism of HR. The absorption of light by the all-*trans* form of the retinal chromophore triggers a cyclic reaction in HR, as it does in BR. A schematic representation of the photocycle is shown in Figure 49.5. HR absorbs light at around 580 nm, and the photoexcitation results in the sequential appearance of various photointermediates (K_{600} , L_{520} , N_{520} , and O_{600}), followed by a return to the unphotolyzed form of the protein, as it does in BR, except for the lack of the M-intermediate.⁴⁴

The retinal Schiff base of HR is protonated, as in BR, but the counterion Asp85, which is essential for the proton pump, is replaced by a Thr residue (Thr111) (Figure 49.6). As previously described for BR, the proton of the PSB is transferred to the nearby deprotonated counterion upon formation of the M-intermediate, and therefore, the photocycle of HR lacks the M-intermediate.⁴⁴ The high-resolution crystal structures of HR molecules from *H. salinarum* (*HsHR*),⁴⁵ and from the related archaeon *Natronomonas pharaonis* (*NpHR*),⁴⁶ were reported in 2000 and 2010, respectively. Figure 49.6 shows the Schiff base region of *HsHR*, which contains a quadrupole with positive charges located at the PSB and at Arg108, and counterbalancing negative charges located at the chloride ion and Asp238. Both in the crystal structures of *HsHR* and *NpHR*, the Cl^- is only $\sim 4 \text{ \AA}$ from the PSB, indicating a strong electrostatic interaction, as extrapolated previously from FTIR data and changes in the visible spectrum upon halide binding.⁴⁷ From the spectral shift, its affinity is determined as about 10 and 2.5 mM for *HsHR* and

FIGURE 49.5 Photocycle of HR.

FIGURE 49.6 X-ray structure of the Schiff base region in *HsHR*.

NpHR, respectively. The chloride ion also forms a direct hydrogen bond with a conserved Ser residue (Figure 49.6). Upon formation of the K-intermediate, the Cl^- follows the flipped dipole of the N–H Schiff base bond (see Figure 49.2) and forms a strong hydrogen bond with the PSB. The opening of an EC pathway from the CP release site toward the protein surface was attributed either to a spectroscopically silent transition between two L-like intermediates, L1 and L2, or to an $\text{L2} \leftrightarrow \text{O}$ transition.⁴⁸ According to stopped-flow experiments on *NpHR*, Cl^- uptake itself is mostly ruled by passive diffusion through an EC pathway during later stages of the photocycle.⁴⁹ Other features of the transport site have not yet been defined. Thus, compared with BR, the ion transport mechanism of HR is still ambiguous. Of note, genes encoding a HR-like protein have also been found in the eubacterium *Salinibacter ruber*, and in other related species,^{1,50} implying that anion pumps are distributed not only in archaea, but also in bacteria.

49.3 Photosensory Rhodopsins

Motile microorganisms, such as bacteria and archaea, sense and respond to EC stimuli to survive in the various environments in which they live, by changing their swimming mode to migrate toward more favorable habitats. This behavior, termed *taxis*, is achieved by a signaling system from membrane-embedded receptors (input) to the flagellar motor (output) (Figure 49.1).⁵¹ Light is one of the most important signals providing critical information to biological systems, and therefore, many organisms utilize light, not only as an energy source, but also as a signal. Similar to vision in vertebrates, microorganisms can also sense light; they show avoidance or attractive behavior from or toward light. In spite of being nonspecific, the behavior is generally called phototaxis; when a cell moves toward a certain wavelength of light, this behavior is designated as positive phototaxis, while behavior in which a cell avoids a certain wavelength of light is designated as negative phototaxis (Figure 49.7). The phototaxis of *H. salinarum* (*halobium*) was the first to be described, and those cells show both positive and negative phototaxis.

FIGURE 49.7 Phototaxis behavior of *H. salinarum*.

49.3.1 Sensory Rhodopsin I and Sensory Rhodopsin II

What are the receptors (sensors) for phototaxis? The first clue for the receptor was obtained by investigation using a BR minus mutant that was believed to express only HR at that time (in 1983); however, it has since been found that there are two independent (fast and slow) photocycles.⁵² The pigment having the slow photocycle was identified as the receptor for phototaxis, and the receptor protein was named sensory rhodopsin I (SRI).⁵³ Interestingly, the original state of SRI functions as a sensor for the positive phototaxis, whose action maximum is located at ~587 nm, while the long-lived photointermediate, absorbing maximally at 373 nm, works as a sensor for negative phototaxis.⁵³ In 1985, a fourth retinal protein was discovered in *H. salinarum*, and it functions as a sensor of negative phototaxis, whose action maximum is located at ~500 nm.¹⁴ This retinal protein was named sensory rhodopsin II (SRII) or phoborhodopsin (pR) after its function. Thus, *H. salinarum* is attracted to light with wavelengths longer than 520 nm, and avoids light shorter than 520 nm by SRI and SRII. Light of >520 nm can activate BR and HR to obtain the light-energy, and cells avoid the shorter wavelength light, which contains harmful near-UV (Figures 49.1 and 49.7).⁹ Although the function is not yet identified, a third sensory rhodopsin molecule [named sensory rhodopsin III (SRIII)] has been recently found in the halophilic archaeon *Haloarcula marismortui*.^{54,55}

In the cell membrane, SRI and SRII form a 2:2 signaling complex with their cognate transducer proteins HtrI and HtrII, respectively.^{56,57} Light absorption by SRI and SRII triggers the *trans*–*cis* photoisomerization of retinal chromophores, leading to the photocycle. The essential photocycle of SRI is SRI (587)→SRI_K(620)→SRI_L(540)→SRI_M(373)→SRI (Figure 49.8).⁹ Here, the P₅₂₀ intermediate is produced by a second photon absorption by the near-UV light. The M- and P-intermediates are thought to be essential for the positive and negative phototaxis, respectively.⁵³ On the other hand, the essential photocycle of SRII is SRII(498)→SRII_K(540)→SRII_L(488)→SRII_M(390)→SRII_O(560)→SRII (Figure 49.8).⁵⁸ The M-intermediate of SRII is thought to be essential for the negative phototaxis.⁵⁹ During the photocycle, light signals are transmitted from the SRI–HtrI and SRII–HtrII complexes to the CP two-component signal transduction cascade, consisting of the kinases CheA and CheY, which regulates the rotational direction of the flagellar motor, resulting in positive or negative phototaxis.⁹ Ion-pumping rhodopsins, such as BR and HR, have been optimized by nature to have relatively fast photocycling rates (~10 ms), making them efficient pumps, whereas the sensory rhodopsins SRI and SRII have slow photocycles, persisting for several seconds, which allow the transient accumulation of long-lived signaling states (M-intermediate) of the receptors to catalyze a sustained phosphorylation cascade. The slow photocycle of sensory rhodopsins is thought to be caused by the lack of Asp96 in BR,⁶⁰ which works as a proton donor at the M-state, as described earlier.

The close relationship between the transport and sensory signaling activities of microbial rhodopsins was revealed when SRI was separated from its tight complex with HtrI and was found to exhibit light-driven electrogenic proton transport across the membrane. The transport activity of SRI is blocked by HtrI binding.⁶¹ Such a latent proton transport activity was also shown in SRII and similarly was

FIGURE 49.8 Photocycles of SRI and SRII.

blocked by HtrII binding.⁶² These findings demonstrate that the essential features of the proton transport mechanism are conserved in the signal transduction mechanism of SRI and SRII. Phylogenetic analysis strongly supports the concept that rhodopsin photosensors, like SRI and SRII, evolved from light-driven proton pumps.¹ The pumps function as individual functional units, without the need for interaction with other proteins, and therefore, they readily undergo lateral gene transfer, duplication, and modification to develop a functional interaction with the signal transduction machinery of the new host. What changes would be required to convert a proton pump into a sensory receptor; in other words, how extensive need be the modifications to evolve the new sensory function? The answer to this was resolved by the site-specific mutagenesis of BR to confer the ability to transmit signals through HtrII, which normally exists as a subunit of the SRII–HtrII heterotetrameric complex. As a result, three distinct mutations converted BR into an SRII-like photosensor,⁶³ and this is discussed in the following.

49.3.2 Signal Transfer Mechanism of the SRII–HtrII Complex

In 2000, the crystal structure of SRII was reported by two independent research groups.^{64,65} In their experiments, SRII from *N. pharaonis* (*Np*SRII) was used instead of *H. salinarum* SRII (*Hs*SRII) because *Np*SRII is much more stable than *Hs*SRII, especially in dilute salt solutions, and is much more resistant against detergents.^{66,67} The solved atomic structure of *Np*SRII was superimposed on those of BR and *Hs*HR, as shown in Figure 49.9. Although ~74% of residues in *Np*SRII differ from those of BR and *Hs*HR, their crystal structures show close similarities in architecture, helix positions and locations of the retinal-binding pocket, indicating that functional differentiation is regulated by differences in the detailed structures including the amino acid side chain(s), ions, and water molecules. Thus, in spite of the structure being very similar, the question arises of how these proteins function differently? This issue will be discussed later.

The crystal structure of *Np*SRII, bound to an N-terminal fragment of HtrII, provided atomic details of the two proteins' interaction surface in the periplasm and within the membrane (Figure 49.10).⁵⁷ The crystal structure of the SRII/HtrII complex suggests the formation of two specific hydrogen bonds, between Tyr199–SRII and Asn74–HtrII, and between Thr189–SRII and Glu43–HtrII/Ser62–HtrII (Figure 49.10). To investigate the importance of these hydrogen bonds, the dissociation constants for the binding of various mutants of BR, HR, SRI, and SRII with HtrII were estimated using isothermal titration calorimetry

FIGURE 49.9 X-ray structure of *Np*SRII with those of BR and HR.

FIGURE 49.10 Interaction surface between SRII and HtrII.

(ITC) and spectroscopic techniques.^{68–70} These studies concluded that these two specific hydrogen bonds play important roles in the binding between SRII and HtrII. In addition, an interaction of the HtrII membrane-proximal domain with the CP domain of SRII has been demonstrated by various biophysical and spectroscopic techniques.^{71–75} From these experiments, the stoichiometry of the SRII–HtrII complex is estimated as 1:1, which is in accord with the 2:2 stoichiometry resolved by x-ray structure.

A clue about the signal relay mechanism from SRII to HtrII was obtained from the FTIR data. The dark minus K difference spectra of SRII possess positive and negative vibrational bands of SRII at $3479(-)/3369(+)$ cm^{-1} , which are observed only in the presence of HtrII.⁷⁶ Mutational studies showed that the bands originate from the O–H stretch of Thr204,⁷⁷ which indicates that a stronger hydrogen bonding alteration of Thr204 takes place upon the retinal photoisomerization (Figure 49.11, upper panel).

FIGURE 49.11 Structural changes upon formation of the K-intermediate of SRII.

The structural changes are important for the HtrII activation by SRII at the following intermediates. In fact, mutations of Thr204, and its hydrogen-bonding residue Tyr174, disrupt the negative phototaxis function.⁷⁸ In addition, using deuterated retinal analogs, it was demonstrated that a regiospecific steric hindrance between the C14–H group of the retinal (see Figure 49.2) and Thr204 occurs upon formation of the K-intermediate (Figure 49.11, lower panel).⁷⁹ Although SRII_K is not considered to be an active state (signaling state), the A215T mutant of BR, which corresponds to Thr204 of SRII, confers weak phototaxis signaling activity, and structural changes, upon formation of the K-intermediate of the A215T, which are quite similar to the structural changes of SRII.⁸⁰ The signaling is greatly enhanced by two additional substitutions, P200T and V210Y, which correspond to Thr189 and Tyr199 of SRII, respectively, indicating that the BR triple mutant (BR-T) transmits light signals to the motility apparatus through the HtrII protein.⁶³ The interpretation of these findings is that the hydrogen bonds of Thr189–Glu43/Ser62 and Tyr199–Asn74 that pin the receptor to the transducer are important for aligning the two proteins, but do not necessarily participate significantly in the signal relay process. Therefore, remarkably, it appears that a single hydrogen bond (i.e., that between Thr204 and Tyr174 in SRII) determines the essential difference between a sensory receptor and a proton pump in the microbial rhodopsin family. These results suggest a chemical mechanism for the signaling that entails an initial storage of the energy of photoisomerization in SRII's hydrogen bond between Tyr174, which is in contact with retinal, and Thr204, which borders residues on the SRII surface in contact with HtrII. This is followed by the transfer of this chemical energy to drive structural transitions in the transducer helices. These results also demonstrate that the distinct functions of active transport and signaling can be produced by a small number of modifications of the same protein structure, and the nature of the changes needed to convert the proton pump BR into a signaling receptor provides insight into the essential core of the signal relay mechanism.

Although it has been concluded that the M-intermediate is one of the active (signaling) states from the studies of *HsSRII*,⁵⁹ this is also considered valid for *NpSRII*. Upon formation of the SRII_M, the primary proton transfer occurs from the Schiff base to the proton acceptor, Asp75, which is a counterion of the PSB, as well as BR.⁸¹ It is known that the photo-dependent structural changes of BR occur at the CP ends of helices F and G upon formation of the M-intermediate (and/or the N-intermediate). These movements open a narrow water-accessible channel in the protein,³³ which enables the transfer of a proton from the proton-donating Asp residue to the Schiff base nitrogen. Similar helix movements of SRII, an outward tilting of helix F, during the photocycle are also suggested by various studies,^{82–84} and they are thought to be an essential step for the HtrII activation. Also the HAMP domain of HtrII, a 50 aminoacid segment which is conserved among histidine kinases, adenylyl cyclases, methyl accepting chemotaxis proteins (MCPs) and phosphatases, is thought to have a critical role in the signaling.

On the basis of these results, and other findings, a model for the signal transduction by the SRII–HtrII system was proposed as follows (Figure 49.12)⁵¹: (i) *trans*–*cis* photoisomerization of the retinal chromophore, (ii) steric hindrance between C14–H of retinal and Thr204, (iii) hydrogen bonding alteration between Thr204 and Tyr174, (iv) F-helix outward tilting of SRII, (v) TM-2 rotation of HtrII, (vi) dissociation of the HAMP domain of HtrII from SRII, (vii) structural changes of the highly conserved domain (HCD), and (viii) activation (phosphorylation) of CheA.

49.3.3 Signal Transfer Mechanism of the SRI–HtrI Complex

SRI has received considerable attention because of its function in mediating opposing signals (on/off switching of CheA), depending on different colors of light, by the photochromic reaction as described earlier. However, compared with SRII, little is known about the molecular mechanism(s) of interactions between SRI and HtrI, about structural changes, or about the signal relay mechanism of the phototaxis. One reason is that SRI from *H. salinarum* (*HsSRI*) is unstable in various conditions, and its inherent instability hampers the elucidation of its molecular mechanism.²² In fact, the x-ray crystal structures of BR, HR, SRII, and the SRII/HtrII complex have been solved over the past 10 years; however, almost no structural information at the atomic level has been obtained for SRI. Spudich and coworkers have

FIGURE 49.12 Model for signal transduction mechanism of SRII–HtrII complex.

proposed a model for the signal transduction by the SRI–HtrI system on the basis of experimental evidence (Figure 49.13).^{85,86} As described earlier, the PSB plays an essential role in the functions of microbial rhodopsins, deprotonating in the first half of the photocycle, by transferring its proton to an Asp (counterion) residue in the EC half-channel, and reprotonating in the second half of the cycle from the Asp residue in the CP channel. In the ion-pumping rhodopsins, the key step, known as the “Schiff base connectivity switch,” consists of a structural change of the photoactive site that occurs in the photocycle and changes the accessibility of the retinylidene Schiff base nitrogen from the EC to the CP channel. In the dark, the SRI–HtrI complex exists in two conformational states, which differ by their connection of the Schiff base in the SRI photoactive site to inner or outer half-channels. In single-quantum photochemical reactions, the conformer with the Schiff base connected to the CP half-channel generates an attractant signal, whereas the conformer with the Schiff base connected to the EC half-channel generates a repellent signal. The opposite signals from the two conformers are integrated in the downstream transduction pathways, leading to one or the other sign of the behavioral response. In the wild-type SRI–HtrI complex, the conformer equilibrium is poised strongly in favor of that with the CP-accessible Schiff base. The inverting mutations shift the equilibrium in favor of the EC-accessible Schiff base form, whereas the suppressor mutations shift the equilibrium back toward the CP-accessible Schiff base form, restoring the wild-type phenotype. This implies that the sign of the behavioral response directly correlates with the state of the connectivity switch.

In an effort to improve the stability of *HsSRI*, a novel SRI protein from the eubacterium *S. ruber* (*SrSRI*) was cloned and characterized with its transducer protein, *SrHtrI*.²² *SrSRI* is the first eubacterial SRI identified as a functional protein, and it has all-*trans* retinal as a chromophore, with an absorption maximum

FIGURE 49.13 Model for signal transduction mechanism of SRI-HtrI complex.

at a longer wavelength (557 nm) than SRII (500 nm). It also has a slower photocycle than the light-driven ion-pumping rhodopsins,²² indicating similarities to the prototypic SRI (*HsSRI*). *SrSRI* was expressed in *Escherichia coli* and shows high protein stability, even in various detergent micelles, making it possible to prepare large amounts of protein. This also allows new approaches to investigate the photo-signaling process in the SRI-HtrI system. In fact, it provided new information about structural changes⁸⁷ and Cl⁻ binding,⁸⁸ which are conserved in SRI from the archaeon *Haloarcula vallismortis* (*HvSRI*).⁸⁹ In the original state, the absorption maximum of *SrSRI* is shifted from 542 to 556 nm, in a Cl⁻-dependent manner, with a K_d of ~300 mM. The bathochromic spectral shift was caused not only by NaCl, but also by other salts (NaI, NaBr, and NaNO₃), implying that anion-binding (I⁻, Br⁻, and NO₃⁻) site(s) exist in *SrSRI*. A conserved residue, His131, was identified to be a residue involved in the Cl⁻-binding site.⁸⁸ It was assumed that a positive charge located on the Schiff base nitrogen moves to the β-ionone ring of the retinal chromophore by chloride ion binding to His131 (Figure 49.14). Although the high-resolution structure of SRI has not yet been solved, it is predicted that the space around His131 is significantly narrow for the Cl⁻ binding, suggesting large structural changes of *SrSRI* upon Cl⁻ binding. Interestingly, *HvSRI* exhibited similar alterations due to chloride ion binding.⁸⁹ The binding to *SrSRI* is likely to be important for the function of the SRI protein family.

FIGURE 49.14 Structural model of SRI and its identified Cl⁻-binding site.

Recently, FTIR spectroscopy was performed with *SrSRI*, and the spectral changes were compared with those of other archaeal rhodopsins (BR, HR, and *SRII*).⁸⁷ Briefly, in the K-intermediate, the extended chromophore distortion takes place in *SrSRI* and *HsSRI*, as well as in *SRII* and BR-T, as judged by the hydrogen-out-of plane (HOOP) vibrations of the retinal chromophore, whereas the distortion is localized in the Schiff base region in BR and HR. It appears that the sensor and pump functions are distinguishable from the spectral feature of the HOOP modes. The C14–HOOP band at 864 cm⁻¹ for *NpSRII*, which is important for negative phototaxis in *SRII*, is absent in *SrSRI*, suggesting that the changes of C14–H HOOP are a specific feature among sensors for negative phototaxis. This is reasonable because the counterpart of the C14 atom, Thr204 of *SRII*, is not conserved in other microbial rhodopsins, including *SRI*s. In the M-intermediate, the frequency shifts of amide-I and amide-A vibrations, which probe structural changes in the α -helix, were opposite between *SRI* and *SRII*, where a downshift and an upshift were observed, respectively. This indicates that the M formation accompanies a weakened hydrogen bond of the α -helix in *SRI*, but a strengthened hydrogen bond of the α -helix in *SRII*. In other words, activation of *SRI* or *SRII* may involve breakage or formation of the helical structure. The different modes in protein structural changes between *SRI* and *SRII* are consistent with a model proposed by Spudich and coworkers⁸⁶ and may correlate with their functional differences. Thus, as expected, *SrSRI* can be a key protein to investigate the functions of *SRI* at the molecular level.

49.4 New Types of Microbial Rhodopsins

Since the discovery of BR, “rhodopsins” had been thought to be unique proteins, found only in extremely halophilic archaea, and in animal photoreceptors, for nearly three decades. It was concluded as merely a coincidence that these two groups of rhodopsins have common features because of their large differences in primary structure, and the lack of evolutionary evidence to link them. However, new discoveries started at the end of the last century when the techniques in mass genome sequencing and bioinformatics started to advance dramatically. Today, the number of rhodopsin genes identified is up to several thousand and keeps growing (Figure 49.15).¹ Most of them are found

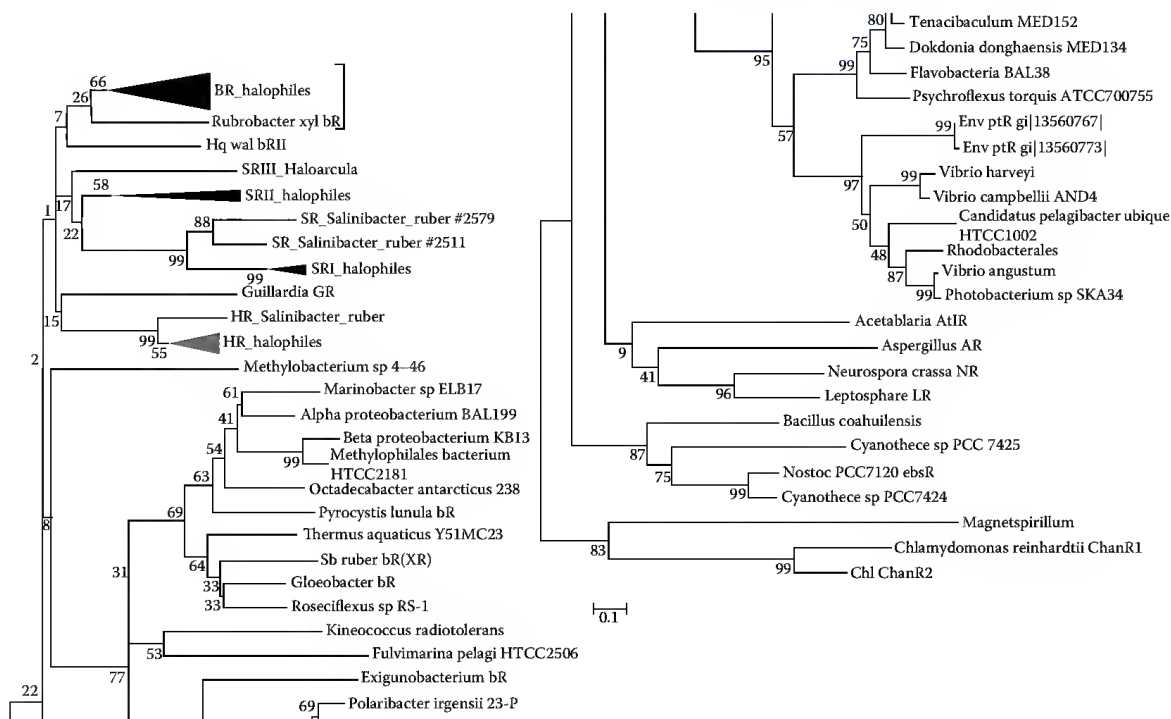

FIGURE 49.15 Microbial rhodopsins from various species.

in eubacteria and fungi, and are therefore of microbial origin, and are presumed to have some evolutionary relationship to the well-studied archaeal rhodopsins.

49.4.1 Fungal Rhodopsins

The first microbial rhodopsin discovered outside the archaea was identified as the *nop-1* gene of *Neurospora crassa*.⁹⁰ Nop-1 (NR) was successfully bound to retinal after heterologous expression in *Pichia pastries*, and its photocycle was characterized.⁹¹ A homologous gene of *nop-1* was also found in another ascomycete *Leptosphaeria maculans*. This fungal rhodopsin, LR, has an aspartic acid in place of the proton donor of the PSB. Unlike NR, spectroscopic studies showed that reconstituted LR can transfer protons as efficiently as BR.^{20,92} Replacement of the Asp residue (proton donor) of LR to Glu resulted in an NR-like conversion of LR.^{93,94} Even though NR and LR are successful examples of spectroscopically characterized fungal rhodopsins, genome-sequencing projects, and bioinformatics, have identified several hundreds of other fungal rhodopsins.³⁵ According to the residue conservation at the proton donor position, and the Lys residue on the G helix, these fungal rhodopsin genes can be classified into three groups: NR-like rhodopsins, LR-like rhodopsins, and those without the capability of covalent bonding with retinal. So what are their functions? Since LR shows significant resemblance in photocycle and photokinetics with BR, LR-type rhodopsins are probably relevant in photosynthesis, as is BR in archaea. On the other hand, NR has a very slow photocycle, which suggests that maintenance of an intermediate state itself has relevance, as in the case of SRI and SRII. *nop-1* is not photoinducible and is negatively regulated by blue light, which NR does not absorb. Also, *nop-1* expression increases as conidiation proceeds, and the NR level influences some other conidiation genes.⁶ This evidence supports the sensory role of NR and some kind of signal transduction in the conidiation gene cascade.

49.4.2 Proteorhodopsins

The first eubacterial rhodopsin discovered was identified in an uncultivated (or more precisely unculturable) gammaproteobacterium.³⁷ This protein demonstrates BR-like light-driven proton transport and is called PR. Later, the presence of PR was confirmed in a bacterioplankton membrane fraction, taken from oceanic surface water, and its density in the membrane was estimated to be similar to that of BR,³⁸ suggesting there is a significant physiological role for PR in the bacterium. PR has two aspartates, consisting of a proton donor, and an acceptor (homologs of Asp85 and Asp96 in BR), although the latter is replaced by glutamate, whereas EC glutamates constituting the proton-releasing complex in BR are missing. Biochemical and biophysical studies have been performed with PR over the past 10 years. Briefly, although there are several notable differences between PR and BR, it is concluded that the structure and structural changes of PR are very similar to those of BR, indicating that the proton gradient produced by PR is utilized by ATP synthesis, generating biochemical energy from light. The potential influence of PR-based light-driven energy flux in ocean ecosystems would be significant, but is still difficult to quantify directly. Of note, PR-like proteins are also found in eubacterial groups other than proteobacteria.⁶

49.4.3 Rhodopsins with Auxiliary Carotenoid Antenna

The extreme halophile *S. ruber* has been found to have a proton-pumping rhodopsin XR with an additional carotenoid, salinixanthin, as a light-harvesting antenna.⁴⁰ XR has similarity in its primary structure with both BR and PR, and attaching salinixanthin to XR almost doubles the flow of light quanta to energize proton transport.⁴⁰ The efficiency of energy transfer from salinixanthin to retinal has been calculated as approximately 45%.^{40,95} The crystallographic structure of XR revealed that salinixanthin lies on the outer surface of the F-helix, with its keto-ring immobilized between the EC ends of the E and F helices, and placed within van der Waals distance of the retinal β -ionone (Figure 49.16).⁹⁶ The Schiff

FIGURE 49.16 X-ray structure of XR, with salinixanthin as light-harvesting antenna.

base proton donor of XR is Glu (as in PR), but this Glu side chain does not make hydrogen bond coupling with the Ser residue (as does PR), but forms a hydrogen bond with a water molecule (Wat-502) that connects to the carbonyl of the retinal-bound Lys residue.⁹⁶

In the sequence alignment, XR appears between BR and PR, but there is another rhodopsin from cyanobacterium *Gloeobacter violaceus* (GR), which has a significant sequence similarity with XR. In the dark state, GR contains primarily all-*trans* retinal, but replacement of the proton donor Glu residue significantly increases the 13-*cis* content, which had been seen for BR mutants, but not for the homologous mutant of PR.²¹ The photocycle of GR over-expressed in *E. coli* is much like PR, having a low accumulation of the M-intermediate, and proton uptake preceding proton release.²¹ The most interesting similarities with XR lie in the E and F helices, where salinixanthin docks on XR. In BR, the space where the keto-ring of salinixanthin, and the adjacent Tyr ring, is immobilized in XR is occupied by two Trp rings. GR has an almost identical feature for this with XR, and reconstitution of GR with salinixanthin was performed, and the change in action spectra was observed, which resembles that of XR.⁹⁷

49.4.4 Anabaena Sensory Rhodopsin

In 2003, the first bacterial sensory rhodopsin was identified in the freshwater cyanobacterium *Anabaena* PCC7120 and was named ASR.¹⁹ Sensory rhodopsin-like genes and Htr-like genes were also discovered in proteobacteria through the genome-sequencing projects, although the properties of those proteins have not yet been identified because of the difficulty of heterologously expressing them. ASR is encoded in an operon, along with a second gene that encodes a small soluble CP protein, named the ASR transducer (ASRT).¹⁹ This is very different from the haloarchaeal phototaxis transducers, HtrI and HtrII, which are membrane-embedded proteins. Crystallographic analysis revealed the photochromic nature of ASR, and the water molecule network in its CP half region, where it possibly interacts with ASRT (Figure 49.17).^{98,99} ASR accommodates both all-*trans* and 13-*cis* retinal in the original state, which can be interconverted by illumination with blue (480 nm) or orange (590 nm) light.¹⁰⁰ Such photochromic behavior has never been observed in other archaeal rhodopsins such as BR, HR, SRI, and SRII and is characteristic to ASR. Therefore, ASR is the first rhodopsin that exhibits a photochromic reaction, and now, it has been determined that all photochemical reactions of ASR are photochromic, and there is

FIGURE 49.17 X-ray structures of ASR (left) and ASRT (right).

no photocycle such as those observed in all other microbial rhodopsins.¹⁰¹ ASRT forms tetramers in solution, and the ASRT tetramer binds to ASR with a stoichiometry of one ASRT tetramer per one ASR with a dissociation constant of $8\mu\text{M}$. What are the functional roles of ASR and ASRT? One possible possibility is the regulation of gene expression in response to light intensity and/or quality. This control could occur via direct transcriptional regulation by ASRT (making ASRT a transcription factor) or via transcription factors further downstream in an uncharacterized signaling cascade.⁹⁹

49.4.5 Channelrhodopsins

Two rhodopsins (ChR1 and ChR2) that account for the phototactic behaviors of *Chlamydomonas* were identified in 2002.^{16,17} Both rhodopsins function as direct light-gated cation-selective ion channels, but they differ in the saturating light intensity (e.g., ChR1 saturates with higher-intensity light).¹⁷ Although both rhodopsins can conduct Na^+ , K^+ , and Ca^{2+} at a similar rate, the conductance of both rhodopsins for these ions is much smaller than that for protons,¹⁸ that is, these two rhodopsins basically function as proton channels to quickly depolarize the plasma membrane, especially when illuminated with light intensity sufficient to saturate the ChR1 population. However, the delayed rise, and slower decay, of biochemically amplified current (or the photoreceptor current under lower-intensity light) is mediated by ChR2, and this long-lived conducting state is essential for low-intensity light excitation to cause any change in flagellar movement.¹⁰² In addition, ChR1 consists of two isoforms with different absorption maxima that are in a pH-dependent equilibrium; thus, the photochemical nature of ChR1 is photochromic and protochromic.¹⁰³ By taking advantage of ChR2 producing a long half-life current, ChR2 has been widely utilized as a tool to control membrane potential, which seems to have potential to cure blindness, and to control synaptic activity.^{104,105}

In conclusion, rhodopsins are widely spread in the microbial world, and despite showing close similarities in architecture, they display a large variety of different functions, including, but not limited to, ion transporters, photosensors, and ion channels.

50.1 Introduction

Our belief about visual system as functional tool providing only image formation, and in a common sense an interpretative depiction of the surrounding real world, has been drastically changed by recent (and old but revised) achievements on nonimage-forming vision, more widely termed as nonvisual photoreception or nonvisual photosensitivity (NVP for both). Classical studies in invertebrate and lower vertebrate species have described, namely, at time, extraocular or extraretinal photosensitive cells which exerted an ancillary role to obvious eye-like structures in mere detection of environmental irradiance (one for all the so-called third eye, i.e., the pineal gland, of lower vertebrate organisms). Such role assumes remarkable importance in those animals that lack obvious eyes or with poor optical apparatus.

Several stereotyped behaviors and vital functions, both strictly related to a precise temporal fluctuation, are strictly linked to nonvisual photoreception.

That adaptive role seemed restricted to primitive or phylogenetically old animal species until when in the 1990s a new kind of intrinsically photosensitive cells, and their photopigment melanopsin, has been identified in the vertebrate retina in addition to the rod and cone photoreceptor cells. Those findings unveil a fast-growing research field that has showed and confirmed by molecular, cellular, and physiological studies a new non-rod non-cone photoreception pathway that supplies nonimage-forming vision.

Therefore, an unconventional kind of light sensitivity that was trivially (and erroneously) considered as an evolutive residue typical of invertebrate species is present also in higher species of vertebrates, including mammals up to humans, retaining the same physiological role and value.

In the animal kingdom, nonvisual photoreception is a photosensory capability involved in the regulation of several expressions of temporal physiology such as photoperiodism, locomotion, neurogenesis, entrainment of circadian rhythms, and the timing of biological clocks (in addition to other functions of vital importance such as the sleep/wake cycle, the melatonin regulation, and the constriction of the pupil).^{1,2} Photic information mediated by nonvisual photosensitivity parallels and integrates, to some extent, the function of canonical visual system, being involved in circadian vision (i.e., the measurement of daily environmental irradiance to serve photoentrainment of circadian rhythms).^{3,4}

The ubiquity of circadian rhythms points to an earlier evolutive origin of their molecular machinery as adaptation to light/dark daily cycles in the external environment. Endogenously generated oscillation strictly linked to circadian rhythms evolved and “incorporated” in animals to time several vital functions. Analogously, nonvisual photic input driving and interacting with circadian rhythms has determined temporal features of several functions and behaviors.

This review, far to be comprehensive above all for what it concerns the molecular and genetic machinery of circadian clocks, summarizes the current state of art of NVP and its relationships with circadian vision. In particular, this chapter focuses on the molecular and functional properties of the so-called nonvisual opsins, which are the candidate photopigments of the novel retinal and extraretinal photosensitive cells in both vertebrates and invertebrates. The aim is to provide the reader with a sketch of the evolutionary course of the animal vision based on the comparative/phylogenetic analysis of the molecular and functional mechanisms of photoreception and of the regulation of circadian rhythms exerted by light input.

50.2 Biological Time and the Origin of Circadian Rhythmicity

The physiology and the behavior of all living forms on our planet have been influenced by light periodic changes due to seasonal and day/night cycles. During evolution, the endowment for an organism to develop mechanisms for irradiance measurement, to fine-tune its biological time according to environmental conditions, and to anticipate the light periodic changes have been developed as a whole to provide crucial adaptive responses.

Living organisms, in fact, have evolved different biological clocks, some, with an endogenous period of approximately 24 h (due to the daily rotation of the Earth) controlling circadian responses and other ones, with a longer photoperiod, regulating seasonal behaviors (migration, reproduction, hibernation, etc.).

Rhythms are not just a passive reaction to light, but they are programmed by endogenous mechanisms which are continuously synchronized by changes in quantity and quality of light at dawn and dusk.⁵

Light is the predominant *Zeitgeber* (from German, literally “time giver”) for the resetting of this machinery, and photoreceptor proteins are the molecules responsible for its photoentrainment.⁶

A circadian system is often described as consisting of three parts: the rhythm generator that autonomously generates rhythmicity is continuously entrained to environmental signals by clock input components (such as photoreceptors) and relays to clock output components (the peripheral oscillators) present in all tissues throughout the body to drive rhythmicity (Figure 50.1a). Outside this system, light acts as *Zeitgeber*.⁷ This scheme is not so simple because clock components can feedback on themselves generating multiple overlapping loops. In fact, important transcription/translation feedback loops of clock components intervene to fine-tune this complex machinery (Figure 50.1b).

Current literature depicts a comprehensive account of the molecular and genetic issues of the circadian system's machinery above all for what it concerns the clock genes and relative signal pathways in both vertebrates and invertebrates (e.g., mouse and drosophila, respectively). However, this complex topic deserves an exhaustive coverage that is not proper of this chapter due to space limitation; thus, we refer the reader to recent reviews for detailed results and references.^{8,9}

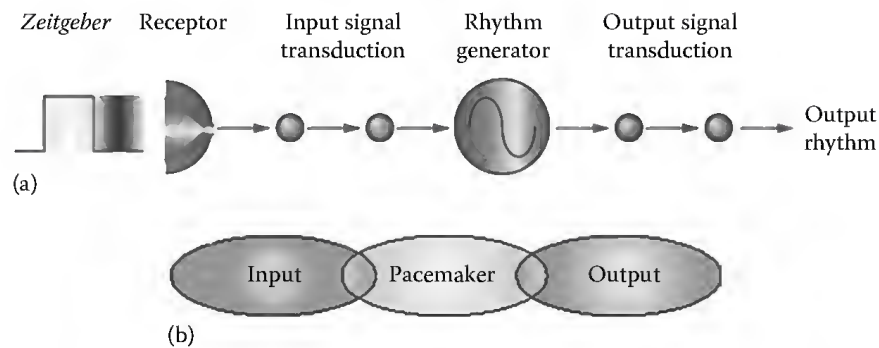

FIGURE 50.1 (a) Conceptual sketch of the circadian system pathway which includes three major components: the input receiving the signal from environmental *Zeitgeber*, the pacemaker generating the circadian rhythm, and the output producing the physiological rhythm. (Modified from Roenneberg, T. and Mellow, M., *Curr. Biol.*, 13, R198–R207, 2003.) (b) At any stage of the pathway, the entrainment may be varied and modulated due to an overlapping and a mutual relationship between the three major components. (Modified from Cermakian, N. and Sassone-Corsi, P., *Nat. Rev. Mol. Cell. Biol.*, 1, 59, 2000.)

50.3 Localization of Photoreceptorial Systems within Receptorial Clocks

In addition to the classical eye or eye-like structures performing image-forming functions by means of classical visual opsins, vertebrate and invertebrates have auxiliary photoreceptor systems committed to the measurement of daily environmental irradiance for the entrainment of circadian rhythms (Figure 50.2).¹⁰ This auxiliary visual modality is named circadian vision and regulates the temporal and behavioral physiology of animals (e.g., photoperiodism in locomotion and reproduction, timing of circadian rhythms, the sleep/wake cycle; the melatonin inhibition and the constriction of the pupil) synchronizing peripheral clocks present in all tissues.^{2–3,11–14}

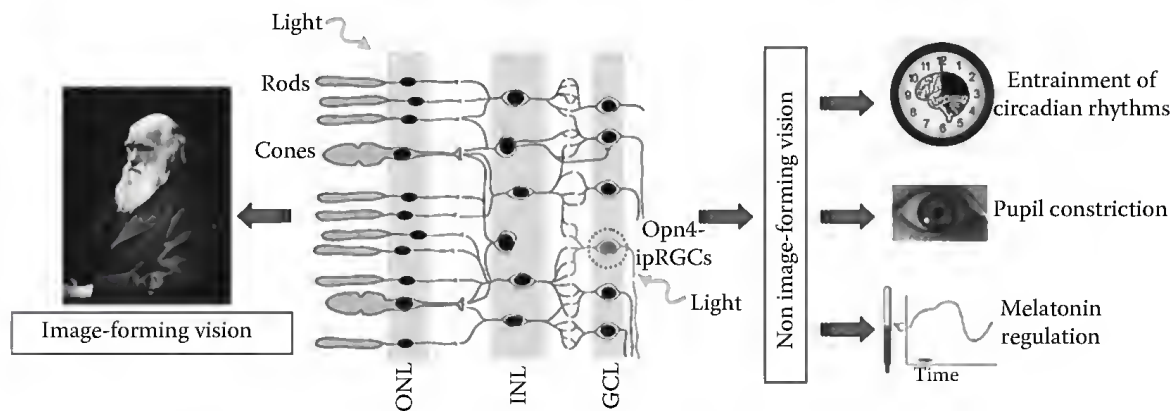

FIGURE 50.2 Schematic drawing of the three kinds of retinal photoreceptive systems in vertebrates. On the left, rod/cone pathway is the first step subserving image-forming vision (including color and spatial vision). On the right, melanopsin-containing intrinsically photosensitive retinal ganglion cells (Opn4-ipRGCs) constitute the building blocks of the nonimage-forming visual system (non-rod non-cone photoreception). Opn4-ipRGCs detect light directly and convey signals of irradiance to the brain triggering nonvisual responses like entrainment of circadian rhythms (including sleep function), the pupil reflex, the entrainment of melatonin suppression, and, in humans, the regulation of body temperature and mood. Abbreviations: ONL, outer nuclear layer; INL, inner nuclear layer; GCL, ganglion cell layer. (Right side images, adapted after Bailes, H.J. and Lucas, R.J., *Cell. Mol. Life Sci.*, 67, 99, 2010; left side image, Charles Darwin (1809–1882) in his later years, photo by J. Cameron, 1869, public domain via Wikimedia Commons.)

FIGURE 50.3 (See color insert.) Action spectrum of intrinsically photosensitive retinal ganglion cells (ipRGCs) compared with action spectra of other photoreceptors of the rat retina. The curve shapes indicate that each photopigment uses a vitamin A-based chromophore. Relative trends of the curves on the wavelength axis reflect differences in the opsin component of the photopigment. Wavelengths: ipRGCs (red), 484 nm; green cones (green), 510 nm; UV cones (purple), 359 nm; rods (blue), 500 nm. (Adapted from Berson, D.M., *Trends Neurosci.*, 26, 314, 2003.)

As shown in Figure 50.2, these photoreceptorial systems are indicated as receptor component clocks and have been identified in the retina as well as in some cerebral extraocular structures and peripheral structures of vertebrate and invertebrates. Pineal complex, deep brain photoreceptors, dermal photosensitive cells, central nervous system photoneurons, peripheral organs, and obviously lateral eyes represent important photoreceptive sites that, sensing light, entrain rhythms.

The retina of lateral eyes (i.e., the obvious eyes) of mammalian and nonmammalian vertebrates processes light information by classical photoreceptors, rods, and cones in the outer layer and photosensitive cells containing novel opsins in the inner layer.¹⁵

Classical photoreceptors provide image-forming vision while the others, defined as non-rod non-cone photoreceptors, are involved in NVP (Figure 50.2). The latter, in vertebrates, include subsets of intrinsically photosensitive retinal ganglion cells (ipRGCs) (Figure 50.3), amacrine and horizontal cells, all expressing melanopsin,^{16–19} teleost horizontal cells expressing vertebrate ancient (VA)-long opsin,²⁰ cyprinid horizontal cell expressing both melanopsin and VA,²¹ and gecko retinal cell expressing pinopsin.²²

Among vertebrates, the pineal complex has different structures and roles (Figure 50.4). In teleosts and lampreys, the intracranial pineal complex includes the pineal organ (*epiphysis cerebri*), and the parapineal organ and light penetrates throughout a translucent area of reduced pigmentation overlying the pineal. The parapineal organ becomes an extracranial third eye, named parietal body in reptiles and frontal organ in anuran amphibians; it is definitively lost in aves, which have only the pineal organ.

The pineal complex, like eyes, originates embryologically from evagination of dorsal diencephalon and represents important photosensitive pathways that in vertebrate nonmammals directly and locally control the melatonin neurosecretory function.

Only in mammals, the pineal organ, although showing opsin-like immunoreaction,²³ has a function exclusively secretory. In fact, light indirectly controls pineal melatonin synthesis by means of the hypothalamic suprachiasmatic nucleus (SCN), the central pacemaker of circadian rhythms, that once synchronized to the external light–dark cycle, relays to all peripheral clocks present in the body (Figure 50.4).⁴

Melatonin is synthesized in the dark phase of a diurnal cycle and acts as a signal of darkness to regulate circadian rhythms and photoperiodic responses.²⁴

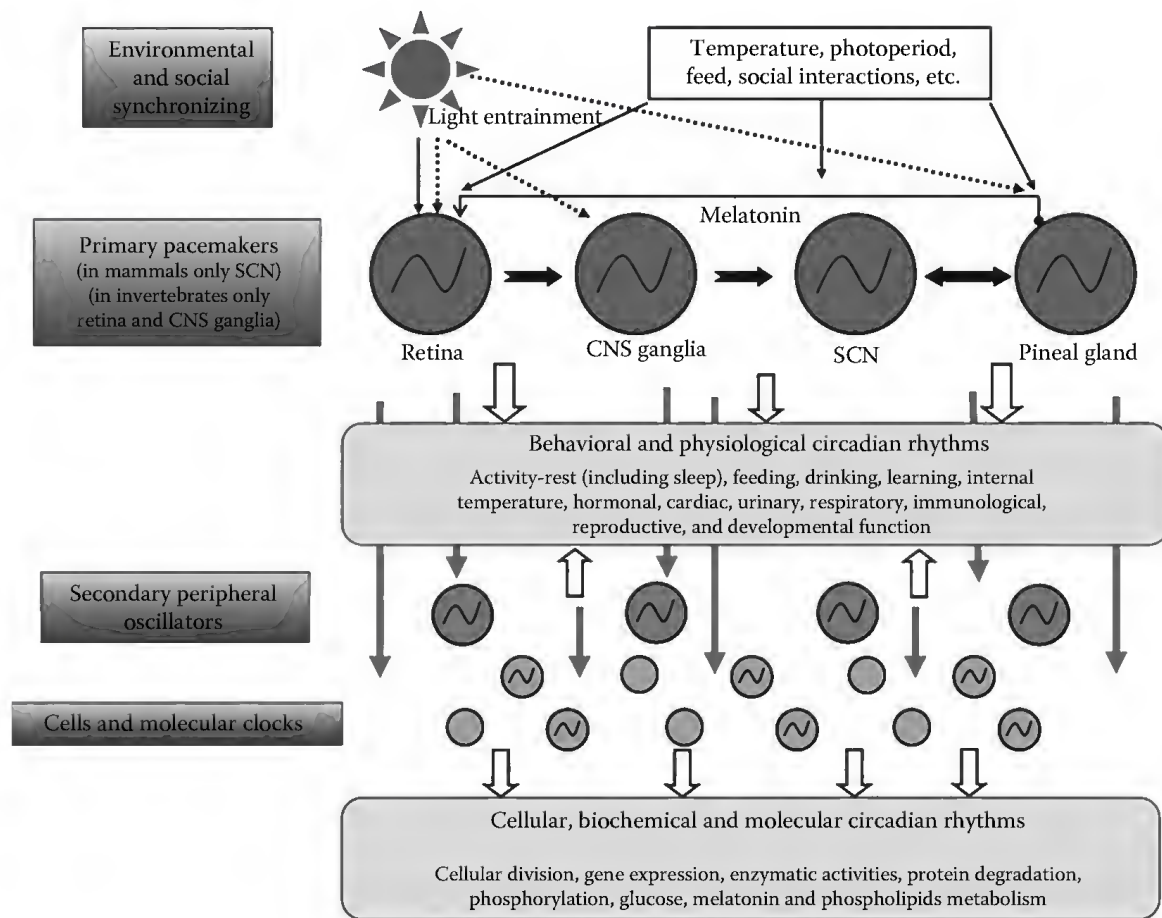

FIGURE 50.4 General scheme of the animal circadian system showing the three main components of the system in relation to the top-down/bottom-up organization of physiological processes and behavior. Entrainment pathways (above all environmental *Zeitgeber*), major pacemakers, and peripheral oscillators are reported with some indications typical of vertebrates and invertebrates. A system of cellular and molecular clocks is coupled to the output signals in order to express circadian rhythmicity at cellular level. See text for details. (Adapted and modified from Guido, M.E. et al., *Neurochem. Res.*, 27, 1473, 2002.)

Many nonvisual opsins have been identified in the pineal complex of various vertebrates: pinopsin from avian²⁵ and lizard,²⁶ exo-rhodopsin and VA opsin from teleosts,²⁷ parapinopsin from catfish²⁸ and lamprey,²⁹ and melanopsin from chicken.³⁰

Circadian clocks are also located deeply in the brain of fish, amphibian, reptile, and bird (Figure 50.4). Light reaches opsins after having crossed neural tissue and helps to control various behaviors like negative phototaxis in European eel³¹ or gonadal growth as demonstrated in blinded and pinealectomized bird.³²

These neurons are intrinsically sensitive to light although lacking of any specialized structures of eye photoreceptors, such as the microvilli or cilia. Their opsin content has been characterized: encephalopsin from mammalian,³³ VA-long opsin from zebrafish,²⁰ neuropsin from mammalian,³⁴ and VA opsin from bird.³⁵

Also in invertebrates, some ganglia present photoreceptive neurons (Figure 50.4): in dorsal ganglia of the mollusk *Onchidium*, they act as modulators of the nonphotoreceptive sensory inputs and of the motor response.³⁶ In the crayfish *Procambarus clarkia*, they contribute to the circadian locomotory activity,³⁷ and serotonin seems to produce a circadian phase shift in their electrical activity.³⁸

In the cnidarian *Hydra*, the first metazoan that shows a nervous system, although primitive and structured as a nervous net, and being eyeless a rhodopsin-like protein has been identified and presumably

localized in epithelial sensory cells³⁹ ascribing the animal's photosensitivity to neuronal NVP instead of dermal light reception as early reported. In this prototypical animal model, the measurements of different phase response curves during light and darkness regimes, in addition to behavioral spectrum with two opposite peaks of responses around 450 and 550 nm, have demonstrated that the photic inputs exert a strong regulatory effect on the oscillatory animal's behavior that is characterized by alternating phases of contraction and elongation of the body column.⁴⁰

In many nonmammalian vertebrates and invertebrates, the dermal photosensitivity controls the density of pigment granules in photosensitive dermal chromatophores,⁴¹ the locomotory activity,⁴² while in frog melanophores the pigment dispersion is regulated by the melanopsin photopigment.⁴³

Finally, photosensitivity is ascertained in several peripheral organs of both vertebrates and invertebrates. In zebrafish, the teleost multiple tissue (tmt) opsin could entrain heart and kidney to light⁴⁴; in addition, a direct muscle photosensitivity has been recently reported in the heart of the isopod *Ligia exotica*⁴⁵ and in the jellyfish *Cladonema* the expression of opsins in the gonads suggests a role in light-controlled releasing of gametes.⁴⁶

In the crayfish, light-controlled rhythms are a primary regulator of neuronal proliferation, and hormonal influences on neurogenesis may represent secondary events in a multicomponent circadian control pathway (Figure 50.4).⁴⁷

A comprehensive coverage of invertebrate behavioral and functional issues dealing with the NVP associated with the regulation of circadian rhythms is provided in Ref. [2].

50.4 Mammalian Receptor Clocks

In mammals, input clock components able to sense external lighting are located only in the retina. In fact, they have lost extraretinal photoreceptors and use their lateral eyes for both image detection and photic regulation of temporal physiology.⁴⁸

Retina projects to the hypothalamic SCN, a structure located deeply in the brain, in the ventral part of the hypothalamus. Its neurons exhibit intrinsic circadian rhythmicity and coordinate daily cycles in behavior and physiology.⁴⁹

The SCN appears to be the central pacemaker of the circadian timing system synchronizing peripheral clocks present in all tissues throughout the body.⁵⁰ Clocks are multioscillatory systems based on complex molecular feedback loops by means they regulate themselves and entrain SCN to external lighting. SCN directly relays on circadian rhythms by both neural efferents and diffusible mechanisms (Figure 50.4).⁴

The photoentrainment of circadian rhythms can occur in the absence of classical visual photoreceptors (rods and cones) but not in animals in which enucleation of the eyes abolishes all responses to light.⁵¹

As above reported, within the mammalian retina, rods and cones are not the only photosensitive cells. Retina also presents in its inner layer a subset of ipRGCs and amacrine and horizontal cells, all containing melanopsin,^{16–19} which is considered a key opsin for circadian vision.

These cells are currently termed as nonimage-forming or nonvisual photoreceptors or, much better, non-rod non-cone photoreceptors to distinguish them from photoreceptors discovered in extraocular sites of vertebrates and invertebrates.²

The ipRGCs directly project to the SCN via the tract retinohypothalamic (RHT) as well as to the other diencephalic and midbrain regions,^{18,52–54} including the olivary pretectal nucleus, the brain center controlling the pupillary light reflex.¹⁸ Pupillary constriction is regulated by both rod and cones but also survive in mammals with photoreception degeneration.⁵⁵

The ipRGCs represent the primary photoreceptors involved in circadian regulation,¹⁶ as their destruction alters the effect of light on circadian rhythms.⁵⁶ Photic regulation of circadian rhythms is also influenced by the classical visual photoreceptors via the polysynaptic rod/cone pathway to ipRGCs as the 20% of the tract RHT is constituted of non-contained melanopsin RGC fibers.^{52,57–59}

50.5 Timing by Opsins

Different experimental approaches conducted on vertebrates and invertebrates have identified for non-visual responses several photopigments referred to as opsin-like proteins.⁶⁰ By now, a putative role for the blue-light flavoprotein cryptochrome (CRY) as the NVP photopigment in the light-regulated behavior of insects,⁶¹ crustaceans,⁶² and corals⁶³ is emerging. Nevertheless, a conserved photoreceptive role for CRY in vertebrate eyes has been discovered recently in chick iris, whose constriction to light *ex vivo* depends on CRY rather than on opsin activity.⁶⁴

Despite inter- and intra-species functional differences, molecular genetic approaches have identified about 1000 opsins belonging to both vertebrates and invertebrates. The updated molecular phylogenetic tree of animal opsins (identified so far) shows seven subfamilies corresponding to a functional classification of opsins based on the specific G-protein type that links each proper opsin receptor.⁶⁰ The opsin subfamilies include (1) vertebrate visual (T-coupled) and nonvisual opsins, (2) encephalopsin/tmt-opsins, (3) G_q-coupled opsins/melanopsins, (4) G_o-coupled opsins, (5) neuropsins, and (6) peropsins and retinal G protein-coupled receptor (RGR) photoisomerase.

The functional diversity of opsins, and their localization, indicates that a high percentage (about 70%) of these proteins deals with nonimage-forming systems.

Recent findings on the molecular evolution of novel nonvisual opsins suggest a strict relationship of the NVP process with canonical vision, which could have occurred in lower organisms of the animal phylogenetic tree. In this regard, the identification of novel opsins suggests that the history of visual pigments is strictly connected with the evolution of photoreceptors and eyes.⁶⁵

In particular, there is strong evidence that opsins evolved according to the main evolutionary lineages of animal visual cells, the ciliary and the rhabdomeric (or microvillar) photoreceptors.⁶⁵ However, although those aspects are not strictly related to the main topics of this chapter, some accounts related to NVP will be given.

More recently, Suga et al.⁴⁶ have reported in jellyfish as many as 18 opsins in *Cladonema* and 2 in *Podocoryne*. Their expression patterns suggest two possible functions: a role in vision by the eye, and the other involved in the timing control of oogenesis or spawning process, possibly in cooperation with CRY.

In the brain of four species of lepidopterans, three kinds of spectrally distinct opsins have been reported outside of the retina: ultraviolet (UV) and blue opsins, which are restricted to adult stemmata (where melatonin is expressed together with opsins), and long-wavelength (LW) opsins, which are specific for dorsal and ventral photosensitive neurons of the optic lobes.⁶⁶ These opsins provide the extra-retinal detection of ambient light variations and are involved in the neuroendocrine output mediated by melatonin, underlying the entrainment of circadian and/or photoperiodic rhythms.

Arendt and coworkers⁶⁷ have found in the ragworm, *Platynereis*, the coexistence of rhabdomeric photoreceptors in the eyes (for phototaxis) and ciliary photosensitive cells in the brain (for entrainment of biological clocks). The latter (referred to as NVP cells) use an opsin closely related to vertebrate rod and cone opsins. A recent study in the honeybee, *Apis mellifera*, has revealed that a ciliary opsin, called pteropsin, is expressed in the brain of this species, indicating the presence of a vertebrate-like light-detecting system in insects.⁶⁸

Indeed, in vertebrates, photoreception is not restricted to the rod/cone pathways but is extended to other neuronal districts of the central and the peripheral nervous system providing the nonvisual processes necessary for circadian vision.¹

Also in those cellular districts, several opsins have been identified as candidate photopigments such as neuropsin, peropsin, and encephalopsin.⁶⁰ However, the corner stone of the field has been the discovery in ipRGCs of melanopsin as the novel photopigment triggering the nonvisual phototransduction (see Section 50.7 for details).

The functional mean of the colocalization of those opsins with other opsin subfamilies still remains unclear and, at same time, the role of deep brain opsins (e.g., encephalopsin, neuropsin) is far to be elucidated.

Interestingly, as reported for vertebrate rhodopsin, evidences for diurnal and circadian regulation of nonvisual opsin expression patterns have been reported in very few species of invertebrates, lower (nonmammalian) vertebrates, and only in mouse among mammals (see Section 50.6 for details). Unfortunately, although a key evolutionary trait is the adaptation to day/night alternation, and its impact on integrated physiology, the photic regulation of opsin gene expression remains rather neglected.

The interest in studying opsin expression has been enhanced by the finding in mouse of correlations between the amounts of expressed opsins with photoreceptor cell death. Light-dependent (diurnal and circadian) opsin expression could have potential clinical implications both with the condition improvements, which are under the circadian control, and in the timing of therapy.

50.6 Opsins as Oscillating Biomolecules

Opsin expression and retina physiology display a daily rhythm and, as previously reported, many opsin genes show a fluctuation in their mRNA pattern expression.

Various works give insights into possible interactions between sensory and circadian systems in the regulation of opsin expression in some species of invertebrates (*Limulus*⁶⁹ and *Apis*⁷⁰), vertebrates (teleost fish,⁷¹ zebrafish,⁷² chicken,³⁰ and chick⁷³), and mammals (mouse⁷⁴).

In zebrafish pineal organ, *exo-rhodopsin* (*exorh*) is the putative opsin mediating the effects of environmental light on pineal rhythms and melatonin synthesis.⁷⁵ It is activated by a transcription factor (*Orthodenticle homeobox 5*) and repressed by a circadian clock component (*Period 3*). Furthermore, light contributes to this transcription rhythm as *exorh* is expressed with a daily rhythm which is higher at night than during the day.

Again, in teleost embryos, the expression of mRNA long-wavelength cone (LC) opsin shows a robust day–night cycle and is regulated by *Clock*, a core circadian gene that contributes to the central circadian pacemaker.⁷² In the lizard, brain cone opsins seems to be the candidate in photic entrainment of behavioral rhythms.⁷⁶

Also in the cnidarian *Hydra*, where an opsin-like photoreceptor protein has been already identified as candidate photopigment,³⁹ preliminary evidences speak in favor of a possible coexistence of putative visual and nonvisual opsins yet in a primitive animal.⁷⁷ In fact, quantitative RT-PCR has shown fluctuations with different trends for daily and circadian cycles of various opsin sequences expressed suggesting that rhythms could be endogenous and light could have a direct role in the regulation of the photopigment molecule supply.⁷⁸

For melanopsin, the principal mediator of the circadian photoentrainment, a daily oscillating pattern has been reported with a peak in the transitional phase from day to night, while the minimum has been observed at the end of the night.⁷⁹ This rhythm appears to be influenced by rod/cone inputs, since melanopsin expression in rats lacking of rod and cone photoreceptors is lower and arrhythmic than in control rats.⁸⁰ Moreover, the elimination of dopamine in the rat retinal circuit alters the mRNA pattern profiling,⁸¹ suggesting that also the aminergic neurotransmitter is involved in this daily oscillation.⁸² Recently, two isoforms of melanopsin have been identified in the mammalian retina, a long (Opn4L) and a novel short isoform (Opn4S), differing each other in the length of their C-tail and in their expression which is higher for Opn4S. In addition, two distinct subpopulations of ipRGC, with different morphologies, functions, and projections, coexist in the inner retina, selectively expressing Opn4L and Opn4S or Opn4L only.⁸³

50.7 Melanopsin: A Key Photopigment in Circadian Vision

The understanding of how nonvisual functions work has derived from the discovery of a novel opsin termed melanopsin.⁸⁴ It was first identified in frog dermal melanophores⁴³ and then in the inner retina of mammalian eye including mice, monkeys, and humans^{58,85} and in retina, pineal, and brain of vertebrates nonmammals.^{30,86}

FIGURE 50.5 (See color insert.) Action spectrum of human melanopsin showing an optimal sensitivity to short-wavelength “blue” light at 480 nm. The spectral sensitivity profile indicates an opsin-based photopigment utilizing a vitamin A-based chromophore. The spectral sensitivity of scotopic (rod-based) and photopic (cone-based) vision is presented for comparison. Although melanopsin sensitivity peaks around 480 nm, it shows in addition a good responsiveness into the green/yellow portion of the spectrum. (Adapted from Bailes, H.J. and Lucas, R.J., *Cell. Mol. Life Sci.*, 67, 99, 2010.)

Melanopsin, a member of the G-protein-coupled receptor family, shares a seven-transmembrane domain. It presents many invertebrate opsins-like features, conversely to those showed by vertebrates, and for this reason, it probably represents, with other nonvisual opsins, a divergent line of photopigment evolved before vertebrates.⁸⁷

Melanopsin, unlike vertebrate visual opsins, presents in counterion position a tyrosine instead of a glutamate⁸⁸ that, in addition to phenylalanine, is the most frequent counterion occurring in invertebrates. Moreover, its third cytoplasmatic loop is surprisingly long (as in *Hydra* melanopsin expressed sequences, Santillo and Musio, unpublished data) respect to the conventional opsins. The melanopsin spectral sensitivity is close to the short-wavelength blue light with peaks ranging from 459 to 484 nm; it overlaps the peak sensitivity for circadian responses and not the spectral sensitivity of rods and cones (Figure 50.5).

Surprisingly, it is a bistable photoreversing pigment^{89,90} and like invertebrate photopigments⁹¹ it requires photon absorption to drive both retinal activation and regeneration conversion of all-*trans*-back to 11-*cis*-retinal (retinoid cycle), a process resident in non-photoreceptor cells of retinal pigment epithelium (RPE). This distinctive aspect enables melanopsin to function as both photoisomerase and sensory photopigment.

Upon cladistic analysis, it segregates with the invertebrate opsins expressed in rhabdomeric cells, the typical invertebrate photoreceptor, and not with vertebrate ciliary ones.^{43,90,92,93} Moreover, it exhibits the typical phototransduction signaling of invertebrate rhabdomeric opsins.^{94,95} In the retinal ipRGCs, it generates a receptor potential difference in several important aspects from that in rod and cone photoreceptors.⁹⁶

Recent studies indicate that melanopsin utilizes a rhabdomeric Gq-type phototransduction with a IP₃-mediated Ca₂ visual cascade⁹⁵ different from ciliary photoreceptors in which activation of transducin (Gi/o) and phosphodiesterase give rise to closure of cyclic nucleotide-gated (CNG) channels and membrane hyperpolarization.¹⁵ As far as we know in ipRGCs and other melanopsin-containing cells, light response is coupled to an opening of a nonspecific cation channel that leads to a cellular depolarization.^{94,97}

In various melanopsins of closely related species, the intracellular domains for G-protein specificity are poorly conserved, suggesting that they could activate multiple signaling pathways by means of multiple G-protein interactions (Gi/o, Gq/G11, and Gs).⁹³

Recently, melanopsin has been identified in the cephalochordate amphioxus, an outlined vertebrate being the most primitive living chordate closest to invertebrates and ancestor of vertebrate lineage.^{87,97}

FIGURE 50.6 Sketch illustrating the evolutionary linkage between invertebrate rhabdomeric visual cells and vertebrate photosensitive retinal ganglion cells from a common ancestral rhabdomeric cell. See text for details. (Adapted and modified from Koyanagi, M. and Terakita, A., *Photochem. Photobiol.*, 84, 1024, 2008.)

The identification of melanopsin in the rhabdomeric photoreceptors of dorsal ocelli and not in frontal eyes and the identification of a Gq phototransductive pathway represent an evolutionary link between photoreceptor cells of higher invertebrates and photosensitive ganglion cells of vertebrates and place the origin of melanopsin before the vertebrate radiation (Figure 50.6).

During evolution, these rhabdomeric cells should have lost their morphology resulting in a photosensitive retinal ganglion cell controlling different light-sensitive signaling systems.^{90,98–100}

50.8 Why Blue Light?

Among photopigments there exists a great diversity in their spectral sensitivity with absorption maxima for the image-forming visual system ranging from medium to long wavelengths. Shorter frequencies, corresponding to the blue monochromatic light, seem to prevail in nonvisual photoreception. Experiments demonstrating the direct effect of blue light on alertness and vigilance in humans¹⁰¹ suggest that nonvisual photoreceptive systems could have had a primary role in animal adaptive response to the environmental changes in both terrestrial and aquatic species. Blue-light wavelength dominates at dawn and dusk, it also penetrates deeply in seawater, and consequently, both ocean and antarctic under-ice species are blue-light sensitive.

An ancestral nonvisual photoreceptor system should have evolved by means of a blue-light key *Zeitgeber* to develop such aquatic and terrestrial adaptive responses. Otherwise, no excitatory input and evolving responses should have obtained in deeply water with a light key *Zeitgeber* of a longer wavelength.¹⁰² Many fishes are active near dawn and dusk¹⁰³; indeed, it is possible that when marine vertebrates began to colonize terrestrial habitats, a blue photoreceptive clockwork had just evolved.

Interestingly, a hypothesis explaining possible coevolution between blue-light photoreceptor systems and circadian rhythms has been reported by Gehring and Rosbash.¹⁰⁴

50.9 Conclusions

As a matter of fact, the achievements of the last decade on molecular, cellular, and functional properties of nonvisual photoreception have disclosed challenging and unexpected issues in this research field.

The study of the molecular evolution of novel nonvisual opsins is necessary to unveil the evolution of photoreceptors, and definitely of visual function. In addition, the comparative physiology of the

nonvisual photoreceptor may shed light on the events of the phototransduction cascade along the phylogenetic tree as showed by interesting scenarios recently proposed.^{67,93}

The desirable identification of novel opsins in a wide number of animal species, their molecular evolution, and phylogenetic analysis will help to untangle the evolutionary relationship between invertebrate nonvisual cells and photosensitive ganglion cells, since it concerns the putative common molecular and photochemical strategies of phototransduction.

From the functional side, a crucial point is the cross talk between NVP and the image-forming visual system, and the resultant signal streaming to the circadian system. Accordingly, only some accounts are available about the merging of nonimage-forming vision and image-forming vision and the capability of NVP in sending both irradiance and color information, previously gathered by the rods and cones, to the brain.

Another key topic is the modulatory role of NVP on temporal physiology and photoentrainment of circadian rhythms. In addition, due to the close link between nonvisual extraocular photoreception and circadian regulation, the study of NVP could be extended to pharmacological and clinical aspects. In this regard, following the recent demonstration of a direct role of melanopsin in mediating the photic regulation of sleep,¹⁰⁵ the melanopsin signaling systems could potentially be a new pharmacological target for the selective manipulation of sleep and arousal states as recently reported.¹⁰⁶

The study of the modulatory role of NVP could be extended also to those issues of visual system in which a clear link between circadian rhythm dysfunctions and pathological conditions has been ascertained.¹⁰⁷ In these terms, a sharp confirmation of NVP as possible regulatory player in the molecular clock machinery would be really challenging.

In summary, we can assert that nonvisual photoreception is a renewed and fast-growing area of photosensory biology and visual neuroscience. The study of NVP can provide crucial details on the evolution of visual systems and its relationships with chronobiology. Moreover, it can be a powerful tool to investigate important clinical implications for several pathological conditions (e.g., blindness and sleep/wake alterations) whose defects nowadays can be related to defects occurring in the nonvisual phototransduction pathway(s). Finally due to the close functional link between biological clocks and pathophysiology of several disorders, the study of NVP could provide novel indications concerning chronotherapy protocols.¹⁰⁸ Currently, it has been well ascertained that nonpharmacological (light therapy, sleep deprivation, and rhythm therapy) and pharmacological (lithium, antidepressants, etc.) therapies of several time-dependent disorders influence circadian rhythms.¹⁰⁹

Acknowledgments

We are indebted to Cloe Taddei-Ferretti, who introduced us to this research field. Carlo Musio is sincerely grateful to Francesco Lenci for his friendly support and encouragement, and to the editor Francesco Gheti for his kind patience and indulgence. Few parts of this chapter have been inspired from a previous review² and from lectures and discussions that took place in the Symposium “Classical and novel photoreceptors in circadian vision—Nonvisual photoreceptors” (of which Carlo Musio was the organizer and chair) held at the 13th Congress of the European Society for Photobiology (ESP), Wrocław University, Poland, 5–10 September, 2009.

51.1 Introduction

The retina is the crucial component of the eye that is responsible for converting environmental light into neuronal signals by a process called phototransduction. Photoreceptor cells are specialized phototransducing neurons within the retina and are divided into two families: rods and cones. Rods mediate low-light monochromatic vision, and cones mediate color and bright-light vision. Their patterns of distribution differ within the human retina; rods are found throughout, whereas cones are localized mainly within the fovea to mediate central vision. Although both rods and cones contribute to sight, humans, like other diurnal animals, exhibit a far greater dependence on cones for daily activity. Intrinsic to the phototransduction pathway are vitamin A derivatives called retinoids that are used to generate the chromophore for visual pigment formation within rods and cones [1,2]. After light excitation, the ligand/chromophore is recycled through a multistep enzymatic process called the visual cycle, with the retinal pigment epithelium 65 kDa protein (RPE65) playing an essential role as the isomerohydrolase. In the following chapter, we will explore the contributions of retinoids and RPE65 to cone function, as well as the pathogenesis of cone loss associated with RPE65 dysfunction.

51.2 Dietary Sources of Vitamin A

Retinoids have many important and diverse functions throughout the body including roles in vision [3], regulation of cell proliferation and differentiation [4], and immune function [5,6]. Retinal is the aldehyde derivative of retinol, commonly referred to as vitamin A, which naturally exists in the all-*trans* configuration (all-*trans* retinol). Along with retinoic acid, the oxidized form of retinal, the three compounds compose the three oxidized states of retinoids (Figure 51.1A).

All-*trans* retinol is one of the essential fat-soluble vitamins for humans and is obtained mainly through dietary consumption [7]. A major source is the enzymatic modification of β -carotene (Figure 51.1B) from plants [7,8]. Each molecule of β -carotene is converted into two molecules of all-*trans* retinal, through an irreversible oxidative cleavage mediated by either a monooxygenase or a dioxygenase enzyme. All-*trans* retinal can either be reduced to all-*trans* retinol by retinol dehydrogenases (RDH) or oxidized to all-*trans* retinoic acid by retinal dehydrogenases and retinal oxidases, depending on the requirements of each cell. The second source of all-*trans* retinol is derived from retinyl esters found in animals [7]. A retinyl ester is composed of retinol bound to a fatty acid (most commonly palmitate) through an ester linkage (Figure 51.1B). Retinyl esters are hydrolyzed in the intestinal lumen to yield free all-*trans* retinol and the corresponding fatty acid. After hydrolysis, all-*trans* retinol is taken up by enterocytes and released into the gastrointestinal circulation. The majority of dietary all-*trans* retinol from both sources is stored within the liver and adipose tissue for long-term use.

FIGURE 51.1 Structural characteristics of retinoids. (A) The three oxidized states of retinoids: RAL, retinal; RA, retinoic acid; ROL, retinol. (B) Dietary source of retinoids. β -Carotene is the main source from plants; retinyl palmitate and other esters are the major source from animals. (C) Photoisomerization of 11-*cis* retinal to all-*trans* retinal.

The 11-*cis* form of retinal (11-*cis* retinal) serves as the chromophore for visual pigment formation within both rods and cones. As 11-*cis* retinal is not synthesized *de novo* in the eye, its necessary substrate, all-*trans* retinol, is taken up by the RPE from circulation [9,10]. Transport of all-*trans* retinol through the blood is mediated by carrier proteins such as the family of retinol-binding proteins (RBPs) [10]. Once all-*trans* retinol enters the RPE cells, it is converted to 11-*cis* retinal through a series of enzymatic steps that is explained in further detail later in this chapter.

51.3 Structure and Function of Visual Pigments

The retina is organized into numerous layers, with the outer segment, nucleus, and synapse of the photoreceptor cell spanning the outer segment, outer nuclear, and outer plexiform layers, respectively (Figure 51.2A). 11-*cis* Retinal serves as the ligand for G-protein-coupled receptors called opsins in both rods (rod opsins) and cones (cone opsins). When 11-*cis* retinal and the various protein opsins are covalently

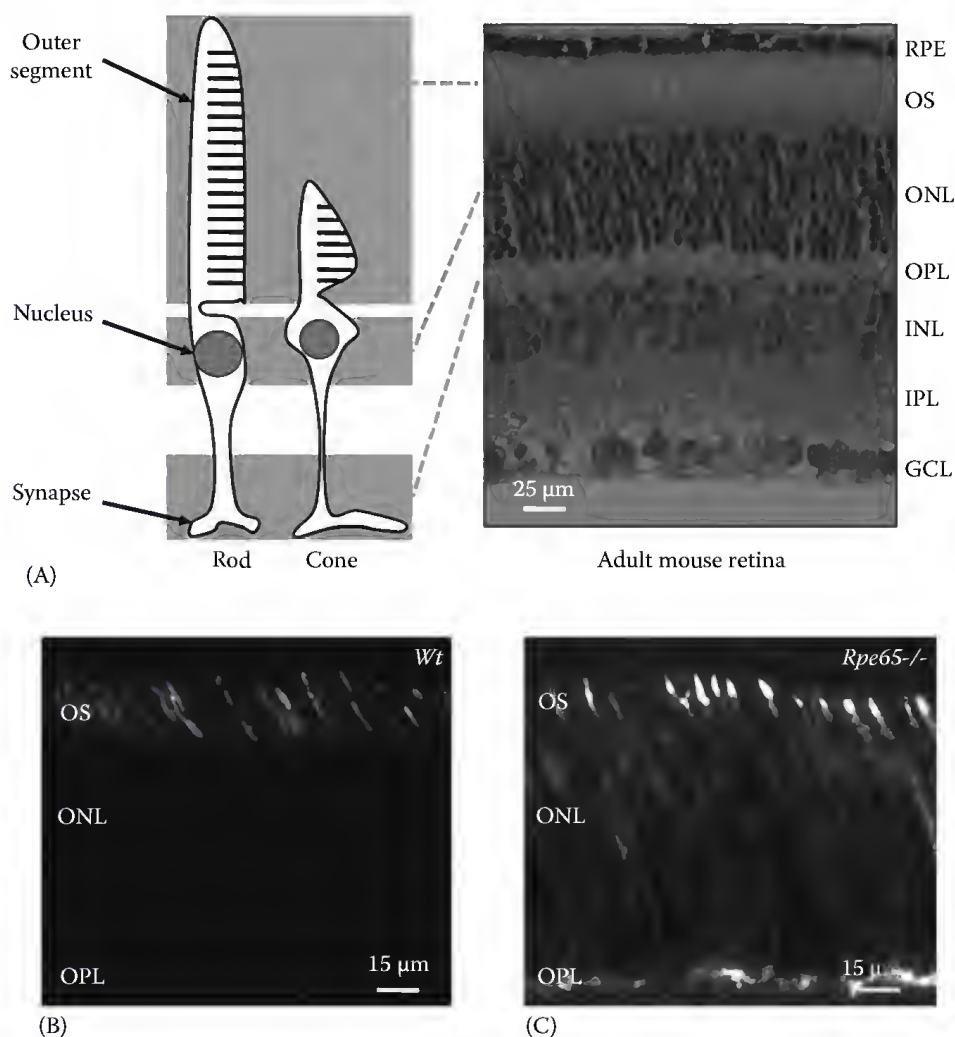

FIGURE 51.2 Retina morphology and cone visual pigment S-opsin distribution. (A) Morphology of mouse retina and epithelium (left); schematic diagram of photoreceptor cells (right). RPE, retinal pigment epithelium; OS, outer segment; ONL, outer nuclear layer; OPL, outer plexiform layer; INL, inner nuclear layer; IPL, inner plexiform layer; GCL, ganglion cell layer. (B, C) S-opsin distribution in C57BL/6 (*Wt*, B) and *Rpe65*^{-/-} (C) mouse cones at 2 weeks of age. While the cone visual pigment S-opsin is properly localized to the outer segment of the *Wt* cone, it is mislocalized throughout the *Rpe65*^{-/-} cone, including the soma and synapse. Immunofluorescence staining performed with antibody specific for S-opsin (1:500 dilution; Cat# sc-14363; Santa Cruz Biotech, Santa Cruz, CA).

bound, the resulting visual pigments have absorption in the UV-visible region (300–700 nm). Although differences exist between rod and cone opsins [11], there are numerous similarities. Opsins are integral membrane proteins located within the outer segment disks of photoreceptors and are composed of seven transmembrane helices linked by six loops of various lengths [12,13]. 11-*cis* Retinal binds to a lysine residue in helix VII via a protonated Schiff base linkage and acts as an inverse agonist to maintain the pigment in an inactive conformation [14]. Upon excitation with light, 11-*cis* retinal isomerizes to an all-*trans* arrangement (Figure 51.1C), inducing the pigment to change into an active conformation and triggering the phototransduction pathway that begins with activation of transducin, the opsin-associated G-protein, and ends with hyperpolarization of the photoreceptor cell to terminate synaptic release of the neurotransmitter, glutamate (for reviews, see Refs. [15–18]).

To mediate the spectral range of light detection, rhodopsin and cone pigments differ in their absorption spectra. In human and mice retina, rods express a single type of opsin; therefore, only one form of rhodopsin exists and absorbs maximally at 500 nm [11,19]. Cones can express numerous types of opsins, leading to cone types with pigments that absorb maximally at various wavelengths. For example, human cones can express three types of cone opsins to generate pigments that absorb maximally at 420 nm (S, short-wavelength), 530 nm (M, mid-wavelength), or 560 nm (L, long-wavelength) [11], and mouse cones can express two types of opsins (359 nm, S; 505 nm, M), depending upon its retinotopic location [20]. Distinctive visual function within the retina is dependent upon the spatial arrangements of these cone types, such as the high concentration of cones within the fovea of humans and the dorsoventral gradients of cone opsin expression in mice [21,22].

51.4 Classic and Cone-Specific Visual Cycles

Photoisomerization of the chromophore underlies the ability of the photoreceptor cell to convert light into neuronal signals to be processed by the visual cortex for vision. Regeneration of the chromophore relies upon the visual cycle. Although a large amount of information has been gathered about the “classic visual cycle,” which is characterized by the interactions of both rods and cones with RPE cells for pigment regeneration, less is known about the proposed alternate visual cycle that specifically supports cone pigment regeneration (cone-specific visual cycle). Both visual cycles overlap at numerous enzymatic steps (Figure 51.3) and are explained in further detail in the following.

51.4.1 Classic Visual Cycle

The classic visual cycle has been mainly characterized as an interaction between RPE cells and rods (for reviews, see Refs. [2,3,23,24]); however, it is assumed to function similarly for cones. The main role of RPE cells within the classic visual cycle is to convert all-*trans* retinol to 11-*cis* retinal, and it obtains its substrate from two sources. The first source involves the delivery of RBP-bound all-*trans* retinol from the liver or adipose tissue through the circulation to RPE cells, where RBP docks with the RPE cell multitransmembrane domain protein STRA6 and releases all-*trans* retinol for uptake [9,10]. The second source involves recycling the all-*trans* retinal produced after excitation of the visual pigment by light. After 11-*cis* retinal is photoisomerized to all-*trans* retinal, it is released from opsin into the cytoplasm of the photoreceptor outer segment and reduced to all-*trans* retinol in a reaction that requires both an all-*trans*-specific RDH enzyme and nicotinamide adenine dinucleotide phosphate (NADPH) as a cofactor [25,26]. All-*trans* retinol is then shuttled across the extracellular interphotoreceptor matrix (IPM) to the RPE cell by interphotoreceptor retinoid-binding protein (IRBP) [27,28], which can also bind and shuttle 11-*cis* retinal [29–32].

Once all-*trans* retinol is released into the RPE cell, it is esterified by lecithin:retinol acyltransferase (LRAT) to form all-*trans* retinyl ester for storage [33]. RPE65 acts as the isomerohydrolase enzyme within RPE cells to catalyze the hydrolysis of all-*trans* retinyl ester and its subsequent isomerization to 11-*cis* retinol [1,34,35]. 11-*cis* Retinol can either be esterified again by LRAT to the storage form 11-*cis*

While the function of RPE65 has been well documented to support the classic visual cycle, there is a growing amount of evidence to suggest that there is a second isomerase enzyme that specifically supports rapid cone pigment regeneration (for reviews, see Refs. [24,39]). This alternate visual cycle

has been observed to exist entirely within the retina and functions in parallel with the classic visual cycle [40–43]. Salamander cones within retina that were isolated away from the RPE were observed to recover light sensitivity after photobleaching; however, this recovery disappeared in photobleached cones disassociated from the retina [40]. Previous work in the isolated frog retina produced similar results [44,45].

This second isomerase enzyme has yet to be identified, but studies have provided insight into its characteristics. There is evidence to suggest that RPE65 may be this second isomerase enzyme, and that it is expressed by cones in addition to the RPE. Isolated salamander cones have been shown to express RPE65 mRNA [46], and immunohistochemistry analysis of mouse retina has shown cones to express RPE65 protein [47]. Further studies are needed to clarify the expression of RPE65 in cones.

Further evidence was recently obtained in the cone-dominant chicken retina, where synthesis of 11-*cis* retinyl esters from all-*trans* retinol by retina microsomes required palm-CoA as an acyl donor, suggesting the dependence of the novel isomerase on acyl CoA:retinol acyltransferase (ARAT) instead of LRAT, as in RPE65 [41]. Together, these data implicate the existence of a novel isomerase within the retina that has different characteristics from RPE65, and that physical associations between cones and neighboring cells must be preserved in order for the alternate visual cycle to function.

Several important observations have implicated Müller cells to express the novel isomerase enzyme and to deliver the regenerated chromophore to cones. The ability of Müller cells to isomerize all-*trans* retinoids into 11-*cis* forms *in vitro* was confirmed, where cultured chicken Müller cells treated with all-*trans* retinol generated and released 11-*cis* retinol into the surrounding medium [48]. This was further supported by the observation that Müller cells express cellular retinol-binding protein (CRBP) and cellular retinal-binding protein (CRALBP), both of which are also found in RPE cells where they enhance the uptake of all-*trans* retinol and stabilize both 11-*cis* retinal and 11-*cis* retinol, respectively [49,50]. Within the intact isolated salamander retina, lesioning Müller cells with a Müller cell-specific gliotoxin inhibited the ability of photobleached cones to recover light sensitivity [40]. Additional work is needed to identify the specific isomerase protein within the Müller cell.

How does the alternate visual cycle mediate its specificity for supporting cone pigment regeneration? The previously mentioned observation that cultured Müller cells generate 11-*cis* retinol from all-*trans* retinol [48] may indicate its mechanism. While rods are only able to utilize 11-*cis* retinal for generating pigment, cones are capable of utilizing either 11-*cis* retinal or 11-*cis* retinol. This was shown through electrophysiologic recordings from isolated salamander rods and cones, where treatment with 11-*cis* retinal recovered light sensitivity in both rods and cones, but treatment with 11-*cis* retinol only recovered light sensitivity in cones [32]. Furthermore, 11-*cis* retinal could only restore light sensitivity in cones when specifically delivered to the cell body [51], coinciding with morphologic data showing that the Müller cell processes make numerous associations with the cone specifically at its cell body [40,52]. Finally, IRBP may play an essential role in shuttling 11-*cis* retinol and all-*trans* retinol between the Müller cell and the cone, as IRBP binds 11-*cis* retinol endogenously [53], is colocalized with Müller cell processes surrounding the cone cell body [54] and is found in high concentrations around cones [55,56]. Although IRBP has also been shown to function in the classic visual cycle between photoreceptor outer segments and RPE cells, knocking out the gene in mice appears to have the most detrimental effects on cone function [57]. Therefore, the cone-specific nature of the alternate visual cycle is dependent upon Müller cells generating and delivering 11-*cis* retinol to cones. The novel isomerase enzyme within the Müller cell is proposed to use all-*trans* retinol as a substrate. IRBP mediates the movement of both all-*trans* retinol and 11-*cis* retinol between Müller cell processes and the cone cell body. Once inside the cone, 11-*cis* retinol is oxidized to 11-*cis* retinal by an unidentified RDH, and it binds to cone opsin to form visual pigment. Rods apparently do not utilize the alternate visual cycle as 11-*cis* retinal is not oxidized within these cells and, indeed, is quite toxic [14].

51.5 RPE65 Dysfunction and Leber Congenital Amaurosis

The visual cycle is composed of numerous enzymes that function at various steps of an organized pathway to support pigment regeneration. Genetic defects leading to the disruption at any one of these steps can have a detrimental effect on the ability of the visual cycle to generate an adequate supply of chromophore, causing a subset of recessively inherited retinal diseases known as Leber congenital amaurosis (LCA) (for review, see Refs. [3,58]). LCA is rare (population frequency is between 1/30,000 [59] and 1/81,000 [60]), presents at a young age (around 6 weeks after birth), and is generally characterized by four clinical features including severe loss of vision, sensory nystagmus, amaurotic pupils, and absent electrical signals on electroretinography (ERG) [58]. Mutations in genes encoding for a wide variety of proteins that function within the retina can cause LCA, including those involved in photoreceptor morphogenesis (CRB1 and CRX), phototransduction (AIPL1 and GUCY2D), chromophore regeneration (LRAT, RDH12, and RPE65), guanine synthesis (IMPDH1), outer segment phagocytosis (MERTK), and intra-photoreceptor ciliary transport processes (CEP290, LCA5, RPGRIP1, and TULP1) [58]. Online Mendelian inheritance in man (OMIM) currently recognizes 13 forms of LCA, with the second form (LCA2) caused by a defect in the gene encoding for the isomerase protein RPE65 [34,61].

51.5.1 Early Onset of Cone Loss

The use of animal models for LCA2 has greatly enhanced our understanding of the mechanisms underlying this disease, as well as strategies for therapeutic development. In the rod-dominant human retina, cones compose around 3% of the total number of photoreceptors and are located mainly within the fovea, which is responsible for central vision. The symptoms of LCA2 are attributed to the loss of cones within this region of the retina beginning in the early years of life [61]. To develop an appropriate mouse model to further investigate this clinical feature, the gene encoding for RPE65 protein was knocked out (*Rpe65*^{-/-}). The lack of a rod photoresponse measured by ERG [62,63] and the accumulation of all-*trans* retinyl esters within the RPE [34] confirm the disruption of the classic visual cycle at the RPE65-mediated retinoid isomerization step within these mice. The mouse retina is also rod-dominant; however, its cones are uniformly distributed throughout the entire retina. To quantify the amount of cones present within an area, the whole mouse retina was fluorescein isothiocyanate (FITC)-conjugated peanut agglutinin (PNA), a marker for the cone outer segment sheath, and mounted flat onto a microscope slide for counting. Results indicated a dramatic and rapid loss of cones within the retinæ of *Rpe65*^{-/-} mice between 2 and 4 weeks of age. By 4 weeks of age, large areas of the central and ventral *Rpe65*^{-/-} retina showed almost no positive PNA labeling [64]. The lack of chromophore generation in *Rpe65*^{-/-} mice was confirmed to cause this rapid loss of cones, as the delivery of exogenous 11-*cis* retinal to the retina beginning at 2 weeks of age significantly decreased the rate of cone loss [64–66].

51.5.2 Cones Expressing High Levels of S-Opsin Are More Susceptible to Degeneration

While a significant proportion of cones within the fovea are lost at a young age in LCA2 patients, a residual amount survive well into later ages [61]. Assessing the functionality of specific subsets of cones within LCA2 patients of various ages, it was discovered that the earliest loss of function occurred in cones expressing S-opsin, while the function of cones expressing L-opsin was significantly reduced in later ages, but was still present [61]. Thus, it would appear that, within the LCA2 human retina, cones expressing S-opsins degenerate at a faster rate than those expressing L-opsins.

Although mouse cones differ from human cones in their opsin expression patterns within the retina, mouse models for LCA2 can be used to further investigate this clinical feature. Unlike human cones, mouse cones only express two types of cone opsins (S and M). Both opsins may be coexpressed within a

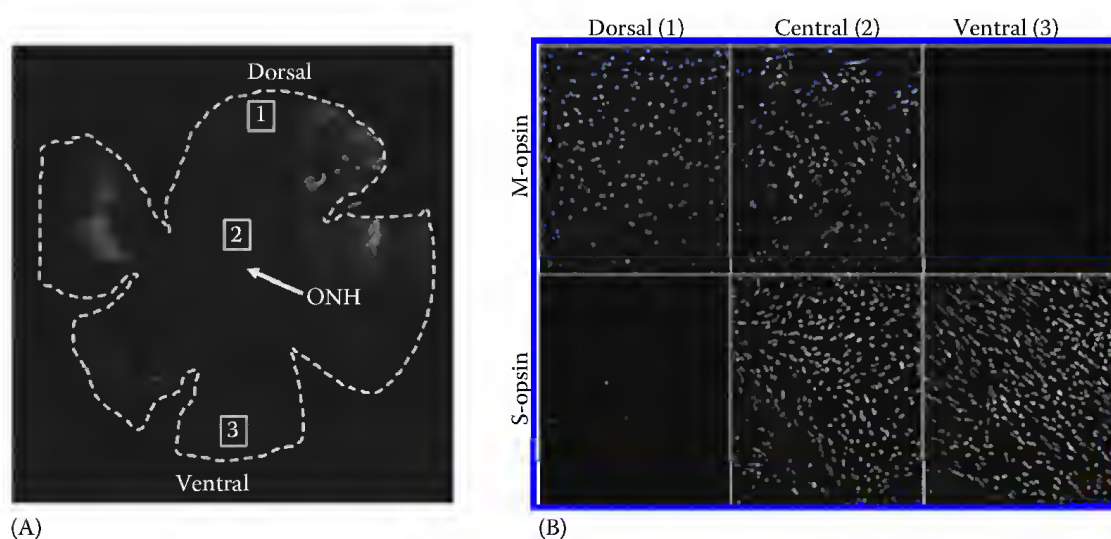

FIGURE 51.4 M/L- and S-opsin distribution along the dorsal–ventral axis of the mouse retina. (A) Low magnification of 2 week old *Wt* flat-mounted retina indicating three regions (1–3) analyzed for cone M/L- and S-opsin distribution. ONH, optic nerve head. (B) High magnification immunofluorescence images of M/L- (top panel) and S- (bottom panel) opsins from the dorsal (1), central (2), and ventral (3) regions of the retina. Immunofluorescence staining performed with antibodies specific for M/L-opsin (1:500 dilution; Cat# AB5405; Millipore, Billerica, MA) and S-opsin (1:500 dilution; Cat# sc-14363; Santa Cruz Biotech, Santa Cruz, CA).

single cone depending upon its retinotopic location [20]. While cones within the majority of the retina express M-opsin, those in the most ventral region do not. S-opsin distribution is in an opposite gradient, where cones within all but the most dorsal regions of the retina express it (Figure 51.4). Numerous developmental factors mediate this pattern of opsin expression, including thyroid hormone and the b2-isoform of its receptor (TRb2) [67,68]. This results in the establishment of unique M- to S-opsin ratios within cones along the dorsal–ventral axis of the mouse retina [20,22].

Data collected from the *Rpe65*^{−/−} mouse retina support the clinical observation that cones expressing a high amount of S-opsin degenerate at a faster rate than those that do not. Using fluorescent PNA labeling as a general marker for cones to assess survival at various regions of the *Rpe65*^{−/−} retina over time, it was observed that cones within the dorsal region of the retina, which express low amounts of S-opsin, exhibited a much slower rate of decline compared to cones within the central and ventral regions, which express high amounts of S-opsin [64–66]. This was confirmed through analysis of cone opsin mRNA expression in the *Rpe65*^{−/−} retina, where the reduction of M-opsin mRNA expression progressed more slowly than that of S-opsin [64].

Morphological analysis of opsin distribution within the *Rpe65*^{−/−} mouse cone provides insight into the correlation between a high level of S-opsin expression within the cone and its faster rate of degeneration in an environment of limited chromophore supply. Integral membrane proteins of the outer segment, such as opsins, are produced within the inner segment and subsequently trafficked through the connecting cilium to the outer segment [69] (Figure 51.2B). During the normal development of mouse cones, S-opsin expression begins immediately before birth and M-opsin expression begins at the end of the first postnatal week [65,66]. The mechanism for targeted transport of integral membrane proteins to the outer segment is active after the second postnatal week, as both opsins are localized indiscriminately throughout the normal mouse cone beforehand. 11-*cis* Retinal appears to play an important role in promoting this mechanism. In untreated *Rpe65*^{−/−} mice, S-opsin appears to be more susceptible to mislocalization than M-opsin, and degeneration follows immediately afterward [66,70] (Figure 51.2C). Repeat 11-*cis* retinal supplementation at an early age is able to correct cone opsin mislocalization, restore function, and arrest degeneration [64–66,71].

The mechanism by which the mislocalization of cone opsin in *Rpe65*^{-/-} retina triggers cone degeneration is not well understood; however, it may be due to the decreased amount of opsins that are properly trafficked in the absence of chromophore production [65,66,71]. As S-opsin constitutes the majority of the cone opsins expressed within the retina [20,64], its mislocalization plays a greater role in the early cone loss observed within the central and ventral retina of *Rpe65*^{-/-} mice. With M-opsins less susceptible to mislocalization and the relatively low level of S-opsin expression, cones within the dorsal *Rpe65*^{-/-} retina follow a slower degeneration rate and survive for much longer. This occurs in a manner similar to that observed in the rods of a mouse where the gene responsible for expressing rod opsin is mutated, with massive rod degeneration occurring afterward [72,73].

51.5.3 Treatments for LCA2

One of the exciting recent developments for treating congenital disorders has been the pioneering use of viral vectors to deliver functional genes to treat LCA2. The eye is ideally suited as a target organ for gene therapy, as its compartmentalized anatomy facilitates accurate delivery, the blood–retina barrier minimizes systemic side effects, and its relative ease of access and visualization facilitates the delivery process (for review, see Ref. [74]). Two clinical trials using adeno-associated viruses (AAV) to deliver *Rpe65* cDNA to adult LCA2 patients have been successfully completed with dramatic results [75,76]. A third clinical trial aiming to treat pediatric LCA2 patients using a similar approach is currently underway. The potential of AAV-mediated gene therapy for treating LCA2 and other congenital retinal diseases holds great promise and requires further validation to ensure safety and efficacy.

51.6 Conclusion

The intrinsic production of 11-*cis* retinal by the visual cycle is crucial for proper function of photoreceptor cells. RPE65 is a crucial enzyme in this multistep process, and its dysfunction is related to numerous congenital retinal diseases, which lead to early onset cone degeneration. The availability of animal models has allowed us to further investigate the mechanisms by which RPE65 dysfunction leads to cellular degeneration and has provided insights into developing novel treatment strategies such as gene therapy.

52.1 Introduction

Phytochromes are photoreceptors that regulate many aspects of plant growth and development in response to red/far-red light signals from the environment.¹⁻³ Phytochromes in higher plants are encoded by small gene families.⁴ For example, the completed whole genome sequences of *Arabidopsis thaliana* and *Oryza sativa* phytochromes reveal five (*PHYA* to *PHYE*) and three (*PHYA* to *PHYC*) genes, respectively.^{5,6} Phytochromes are dimeric chromoproteins having covalently linked open tetrapyrrole phytochromobilin and exist in two photochromic species, red-light-absorbing Pr and far-red-light-absorbing Pfr forms. They are biosynthesized as the Pr form in the dark, which can be phototransformed into the Pfr form upon exposure to red light. The Pr-to-Pfr phototransformation of phytochromes induces the highly regulated signaling network for photomorphogenesis in plants.⁷⁻⁹ Recent studies on the molecular mechanisms of the phytochrome-mediated light signaling reveal that phytochrome photoactivation impacts on the control of protein subcellular localization,^{10,11} transcription,^{12,13} protein stability,^{14,15} and protein phosphorylation.¹⁶ Here, we highlight the current knowledge about the molecular mechanisms of phytochrome function based on the recent advances.

52.2 Domain Structure of Phytochrome

The phytochrome molecule consists of two major structural domains, the globular N-terminal chromophore-binding domain (~65 kDa) and the structurally open or extended C-terminal domain (~55 kDa).¹⁷ The two domains are connected via a flexible hinge region (Figure 52.1A). A domain swap experiment demonstrated that the N-terminal domains of phyA and phyB determine their photosensory specificity and differential light lability.¹⁸ There are a few subdomains in the N-terminal photosensory domain, including N-terminal extension (NTE), bilin lyase domain (BLD), and phytochrome-specific domain (PHY). The NTE is dispensable for chromophore binding but necessary for a biological activity.¹⁹ The BLD is composed of PAS (PER/ARNT/SIM) and GAF (cGMP phosphodiesterase/adenylate

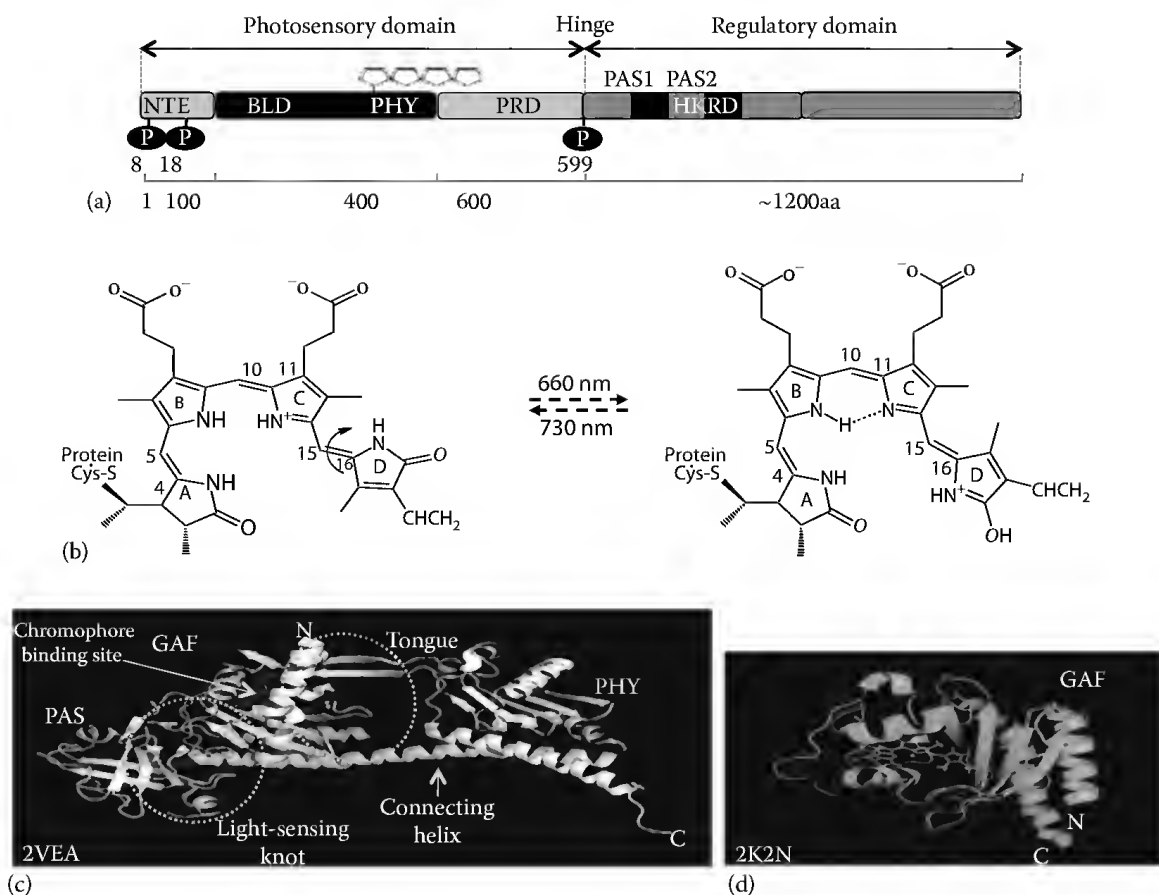

FIGURE 52.1 (See color insert.) Domain and protein structures of phytochrome. (a) Domain structure of phytochrome. Phytochrome has a two-domain structure, N-terminal photosensory domain and C-terminal regulatory domain. The photosensory domain contains both light sensor chromophore (phytochromobilin) and signaling motifs for phosphorylation and interactions with phytochrome-interacting factors (PIFs) (see text). NTE, N-terminal extension; BLD, bilin lyase domain consisting of PAS and GAF; PHY, phytochrome-specific GAF-related domain; PRD, PAS-related domain; PAS1 and PAS2, two PAS repeats; HKRD, histidine kinase-related domain. As examples, *Arabidopsis* phyA and phyB are composed of 1122 and 1172 amino acids, respectively. The four-connected pentagon in the BLD is the chromophore (i.e., phytochromobilin) that binds to the cysteine residue at 322. Three phosphorylation sites on oat phyA are also shown. (b) Photoisomerization of phytochromobilin during the Pr-to-Pfr photo-transformation. (c) The N-terminal photosensory module structure (residues 1–514) of cyanobacterial phytochrome (Cph1).²¹ The complete sensory module (PDB ID: 2VEA) consists of PAS, GAF, and PHY domains. Chromophore-binding site and connecting helix are indicated. The regions for light-sensing knot and the tongue are shown as circles. (d) The structure of the Cph1 GAF domain (PDB ID: 2K2N) assembled with phytycyanobilin.³⁴ N-terminus (N) and C-terminus (C) are labeled, and the chromophore is shown in white.

cyclase/FhlA) domains and is sufficient for chromophore attachment via a conserved cysteine residue that forms a thioester linkage with the A ring of phytochromobilin.²⁰ The PHY domain is a phytochrome-specific GAF-related domain adjacent to the BLD and has been suggested to directly interact with the D ring of the chromophore to maintain its open tetrapyrrole configuration (ZZZ) in the Pr form and to stabilize the Pfr form.^{1,21}

Importance of the C-terminal regulatory domain is highlighted by numerous missense mutations affecting this part of the protein.^{22,23} In the C-terminal domain, there are PAS-related domain (PRD) consisting of a pair of PAS repeats (PAS1 and PAS2) and histidine kinase-related domain (HKRD). The PRD has been reported to have regulatory roles for phytochrome dimerization,²⁴ nuclear localization,²⁵ and protein-protein interaction of phytochromes with their downstream components.^{13,26,27} The HKRD is homologous to a histidine kinase domain, but is suggested to be a nonfunctional kinase domain because the key conserved residues within the histidine kinase domain are absent in the phytochrome HKRD.¹⁶ This domain may play a regulatory role in the phytochrome signaling, because the domain interacts with downstream signaling components such as phytochrome kinase substrate 1 (PKS1)²⁸ and phytochrome-associated protein phosphatase 5 (PAPP5).²⁹ Furthermore, it has been reported that the phyB N-terminal domain by itself is functional *in vivo* when it could exist as dimers and be localized in the nucleus,^{30,31} suggesting a model that the C-terminal domain is dispensable for phytochrome function except for dimerization and nuclear localization. However, phyA requires the C-terminal domain for its full activity in plants, suggesting a regulatory function of the C-terminal domain at least in the phyA-mediated light signaling.

52.3 Conformational Changes during Photoactivation

The striking characteristic of phytochromes is its reversible photochromism between the red- and the far-red-absorbing forms.³² Phytochromes are synthesized in the Pr form ($\lambda_{\text{max}} = 660 \text{ nm}$) which can be phototransformed into the Pfr form ($\lambda_{\text{max}} = 730 \text{ nm}$) upon exposure to red light. The absorption of red light triggers a Z-to-E isomerization of the chromophore in the C₁₅-C₁₆ double bond between the C and D rings of the linear tetrapyrrole (ZZZ to ZZE)³³ (Figure 52.1B). Contrary to the commonly held model for the photoisomerization, Ulijasz et al.³⁵ proposed a C₄-C₅ isomerization (ZZZ to EZZ) for the Pr-to-Pfr phototransformation based on the NMR-elucidated structure of Cph1 GAF domain. However, the configuration/conformation assigned to the presumed Pfr chromophore in the GAF domain does not possess the characteristic Pfr absorbance spectrum, so it remains to be seen if the C₄-C₅ isomerization occurs in native phytochromes. The photoisomerization of phytochromes leads to reversible conformational changes throughout the protein moiety of phytochrome,¹⁷ which constitutes the first step of phytochrome signaling. Due to the promotive effect of the red light on most physiological responses, the Pfr form is considered as the active form. Once the Pfr form is formed, phytochrome moves into the nucleus and regulates the transcription of genes for photomorphogenesis and photosynthesis (see the following). Therefore, a basic molecular mechanism for the on/off switching of the phytochromes is driven by the photochromic transformation between the two forms.

Although the protein structure of plant phytochromes is not currently available, tertiary structures of eubacterial and cyanobacterial phytochrome fragments have been elucidated.^{20,21,34,35} The 35 kDa N-terminal PAS/GAF domain structure (1ZTU) of a bacteriophytochrome DrBph1 from *Deinococcus radiodurans* illustrates how the chromophore buried in the chromophore-binding pocket formed in the N-terminal GAF domain, showing the light-sensing “knot” formed between PAS and GAF.²⁰ In the N-terminal PAS/GAF/PHY domain structure (2VEA) of a cyanobacterial phytochrome 1 (Cph1) from *Synechocystis* 6803, the PAS/GAF and the PHY domains are connected by a tongue-like structure protruding from the PHY domain²¹ (Figure 52.1C and D). The structural information with phytochrome mutant analysis provides the basis to understand how the light signal is intramolecularly processed, in which the light-sensing knot is suggested to play a crucial role in the interaction of phytochrome with phytochrome-interacting factors (PIFs), and the tongue structure is suggested to be a modulator of the

phytochrome activity.^{32,36,37} These structural analyses will be important for understanding how phytochromes perceive light signals and transmit them intramolecularly and intermolecularly with signal transducer proteins.

52.4 Molecular Mechanisms of Phytochrome Signaling

Phytochromes have been studied intensively by a broad range of experimental approaches since their first discovery in 1950s, but there is no definitive picture about how phytochromes transduce light signals into physiological responses so far. However, recent studies have resulted in several important advances in our understanding of phytochrome signaling.

52.4.1 Translocation of Phytochromes from Cytosol to Nucleus

Many plant proteins are known to change their localization in response to stimuli, and nucleocytoplasmic partitioning of proteins is a critical step in the regulation of gene expression.^{10,38} Since phytochromes are biosynthesized as Pr forms and accumulate in the cytoplasm, it was once thought that phytochromes acted in the cytoplasm. However, analysis of phyB fused to β -glucosidase (GUS) demonstrated that phytochrome has nuclear localization activity,³⁹ and subsequent analysis of green-fluorescent-protein (GFP)-fused phytochromes showed that all phytochromes including phyA are translocated into the nucleus.^{40,41} Therefore, the photoactivation of cytoplasmic Pr to Pfr causes translocation of phytochromes into the nucleus, which appears to be the early molecular event for phytochrome signaling. In the case of *Arabidopsis* phyB, the nuclear localization signal (NLS) is located in the PRD (amino acids 594–917), and the latter is both necessary and sufficient for nuclear localization.²⁵ It has been also known that the N-terminal photosensing GAF-PHY domain interacts with the PRD in a light-dependent manner, which provides a mechanistic link between light-dependent Pr-to-Pfr conformational changes and the unmasking of the NLS that regulates nuclear accumulation of phyB. This is consistent with the “intramolecular interdomain crosstalk” model that we previously proposed, based on the results of structural changes in NTE and PRD during phototransformation.¹⁷ In the case of phyA, there is no putative NLS, but the nuclear accumulation of phyA is mediated by several plant-specific factors, including far-red elongated hypocotyl 1 (FHY1), FHY1-like (FHL), FHY3, and far-red impaired response 1 (FAR1).¹¹ FHY1 and FHL have a conserved C-terminal domain and N-terminal NLS and nuclear export signal (NES) sequences.^{42,43} They directly interact with photoactivated phyA (i.e., the Pfr) in the cytoplasm through their conserved C-terminal domain, and the complex is imported into the nucleus.^{44,45} FHY3 and FAR1 are transposase-derived transcription factors and indirectly control phyA nuclear accumulation by controlling the expression of FHY1 and FHL.⁴⁶ Therefore, the light-controlled translocation of the phytochromes from cytoplasm into the nucleus is a key regulatory step for phytochrome-mediated light signaling in plants.

52.4.2 Transcriptional Control of Light-Responsive Genes through Phytochromes

Photoactivation and nuclear localization of phytochromes trigger a transcription cascade that leads to the regulation of light-responsive genes. Recently, DNA microarray analyses have been applied to identify genome-wide set of phytochrome-regulated genes.⁴⁷ Approximately 10% of the genes in the *Arabidopsis* genome (2500 genes) are regulated by phytochromes under prolonged light exposure, whereas about 250 genes are affected at least twofold by continuous red light within 1 h.⁴⁸ Approximately 80% of the light-responding genes are induced, and about 20% repressed. The majority of these genes are strongly related to the various morphogenic changes observed during de-etiolation, including photosynthetic, hormone-pathway-related and metabolic genes, reflecting the transition from heterotrophic to autotrophic growth. To answer how phytochromes can mediate a global response to light at the transcriptional level, many downstream components in the phytochrome signaling have been identified and

characterized by genetic, biochemical, and molecular biological studies.^{12,49} For the early search for the downstream components, yeast two-hybrid screens have identified a few proteins capable of interacting with phytochromes, such as PIF3,⁵⁰ nucleoside diphosphate kinase 2,⁵¹ and PKS1.²⁸ Subsequently, a few other positively and negatively acting factors in the phytochrome signaling have been identified including blue/UV-A photoreceptor cryptochromes, Aux/IAA proteins, protein phosphatases, and F-box protein ZEITLUPE (see reviews, Refs. [2,52]). Among these components, a small set of PIFs are considered as the central players in the phytochrome-mediated light signaling.^{13,53} PIFs are basic helix-loop-helix (bHLH) transcription factors among which PIF3 exhibits phytochrome-mediated and light-dependent binding to G-box promoter regions of various light-responsive genes, providing a plausible mechanism for direct photoregulation of gene expression by phytochromes.⁵⁴ The PIF or PIL (PIF3-like) proteins belong to subfamily 15 of the *Arabidopsis* bHLH superfamily,²⁶ and act to repress seed germination, promote seedling skotomorphogenesis, and shade avoidance through regulated expression of more than a 1000 genes.¹³ Among them, several PIF/PIL proteins are involved in the phytochrome-mediated light signaling, for example, PIF1/PIL5 in chlorophyll biosynthesis and seed germination,^{55,56} PIL1/PIF2 and PIL2/PIF6 in shade avoidance,⁵⁷ and PIL6/PIF5 in circadian rhythms,⁵⁸ as well as PIF3 and PIF4 in deetiolation.^{59,60} These proteins appear to act as negative regulators in the phytochrome signaling,⁶¹ and they are rapidly degraded by Pfr-induced proteasome.^{62,63} In addition, photoactivated phytochromes induce rapid *in vivo* phosphorylation of PIF3 preceding degradation. Considering that phytochromes are known as atypical serine/threonine protein kinases,^{64,65} the molecular mechanism of signal transfer from phytochromes to PIFs involves the degradation of PIFs through their phosphorylation by phytochromes.

52.4.3 Regulated Proteolysis in Phytochrome Signaling

Recent studies have shown that plants make extensive use of regulated proteolysis to modulate signal transduction pathways, including hormone and light signalings.^{14,15,66} PhyA accumulates in etiolated seedlings and degrades rapidly upon light exposure via ubiquitin/26S proteasome-mediated protein degradation pathway.^{67,68} Recently, phyB has been also shown to be degraded upon light treatment.⁶⁹ PIFs are also subject to regulated ubiquitination and subsequent degradation by the 26S proteasome. It appears likely that regulated proteolysis is an important molecular event in phytochrome signaling. Recently, we demonstrated that the autophosphorylation of phyA reduces the protein stability, thus desensitizing the phytochrome signaling.^{65,70} These results are consistent with the previous report that the knockout plants of PAPP5 showed a decrease in photoresponsiveness and a decline in the stability of the phyA protein, while the protein stability increased in plants overexpressing PAPP5.²⁹ Further studies have shown that phosphorylated phyA preferentially associates with the CONstitutive Photomorphogenic 1/Suppressor of phyA-105 (COP1/SPA1) complex, the E3 ligase involved in the degradation of phyA.⁷¹ The phosphorylated form of phyA increased in coimmunoprecipitation with COP1, suggesting that phyA phosphorylation is important for its interaction with the COP1/SPA1 complex. Therefore, the phosphorylation of phyA accelerates its degradation, whereas its dephosphorylation slows the degradation. Likewise, PIFs including PIF1, PIF3, and PIF5 undergo light-induced phosphorylation depending on their interaction with photoactivated phytochromes, which accelerates the proteasome-mediated degradation of the negative regulators in the phytochrome signaling.^{63,72,73} These findings suggest that the levels of both photoreceptors and phytochrome-interacting proteins are regulated by 26S proteosomal degradation during the phytochrome-mediated light signaling in plants.

52.4.4 Phosphorylation and Dephosphorylation in Phytochrome Signaling

Phosphorylation and dephosphorylation of a protein often serve as a signal modulation mechanism in the regulation of cellular activities, and the involvement of protein phosphorylation has been known in almost all signaling pathways in plants.^{74,75} Phytochromes are known as phosphoproteins by phosphate

analysis on purified phytochrome preparations.⁷⁶ The sites of phytochrome phosphorylation have been investigated with purified phyA from oat seedlings, and three serines, Ser8, Ser18, and Ser599, have been identified as the phosphorylation sites.⁷⁷ Phosphorylation at Ser599 in the hinge region prevents the interaction of phyA with its signal transducers such as nucleoside diphosphate kinase 2.⁷⁸ These data suggest that the hinge region of phytochrome serves as a phosphorylatable signal-modulating site which regulates protein–protein interactions between phytochrome and its signal transducers. Ser8 and Ser18 in the NTE have been identified as autophosphorylation sites of oat phyA, and the autophosphorylation provides a molecular mechanism for signal attenuation in phytochrome-mediated light signaling by accelerating the degradation of phyA.^{65,70} Therefore, phosphorylation on phytochrome molecule is important for the regulation of phytochrome interaction with downstream signal transducers and for the regulation of protein stability, which might play an important role in fine-tuning phytochrome signaling. The observation that phytochromes are phosphoproteins also suggests the existence of protein kinase(s) that phosphorylate the phytochromes and protein phosphatase(s) that dephosphorylate them. However, despite extensive studies of phytochrome-interacting proteins, there is no report thus far of a protein kinase that can phosphorylate phytochromes. On the other hand, a few protein phosphatases have been reported as being able to interact with and dephosphorylate phytochromes, including flower-specific phytochrome-associated protein phosphatase (FyPP),⁷⁹ PAPP5,²⁹ and phytochrome-associated protein phosphatase type 2C (PAPP2C).⁸⁰ All these protein phosphatases act as positive regulators in the phytochrome signaling, suggesting that the phytochrome signaling is regulated by phosphorylation and dephosphorylation in which phytochrome is autophosphorylated and then dephosphorylated by FyPPs. Phytochrome autophosphorylation decreases its signaling flux by reducing the amounts of phytochrome proteins, while phytochrome dephosphorylation increases the signaling flux by enhancing phytochrome interaction with its signal transducers and increasing its protein stability.

52.4.5 Phytochromes as Serine/Threonine Protein Kinases

Plant phytochromes are known as autophosphorylating serine/threonine kinases.⁶⁴ It is possible that phytochromes exert their kinase activity to control the downstream signaling components as well as themselves. As mentioned earlier, the autophosphorylation by the intrinsic protein kinase activity of phytochromes provides a signal attenuation or desensitization mechanism for the phytochrome signaling. In addition, phytochromes can phosphorylate downstream signal transducers to regulate them for light signaling. These proteins include PKS1, Aux/IAA proteins, cryptochromes, and more.¹⁶ The Pfr form of phytochromes induces rapid *in vivo* phosphorylation of PIFs preceding degradation,^{63,72,73} suggesting the possible role of the phytochrome kinase activity in photomorphogenesis. We observed that phytochromes phosphorylated PIFs *in vitro* (Kim and Song, unpublished data). Also, phyA mediates rapid red light-induced phosphorylation of *Arabidopsis* FHY1 and FHL in a low-fluence response, probably regulating the protein stability of FHY1 and FHL.⁸¹ Therefore, the phytochrome-induced phosphorylation of proteins such as PIFs may represent a primary intermolecular signal transduction for tagging a target protein for proteosomal degradation. However, the molecular mechanisms about how the phosphorylation of these proteins by phytochromes affects the light signaling are still unknown, so further studies will be necessary to elucidate the signaling pathways related to the phytochrome kinase activity.

52.5 Descriptive Model for Phytochrome Function in Plant Light Signaling

Recent advances in the study of molecular mechanisms for phytochrome functioning provide a plausible model for the regulation of phytochrome-mediated light signaling (Figure 52.2). In the dark, phyA proteins are synthesized and accumulate as the Pr form in the cytosol, composed of autophosphorylated and dephosphorylated phytochromes due to the action of kinases and phosphatases. Upon illumination,

FIGURE 52.2 A model for the molecular mechanisms of phytochrome. Phy-Pr, the Pr form of phytochrome; Phy-Pfr, the Pfr form of phytochrome; Phy-Pfr-P, the phosphorylated Pfr form; AutoP, autophosphorylation; PPase, protein phosphatase; 26S, 26S proteasome. In the dark, phytochrome is synthesized and accumulates as the Pr forms in the cytosol (Phy-Pr). Light-responsive genes for photomorphogenesis are not expressed because the photomorphogenesis-promoting transcription factors such as HY5 and HYH are suppressed by PIFs and degraded by COP1. In the light, the Pr form is photoactivated to the Pfr form (Phy-Pfr), which translocates into the nucleus. The photoactivated phytochromes in the nucleus phosphorylate PIFs and thus PIFs' degradation are promoted, which release the suppression of the photomorphogenesis-promoting transcription factors. At the same time, COP1 is translocated from the nucleus to the cytoplasm. These events finally induce photomorphogenesis in plants. Upon photoactivation, phosphorylated phytochromes (Phy-Pfr-P) are also rapidly degraded for the efficient desensitization of the phyA signal, which is necessary for responses to subsequent changes in fluctuating light environments.

the Pr form is photoactivated to the Pfr form that translocates from cytosol to the nucleus. At this point, the phosphorylated Pfr form is rapidly degraded via the ubiquitin/26S proteasome protein degradation pathway. The balance between the autophosphorylated and dephosphorylated phyA proteins is probably shifted to the autophosphorylated phyA, because the phosphorylated phyA proteins are efficiently degraded by the ubiquitin/26S proteasome through the COP1/SPA1 complex. This rapid phyA degradation mechanism involving autophosphorylation could facilitate the efficient attenuation of the phyA signal. On the other hand, phytochrome protein phosphatases insure the stability of phyA protein for an enhanced light response in photomorphogenesis, resulting from a decline in the autophosphorylated phyA level. If phyA-signaling activity is not modulated by light, plants could globally respond to light by overshooting photomorphogenic signaling events and/or could become desensitized to subsequent changes in light quality or quantity. We suggest that the posttranslational regulation of phyA plays an efficient role in rapidly controlling the number of active phyA photoreceptors available to elicit signaling events, and improve the response of plants to fluctuating light environments.

In the dark, COP1 is a nuclear protein that mediates light control of gene expression through proteasome-mediated targeted degradation of multiple photomorphogenesis-promoting transcription factors including two basic leucine zipper (bZIP) transcription factors long hypocotyl 5 (HY5) and HY5 homolog (HYH).^{82,83} COP1 is also involved in the degradation of phytochromes. However, COP1 is known to be translocated from the nucleus to cytosol upon light illumination, which prevents the degradation of phytochromes and transcriptional factors for light-responsive genes. Once the photoactivated forms of phytochromes enter the nucleus, they could phosphorylate the substrate proteins such as PIFs that suppress the expression of light-responsive genes for photomorphogenesis and photosynthesis. Together with the translocation of COP1 from the nucleus to the cytoplasm, the removal of negative regulators for light signaling (i.e., PIFs) by photoactivated phytochromes turns on the transcription of light-responsive genes, which allows plants to grow and develop optimally in the light environment.

52.6 Conclusions

Understanding of the phytochrome-mediated light signaling has improved dramatically in recent years. Phytochrome migration to the nucleus followed by Pfr–PIF/PIL–DNA element interactions provides a shortcut between light signals and the target genes. The control of COP1 localization by phytochrome coupled to the role of COP1 in the proteolytic degradation of transcription factors for photomorphogenesis provides a second route to control the signaling. The regulation of phytochrome function by phosphorylation and dephosphorylation provides an early signaling mechanism to affect photomorphogenesis. A plausible model for the phytochrome function involves a network of the light signaling cascades with multiple points of convergence and divergence by controlling protein subcellular localization, transcription, protein stability, and protein phosphorylation. Although dramatic progress has been made during the past decade in understanding the molecular mechanisms of phytochrome signaling, largely owing to the use of molecular genetics in the model plant *Arabidopsis*, it is also clear that current information about the nature and extent of the phytochrome-mediated signaling network is still limited and fragmentary. Further research remains to be pursued to dissect the phytochrome signaling network with a better understanding of how the various nodes of the network interact to transmit the light signals.

53.1 Introduction

Following many centuries of observation of plant orientation toward light [1], we have only quite recently become aware that phototropism is regulated by blue-light (BL) sensing photoreceptor proteins that were accordingly coined as phototropins (phot) [2]. Many more physiological processes have been ascribed to the presence of BL photoreceptors in plants, including stomata opening, chloroplast movements, leaf expansion, solar tracking, and circadian rhythms regulation [1,3,4]. The long-sought plant photoreceptors for BL, which represents a ubiquitous, subtle, and dominating (*vide infra*) environmental factor for the living world, presently comprise cryptochromes (Cry) [5,6], phot, Zeitlupe (ZTL), LOV Kelch Protein 2 (LKP2), and Flavin-binding Kelch F-box1 (FKF1) proteins [4]. All these photoreceptors host riboflavin (RB, vitamin B2) derivatives as chromophores, bound within defined protein domains or subdomains: a photolyase (PL)-like domain in Cry binds flavin-adenine dinucleotide (FAD) into an all-helix subdomain; the light, oxygen, voltage (LOV) domain of phot and ZTL/LKP2/FKF1, forming a small α/β unit, binds flavin mononucleotide (FMN) [2]. The blue-light sensing using FAD (BLUF) domain, the third type of flavin (FL)-based photosensing unit, is solely found in Euglenoids and Bacteria

and binds FAD. Cry and the phot-related, so-called LOV proteins appear to be ubiquitous, being widespread in prokaryotes, fungi, and lower plants [7,8]. Cry are present also in animals [6,9,10], whereas LOV proteins are the sole FL-based BL sensors occurring also in Archaea (see also Section 53.2) [8].

It is clear that not only plants, but all organisms have to detect and to respond to environmental stimuli in order to adjust their metabolic activities. Light is a major factor for the adaptation process, be it in relation to photosynthetic activities or for the entrainment of the circadian clock. The BL spectral region deserves particular attention, since light from this wavelength range not only penetrates deepest into a water column [11], but it also excites with high efficiency ubiquitous photosensitizers, for example, endogenous metal-free porphyrins and flavins [12]. From their excited state, these molecules readily form triplets that, decaying to the singlet ground state, generate singlet oxygen ($^1\text{O}_\Delta$) and other reactive oxygen species (ROS) with high quantum yield [12]. The same RB derivatives found in BL sensors are potentially very powerful photosensitizers for $^1\text{O}_\Delta$ (ca. 50% efficiency in aqueous solution for RB and FMN) [13,14]. At the same time, flavins are extremely versatile, that is, they can accomplish one- or two-electron transfer reactions, can function as electrophiles and nucleophiles, and are frequently involved in enzyme catalysis with the formation of covalent intermediates of flavin and substrates [15,16]. Light excitation obviously results in charge redistribution and a changed redox potential, giving rise to a variety of possible photochemical reactions, but also of potential danger: the high redox potential of the flavin triplet (ca. 1.7 V) accounts for the oxidation of several electron rich biological substrates, such as aromatic amino acids and DNA bases, and is responsible for a great part of food degradation in illuminated environments [17]. Flavin photoreceptors must therefore have evolved mechanisms to minimize the yield of potentially dangerous reaction intermediates and to maximize the requirements for signaling and for “beneficial” reactions (Section 53.2).

After the analysis of the basic requirements for BL sensing in FL-based receptors (Section 53.2), we will follow the molecular journey of signal transduction from the chromophore-binding cavity down to interacting partners, based on structural, functional, molecular biology, and cellular data (Section 53.3). Prominent examples of biological responses driven by BL sensors are presented in Section 53.4. Finally, in Section 53.5, we will illustrate some novel trends in this research area, notably the applicability of BL sensors in cellular studies and the uncovering of novel proteins by screening environmental samples.

53.2 “Sine Qua Non” of Flavin BL Receptors: Sensing Light

The first requirement of a photosensory protein is the presence of an absorbing chromophore that undergoes physicochemical and structural changes upon light absorption. The protein moiety hosting it modulates these photochemical aspects and at the same time constitutes the microenvironment that immediately responds to the photoinduced changes of the chromophore, having the important duty to carry this information to partner domains and/or proteins: namely, to carry out the first and essential step in the signal transduction process.

53.2.1 Chromophores: RB, FMN, FAD

RB, that is, 7,8-dimethyl-10-(1-deoxy-d-ribitol-1-yl)isoalloxazine, is biosynthesized by plants, fungi, bacteria, and archaea, whereas it is essential for mammalian cells (vitamin B₂) and must be provided with diet [18–20]. RB kinase and FAD diphosphorylase convert RB to FMN (RB 5'-phosphate) and FAD, respectively, the two RB derivatives predominantly present in cells. FMN and FAD are cofactors of enzymes, mostly involved in biological redox systems. Mammalian cells contain approximately 50 different flavoproteins [21]. Cry bind FAD as an active chromophore (and co-adopts an antenna, see Section 53.2.2), LOV domains bind FMN, and BLUF proteins bind FAD. A scheme of the chromophores is depicted in [Figure 53.1](#) together with the absorption spectrum of fully oxidized RB. The spectrum shows basically three major π – π^* electronic transitions, encompassing the UVB to BL region ([Figure 53.1](#)), and minor n – π^* transitions [22,23].

FIGURE 53.1 (a) The three flavin chromophores of BL sensors. RB consists of a 7,8-dimethyl-isoalloxazine ring linked to D-ribose. FMN and FAD are the phosphorylated and adenosylated forms of RB, respectively. (b) Absorption spectrum of RB in water, scaled to show the absorption coefficients at the different wavelengths. This spectrum exemplifies a fully oxidized form of the chromophore and is basically the same for the three derivatives. I, II, and III indicate the three major electronic transitions in the visible, UVA, and UVB region, respectively, whose approximate transition dipoles are shown in (a). (From Schleicher, E. et al., *FEBS J.*, 276, 4290, 2009. With permission.)

In the spectral region of interest for this presentation, the maximum absorption coefficient is ca. $12,500 \text{ M}^{-1} \text{ cm}^{-1}$ at 450 nm [25,26]. In this form, RB and FMN are brightly fluorescent with a quantum yield of ca. 0.25–0.3 [25,27], and efficiently form triplets with a yield of ca. 0.6 [28–30]. A recent *ab initio* theoretical study on the flavin isoalloxazine ring suggests that, in solution, this high yield of intersystem crossing is related to spin-orbit vibronic coupling between the S_1 $^1(\pi-\pi^*)$ state (BL transition) and the triplet state T_2 $^3(\pi-\pi^*)$, and by the intersection of their potential energy hypersurfaces [23]. FAD in solution is a special case, such that the singlet excited state of the isoalloxazine ring is quenched by stacking interactions with the adenosine moiety [31], consequently rendering a much lower triplet and singlet oxygen yield (<0.1 [14]).

One electron reduction or triplet formation causes a shift to longer wavelengths (lower frequencies) for transition I, for example, around 600 nm for the FMN neutral radical of flavodoxin [32] and 660 nm for the FMN triplet in LOV domains [33,34]. Depending on the surrounding microenvironment, the semiquinone species can be stable on a timescale of several milliseconds or even longer [35], thus providing the possibility for a red-light-driven or secondary photochemistry. In fact, PL is normally purified with FAD in a stable semiquinone state [36]. The fully reduced (two-electron) form, with the loss of a double bond and conjugation, is non-fluorescent and absorbs very poorly in the visible region. Notwithstanding this fact, fully reduced FAD is the active chromophore for the BL-driven DNA repair carried out by PL [6,37]. One- or two-electron reduction can occur from the ground state or from the excited states (triplets or singlets), obviously with different redox potentials. The presence of dissociable protons on the ring (at N1 and N5) of fully reduced flavins accounts for the occurrence of anionic and neutral one-electron (flavin semiquinones) and two-electron (flavin hydroquinones) species, depending on the pH (see [32] and ref. therein). These are the basic facts about the chromophore that we need as a basis to understand how BL sensors become photoactivated.

53.2.2 Photosensing Units: Cry, LOV, and BLUF Domains

Of these three chromoprotein domains, Cry exhibit the most complex composition. They have basically the same structure of PL and are two-chromophore systems, where an antenna (e.g., 5,10-methenyl-tetrahydrofolate (MTHF), 8-hydroxy-8-dimethyl-5-deazariboflavin (8-HDF), FMN, or FAD) is bound to the N-terminal α/β subdomain, and a FAD molecule is bound to an all-helix subdomain. The main

difference between PL and Cry is the presence in the latter of C-terminal or N-terminal extensions, of still poorly defined structure, which are considered to be responsible for signal transduction to protein partners [37–39]. The PL-like, bilobate core encompasses ca. 480 aa while the C-terminal tail is of variable length and aa composition (50–250 aa), but is absent in the Cry-DASH (*Drosophila*, *Arabidopsis*, *Synechocystis*, and *Homo*) family, originally identified in *Arabidopsis thaliana* (also called Cry 3) and *Synechocystis* [40]. The structure of Cry and PL has been recently reviewed [37]. The key photochemical event in PL is the transfer of an electron from the fully reduced FADH^- , excited directly or by energy transfer from the antenna, to the DNA lesion [41]. Conversely, the active form of the FAD chromophore in Cry is most probably fully oxidized, and light excitation promotes electron transfer events from a conserved chain of aromatic amino acids (W324, W377, and W400 in *A. thaliana*, AtCry1; W342, W397, and W420 in *Drosophila melanogaster* DmCry1) to FAD, to form the neutral (FADH^\bullet) or anionic ($\text{FAD}^{\bullet-}$) semi-reduced radical [39,42], thus forming radical pairs (RP) appearing to be the characteristic trait of at least the majority of these BL receptors after photoactivation. Up to now, it appears that some Cry proteins form the anionic semiquinone $\text{FAD}^{\bullet-}$ [43], whereas other Cry proteins form the neutral FADH^\bullet , *via* secondary proton transfer from an aspartic acid residue [42,44]. These electron transfer reactions are reversible, thus building a photocycle whose yield is still under debate [45], but generally low (e.g., ca. 0.02 for Cry1 [46]). The general photoreaction scheme of Cry, as presently understood, is depicted in Scheme 53.1. We note, nevertheless, that the recently discovered CryB from *Rhodobacter sphaeroides* lacks the Trp triad, but undergoes also a light-induced reduction of its FAD chromophore [47]. Also, animal-type 4 Cry form fully reduced FADH_2 or FADH^- after photoexcitation [48].

Both LOV and BLUF domains are small photosensing modules of ca. 100 aa building up quite compact α/β structures. Their topology is depicted in Figure 53.2a. Following a recently proposed nomenclature (Figure 53.2), we assign the following secondary structure elements to the LOV core (from the N-terminal part): $\text{A}\beta\text{B}\beta\text{C}\alpha\text{D}\alpha\text{E}\alpha\text{F}\alpha\text{G}\beta\text{H}\beta\text{I}\beta$, and for the BLUF core: $\beta_1\alpha_1\beta_2\beta_3\alpha_2\beta_3$ [51–57].

The photochemistry of LOV domains, first elucidated for phot and afterward for a variety of bacterial and fungal proteins (reviewed in [39]), involves the formation of the so-called FMN-Cys photoadduct, significantly blueshifted with respect to the dark state and non-fluorescent (referred to as LOV_{390}), which is generated *via* the short-microsecond decay of the FMN triplet state. In LOV_{390} , a covalent bond is formed between the carbon atom at position 4a and the thiol group of a conserved cysteine localized in the $\text{D}\alpha\text{-E}\alpha$ loop. LOV_{390} reverts in the dark to the unphotolyzed state (LOV_{447}) on a timescale ranging from a few seconds to many hours at room temperature [39,60–62]. The quantum yield of LOV_{390} formation ranges from 0.3 to 0.6 after BL excitation, but drops dramatically for UVA excitation, for still poorly understood reasons [63,64]. Despite this well-established photocycle, the details both for LOV_{390} formation from the triplet state and for its reversion are still a matter of

SCHEME 53.1 A general scheme for Cry photocycle. (Modified from Langenbacher, T. et al., *J Am. Chem. Soc.*, 131, 14274, 2009.) BL excitation of FAD withdraws an electron from the distal tryptophan (Trp(I)) of the conserved triad, a fast process occurring on the picosecond to nanosecond timescale. A subsequent proton transfer, most probably from a nearby aspartic acid, occurs on the microsecond timescale with concomitant electron and proton transfer from Trp(I) to the distal tryptophan Trp(III) . The relatively stable RP thus formed decays back to the dark state during a multistep process, not yet entirely resolved, with full recovery of FAD to the oxidized state on the hundreds of seconds timescale [42]. This figure refers in particular to a plant Cry, but an RP as $[\text{W306}^\bullet \cdots \text{FADH}^\bullet]$ has been also observed for a *Xenopus laevis* Cry [44]. Insect Cry by-pass the formation of the neutral semiquinone FADH^\bullet and decay to the parent state directly from the anionic $\text{FAD}^{\bullet-}$ [43,49] (see also [50]).

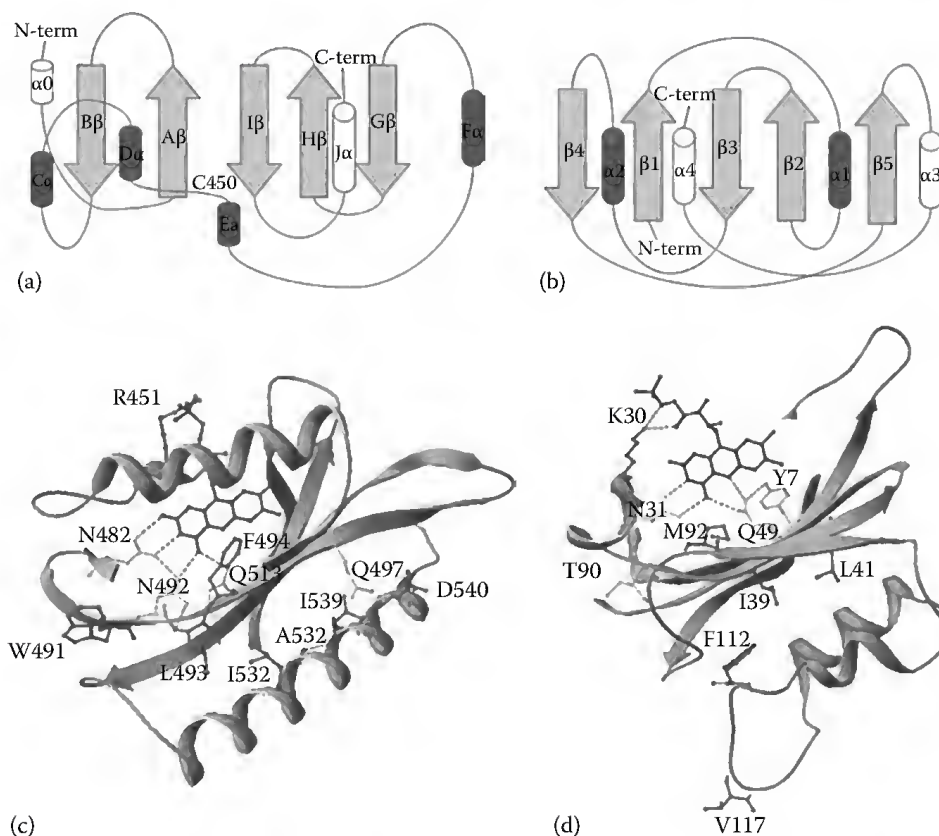

FIGURE 53.2 (See color insert.) Top: topology of (a) light oxygen voltage (LOV) and (b) blue light sensing using FAD (BLUF) domains. Secondary structure elements have been named after [57] and [58]. Arrows: strands, cylinders: helices. The caps at the N- or C-termini of the domain core are given without color. The caps may adopt different conformations/geometries in different proteins or/and in a different state (dark or lit). Relative size of loops, strands, and helices are not respected. In (a) the N-cap has been labeled α_0 . Bottom: structure of a (c) LOV (PDB 1V1A [59]) and of a (d) BLUF (PDB 3GFX [56]) domain, highlighting residues involved in signal propagation, in different LOV and BLUF proteins. Numbering is from *Asphot1-LOV2* and *KpBlrP1*, respectively (*As* = *Avena sativa*, *Kp* = *Klebsiella pneumoniae*), see [Tables 53.1](#) and [53.2](#) for details. We also show residues that are not known to be involved in signal transduction, but participate in the modification of the HB network around the flavin after photoexcitation (N482, N492, and R451 in (c); K30 and N31 in (d)). Some secondary structure elements, or part of them, have been cut to better show the chromophore cavity. Note that, from available data, signal transmission from the α/β light-sensing domain favors, in both cases, the β -sheet/helical cap mechanism (Section 53.3.1). (From Wu, Q. and Gardner, K.H., *Biochemistry*, 48, 2620, 2009. With permission.)

debate, as well as the molecular basis of the dramatically different photocycle kinetics in different proteins, even from the same organism [65,66].

BLUF domains respond to light excitation with a reversible redshift of the absorption spectrum [67,68], dictated by the rearrangement of the HB network involving N5 and O4, and by the flipping of a glutamine residue in the chromophore vicinity (Q49 in [Figure 53.2b](#), protein *KpBlrP1*, that is, *Klebsiella pneumoniae* BL-regulated phosphodiesterase [56] (for a comparative discussion see also [39]). This peculiar photocycle was first described for AppA, a BL receptor from *R. sphaeroides* [67], and afterward for a photoactivated adenylate cyclase (PAC) from *Euglena gracilis* [69] and several further bacterial proteins [51,70–72]. All the BLUF proteins up to now investigated show an AppA-like photocycle, with some differences in the dark state absorption maxima and in the magnitude of the redshift interval and the recovery lifetime, ranging from a few seconds to several minutes (for a comprehensive presentation of these parameters see [73]). Values between 0.24 and 0.9 have been reported for the photocycle

FIGURE 53.3 Steady-state absorption spectra and simplified reaction scheme of (a) LOV-protein-YtvA from *B. subtilis* and (b) BLUF protein-YcgF from *E. coli*. For clarity, the numbering of involved amino acids is the same as in Figure 53.2 (Asphot1-LOV2 and KpBlrP1, respectively).

quantum yield of BLUF proteins (rev. in [39]). Different to LOV domains, triplet formation is just a side reaction for the BLUF photocycle [74], but its yield can be increased by point mutagenesis: in the *Thermosynechococcus elongatus* TePixD protein, the change Q50N (Q50 corresponds to Q49 of KpBlrP1) results in a well detectable formation of a triplet state [75] and the I66C substitution, bringing an LOV-like cysteine in the vicinity of C4(a), permits the formation of an LOV₃₉₀-like photoadduct [76]. There is evidence that photoinduced electron transfer reactions occur in both LOV and BLUF domains prior to the formation of the photoactivated state, forming possible short-living radical intermediates [77,78]. For LOV domains, a time-resolved EPR study at low temperature proposed that after triplet formation an electron transfer step generates a RP in the form $^3[\text{FMN}^{\cdot-} \dots \text{SH}^{\cdot+}]$, whose recombination would give a zwitterionic complex and then the final LOV₃₉₀ observed at room temperature [79]. For BLUF domains, the signaling state formation seems to proceed *via* light-driven electron and proton transfer from the conserved tyrosine (Y7 in Figure 53.2) to FAD, followed by a hydrogen bond rearrangement and radical-pair recombination [78]. In Figure 53.3, the absorption spectra of an LOV and a BLUF protein are shown together with a simplified reaction scheme.

53.3 From BL to Signaling

The photosensing unit continues its work by passing the signal to partner domains (intraprotein pathways) or/and partner proteins. These steps are often the most difficult to be elucidated, given the general paucity of structural data. Furthermore, the soluble domains of BL sensors have the tendency to form dimers or oligomers, whose function and regulation by light is only partially understood. Light-regulated phosphorylation is also emerging as an important aspect during signal transduction. Finally, partner proteins, often shared with other signaling pathways, have the duty to integrate the BL inputs within the cellular signal transduction networks.

53.3.1 Conveying Signals: Intraprotein Pathways of Signal Transduction

53.3.1.1 LOV Proteins

In phot, the activity of the effector S/T-kinase domain is enhanced after LOV photoactivation with BL, resulting in phot autophosphorylation [80–83], a key event in signaling [84]. The same effect is observed for bacterial LOV-HisKinases [85–87]. In other LOV proteins, the effector module can be represented by diverse functional motifs, for example, gene expression regulators, phosphodiesterases, phosphatases [8,88,89]. This poses the question whether LOV domains communicate with effector partners through the same or partially overlapping surfaces, such that the structural basis for light-to-signal transduction is basically the same in the different LOV proteins, with only few residues acting as specific signal transmitters within the different systems. There is increasing experimental evidence that this surface largely involves the β -scaffold of the LOV core (Figure 53.1), which on one side hosts residues directly interacting with the isoalloxazine ring of FMN [90,91] and on the other side communicates with helical regions flanking the LOV core [59,92–94]. In phot, a conserved glutamine on strand I β (Gln513 in *Avena sativa* phot1-LOV2) participates in light-driven conformational changes of LOV2 [94–98], and of the LOV protein VIVID [92] and in the light activation of phot self-phosphorylation [99]. In *Bacillus subtilis* YtvA, two acidic aa localized on strand H β (E105 and D109) are essential for conveying light-triggered conformational changes to the Guanosine-5'-triphosphate (GTP)/Adenosine-5'-triphosphate (ATP)-binding site on the sulfate transporter and anti-sigma factor antagonist (STAS) domain, considered a secondary switch or/and the effector module of the protein [100]. The same two residues are also essential for the *in vivo* light regulation of YtvA activity [101] (see Table 53.1 for a list of residues involved in signal transmission in several LOV proteins).

Autophosphorylation of phot is enhanced by the light-induced unfolding of the so-called J α -linker helix that interacts in the dark with the β -scaffold of LOV2 and connects LOV2 to the kinase domain [58,102,103]. Phot2 also shows light-triggered conformational changes of the J α -linker, although not as

TABLE 53.1 Residues Affecting Signal Propagation in LOV Domains

dramatic as in phot1 [98]. An involvement of the J α -linker in interdomain communication has been demonstrated also in the bacterial protein YtvA [100], but this function is not connected to light-driven unfolding [93]. As a whole, the scenario for the early signal propagation steps in LOV proteins point to a general involvement of the β -sheet/helical cap mechanism, as recently proposed also for BLUF proteins [57], with the involvement of specific residues depending on the different proteins. Also, it is now clear that a conserved “flipping” glutamine, located on strand I β and directly interacting with the chromophore, is important both in signal propagation and in the photochemical reactions (e.g., duration of the photocycle, see Table 53.1 and Figure 53.2) [59,92,94,96,99].

Still we had, until recently, only few hints about the significance of two tandem LOV domains in phot, given that only LOV2 photoexcitation plays a major role in regulating phot1 kinase activation by BL [83,104–106]. This issue was elegantly addressed by the Christie group by means of a domain-swapping strategy, which highlighted the constitutive (not light-regulated) activity of a phot1-LOV1+LOV1 protein and the need of having an LOV2 adjacent to the J α -linker in order to inhibit the kinase [107]. Thus, although it is possible to exchange LOV domains and retain the photobiological function, even among different organisms [108,109], LOV1 is not able to replace LOV2 as inhibitor of the kinase, most probably due to a weaker binding of the β -sheet to the J α -linker [82]. In addition, an involvement of LOV1 in arresting chloroplast accumulation at high light intensities was suggested, thus promoting an efficient transition from accumulation to avoidance movement [107].

BL-triggered enhancement of autophosphorylation activity in LOV kinases is obviously an important observation [80–82,84–87], but this reaction still needs to be linked to the photobiological activity mediated by the receptor. In a bacterial LOV kinase from *Pseudomonas syringae*, the end phosphoacceptor is a fused response regulator, denoting a typical bacterial two-component system [87]. For phot, a substrate other than phot itself is till date not known, but several phosphoacceptor sites have been identified [81,83]. Atphot1 is phosphorylated *in vivo* on multiple serine residues, localized in the N-terminus (S58 and S185) and in the linker region comprised between LOV1 and LOV2 (S350 and S410), with phosphorylation at S185, S350, and S410 being BL-induced [83]. Phosphorylation at these sites is not determinant for phototropism and leaf expansion, but may be necessary for maximizing stomatal performance, light-induced relocalization of phot1, and interactions with protein partners (see also Section 53.3.3) [83,107,110].

53.3.1.2 BLUF Proteins

A recent work dealing with the BLUF domain of KpBlrP1 (see Figure 53.2) has summarized our current understanding about signal propagation within BLUF proteins [57]. Earlier work with the *Escherichia coli* YcgF protein, built of a BLUF domain and a C-terminal EAL domain (a putative phosphodiesterase for cyclic diguanylate, c-di-GMP [111]) and with SyPixD (a short-BLUF protein) suggested that the helical region comprising α_3 and α_4 (Figure 53.2), C-terminal to the BLUF core, is important in signal propagation [112–114]. Although a phosphodiesterase activity of YcgF-EAL has been ruled out [115] (Section 53.3.3), the importance of the α_3 – α_4 region for protein stability and conformational changes has been confirmed [116]. Similarly, the C-helical cap is necessary for the stability of KpBlrP1-BLUF, and the $\alpha_3\alpha_4$ loop undergoes significant light-induced conformational changes, as detected by NMR experiments [57]. Other regions involved in signal propagation comprise the $\beta_4\beta_5$ loop and strand β_5 (see also Table 53.2). These elements host T90 and M92 (in KpBlrP1-BLUF, see Figure 53.2) residues, which are the subject of intense debate regarding their roles in signal activation process for BLUF proteins.

In AppA-BLUF, the W104A mutation (W104 correspond to T90 in KpBlrP1) impairs light-induced structural changes in the β -sheet, without appreciable effects on the photocycle [117]. In functional essays with full-length AppA, the W104A mutation locks the protein in a functionally lit-like state [118]. Recent spectroscopic studies led to the suggestion that light absorption by the flavin causes partial movement/uncovering of W104. However, dramatic changes were ruled out that would support a model of W104 movement as a key output signal [119] (the so-called Trp-in to Trp-out previously proposed on

TABLE 53.2 Residues Affecting Signal Propagation in BLUF Domains

	Light-Driven Changes/Effects of Mutations	Location
RsAppa	Q63L Suppressed photocycle; light insensitivity <i>in vivo</i> [118]	β_3

the basis of alternative dark and light structures [53,120] state) [54,55,117,121,122]. In other words, the initial position of Trp104 in the dark state has no significant influence on the ability of the BLUF domain to undergo a photocycle, but has only an effect on the kinetics of the photocycle [119]. Instead, T90 and M92 appear essential for WT-like conformational changes, FAD binding and photocycling in KpBlrP1-BLUF [57]. As a whole, the extensive work on KpBlrP1-BLUF [57] raises the possibility that, after BL illumination, the C-terminal helical cap undergoes some kind of reorientation process, and that might be associated with the conformational changes of $\beta_4\beta_5$ and $\alpha_3\alpha_4$ loops, and strand β_5 [57].

53.3.1.3 Cry Proteins

A peculiarity of Cry signaling is related to the C-terminal tail (50–250 aa), present in all Cry proteins with the exception of Cry-DASH, and demonstrated to be important for signal transduction/regulation in several cases [38,123]. Transgenic plants overexpressing the C-terminal extension of either AtCry1 or AtCry2 exhibit a constitutive photomorphogenic phenotype in the dark, suggesting a main role of this protein region in mediating Cry interactions with COP1, the main interacting partner of Cry [124]. In *A. thaliana*, an 80 aa long peptide, referred to as NC80, was necessary and sufficient to confer the physiological function of Cry2 [123]. In *D. melanogaster* DmCry, the removal of the C-terminal end renders the protein constitutively active, and it was concluded that this protein region promotes repression of signaling, a repression alleviated by light activation [125]. A detailed analysis of the C-terminal end in AtCry1 and *Homo sapiens* HsCry2 showed that both are intrinsically disordered in solution, although they share little sequence homology, and that they interact with the PL core in the dark [126]. This interaction induces a stable tertiary structure that undergoes a transition to a more disordered state upon light activation of the protein [126], a feature surprisingly reminiscent of the α -linker unfolding in phot.

Like phot and bacterial LOV kinase, both plant- and animal-type Cry bind ATP and display intrinsic autokinase activity, in sharp difference to PL [123,127–130]. The significance of ATP binding and self-phosphorylation is still a matter of debate, but a recent study has suggested that ATP binding induces significant conformational changes, increases the yield of the photocycle, and slows it down, thus configuring as a regulatory factor, even in the absence of a of further self-phosphorylation

activity [131]. Furthermore, ATP renders *AtCry1* more resistant to denaturation. ATP binding might modulate the structure and function of Cry *in vivo*, rather or besides supporting the observed self-phosphorylation activity [128–130,132]. This opens the possibility that ATP binding can regulate the biological effects of Cry, also in the absence of light. In this respect, we note that autokinase activity seems to be light regulated in plant Cry (*AtCry1* and *CrCry*) [127,128,130], but not in *HsCry1* [128,129].

A recently proposed model, based on data obtained for *AtCry2*, links phosphorylation to the C-terminal tail and Cry activation [123]. The PL domain and the C-terminal tail of an unphosphorylated Cry form a closed conformation in the dark to repress the NC80 (last portion of the C-terminal tail) motif from functioning. Upon BL absorption, the C-terminal tail is phosphorylated and electrostatically repelled from the negatively charged PL domain, resulting in an open conformation that derepresses the NC80 motif to trigger the physiological responses [123].

53.3.2 Dimers or More: When and Why?

53.3.2.1 LOV Proteins

Besides conveying signal transmission (Section 53.3.1), the β -scaffold is also involved in LOV–LOV dimerization, with or without the assistance or competition of the helical flanking regions [93,133,134]. In the fungal protein VIVID (a “short-LOV” protein), light activation induces dimerization through the helical N-cap, but dissociation or removal of the N-cap induces dimerization *via* a β -sheet– β -sheet contact [135]. In YtvA, the β -scaffold of the LOV core has been identified as a competitive interface for LOV–LOV dimerization and intraprotein domain interactions [93], and a recently crystal structure confirms the β -sheet-mediated contact within the YtvA–LOV dimer [133]. Dimerization of YtvA–LOV is also observed when both the N- and C-terminal flanking regions to the LOV core are present, and it is solely prevented in the full-length protein [93].

It is of course important to understand if and how LOV–LOV dimerization is relevant for the *in vivo* activity, and if and how dimerization (or oligomerization) is light regulated. Similarly, it has to be questioned whether the full-length LOV proteins are dimeric, in the dark or/and light-activated state. Phot-LOV domains show a tendency to dimerize, in general more prominent for LOV1 than for LOV2 [134,136–138]. By means of pulsed thermal grating, Terazima and coworkers detected a transient, light-induced dimerization in the phot1–LOV2-J α -linker, suggesting a light regulation of dimerization; however, the functional significance remains unknown [139]. Bimolecular fluorescence complementation analysis has shown that *Atphot1* undergoes light-dependent dimerization *in vivo*, coinciding with a mechanism of light-driven autophosphorylation *in trans* [107]. LOV1 is not necessary for this dimerization, occurring also in a phot1 carrying two LOV2 domains. The site(s) of receptor dimerization still need to be defined, and the relevance of the trans phosphorylation for phot signaling remains to be assessed [107].

Finally, we note that fungal white-collar 1 (WC-1; see Figure 53.4), a Zn-finger photoreceptor LOV protein, is active as a dimer, where dimerization is mediated by the non-photosensing PAS domain [140].

53.3.2.2 BLUF Proteins

AppA-BLUF has been suggested to form a dimer in the dark state [141], in good agreement with gel filtration analysis [142]. Light excitation induces the transient formation of a tetrameric state [141], driven by hydrophobic interactions [143]. By gel filtration chromatography, an increase in the apparent molecular weight (MW) to 37 kD in the light-activated state of AppA-BLUF is also indicative of a sharp conformational change, but it is not compatible with the formation of a tetramer [142]. From the dimers within the crystal units, we have a good hint about the dimer interface of AppA-BLUF in solution, conceivably built by the hydrophobic β -scaffold surface [53,120], as recently confirmed by spectroscopic studies on W104 located on strand β_5 [119,120]. The full protein appears instead to be monomeric in solution, as it

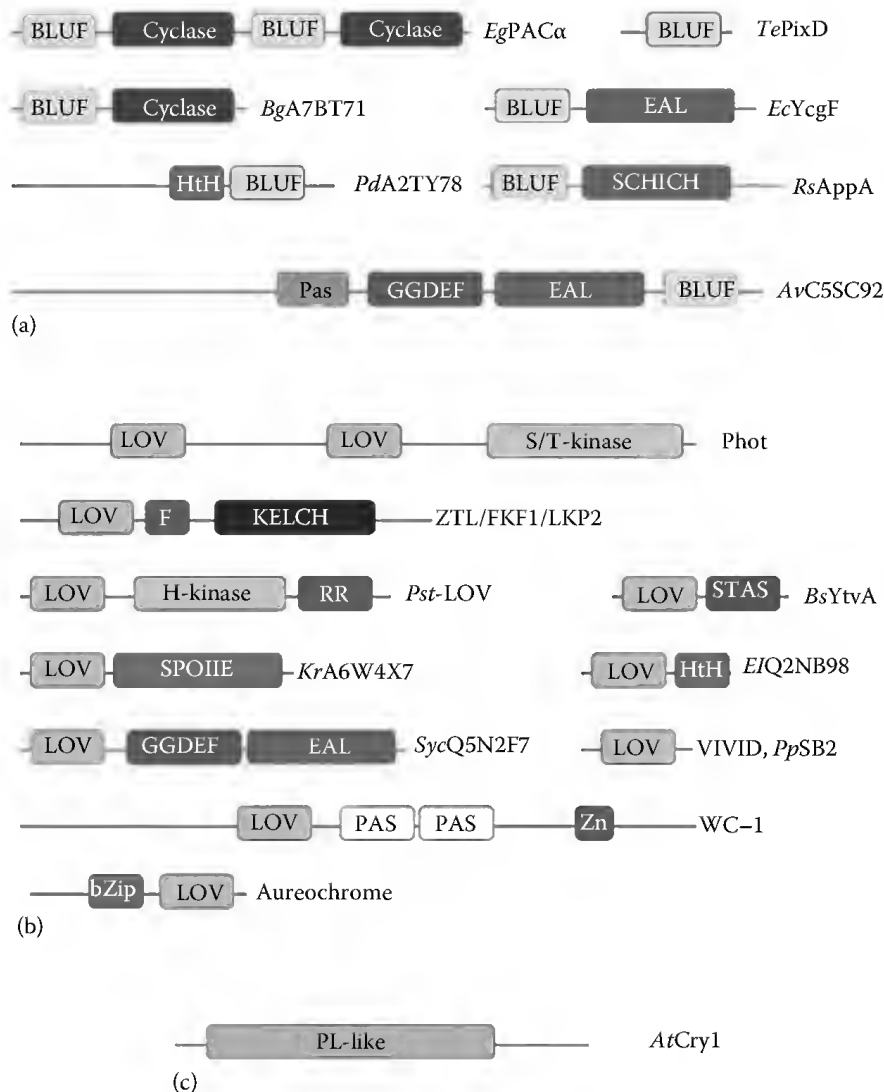

FIGURE 53.4 Domain architecture for a selected ensemble of BL sensors. Panel (a) BLUF proteins. The BLUF domain binds FAD as photoactive chromophore. *E. gracilis* (Eg) PAC is formed of two similar subunits (α and β) and has a counterpart in a bacterial cyclase from *Beggiatoa* sp. PS (*BgA7BT71*). The GGDEF and EAL domains of *AvC5SC92* (*Av*, *Allochrochromatium vinosum*) should act as cyclase and phosphodiesterase, respectively, for c-di-GMP, but note that the EAL domain of *EcYcgF* (*Ec*, *E. coli*) is not a phosphodiesterase (see Section 53.3.1). The “short-BLUF” protein *TePixD* from *T. elongatus*, without a linked output domain, is a prototype for the vast majority (ca. 80%) of bacterial BLUF proteins. *R. sphaeroides* (Rs) AppA binds additionally heme, as a redox sensor, in its SCHICH domain. Panel (b) LOV proteins. The LOV domain binds FMN as photoactive chromophore. Plant phot have a typical Ser/Thr kinase domain, C-terminally to the two LOV domains. The ZTL/FKF1/LKP2 family harbor an F-box and six Kelch repeats [159], suggesting that they act in light-regulated protein degradation [4]. WC-1 and VIVID are fungal proteins, the former bearing a DNA-binding Zn-finger region and two further PAS domains; VIVID is a prototype for “short-LOV” proteins, also well represented in bacteria, for example, the SB2 protein from *P. putida* (*Pp*) [8,65]. Other DNA-binding motifs are present in AUREO from stramenopile algae (bZIP, basic region/leucine zipper) [157,158] and in *ElQ2NB98* (HtH, helix-turn-helix domain; *El*, *E. littoralis*). Besides the GGDEF–EAL domains, introduced for Panel (a) (shown here is a protein from *Synechococcus* sp. PCC 6301, *Syc*), we find also His-kinases and phosphatases of the SPOIIE family. *Pst*, *P. syringae* pv. *Tomato*; *Kr*, *Kineococcus radiotolerans*, RR, response regulator domain. Panel (c). Cry proteins are formed by a PL core, binding FAD as photoredox active chromophore and an antenna molecule absorbing in the UVA–blue spectral region (a flavin or a pterin derivative). A C-terminal end, an extension of variable length and poorly defined structure, is crucial for signal transduction (see Sections 53.3.1 and 53.3.3).

is also evident from the higher degree of exposure of W104 (T90 in [Figure 53.2](#)) with respect to AppA-BLUF alone, showing, as in the case of YtvA, that the same surface is involved in dimerization and intra-protein interactions [119,120]. The blue light receptor B (BLRB) protein, a short-BLUF protein, is dimeric in crystals, adopting a similar conformation as AppA-BLUF dimers [51], referred to as AB dimers. The two cyanobacterial short-BLUF proteins *TePixD* and *SyPixD* form that forms a 10-subunit complex comprised of two stacked pentameric rings [52,54]. These structures show another way how BLUF domains can dimerize: they form β -sheet interfaced, [AB] dimers between subunits from separate rings, while they form the so-called [AC] dimers within the same ring, stabilized *via* the α_3 – α_4 helices [52,54]. From a recent analysis of the interactions of *SyPixD* with the response regulator *PixE*, it was demonstrated that the latter drives aggregation of *PixD* dimers, the stable form in solution, into a *SyPixD*₁₀–*PixE*₅ complex under dark conditions. Illumination of the bound flavin destabilizes the complex into monomers of *PixE* and dimers of *SyPixD* [144]. The light-driven destabilization is most probably triggered by the conformational changes occurring at strand β_5 and at the β_4 – β_5 loop, a region comprising the conserved W91 and M93 residues and comprising a significant portion of the [AB] type of dimer in the complex [144]. It is likely that light-induced disassembly of the *PixD*–*PixE* complex constitutes the “output signal” that regulates a signal transduction pathway that controls motility of *Synechocystis*. Indeed, it was recently shown that M93, but not W91, is essential for the biological response, that is, positive phototaxis, as well as for the light-driven destabilization of the *SyPixD*₁₀–*PixE*₅ complex [145].

Information is also available for the *KpBlrP1*-BLUF domain in solution, which appears to be a stable monomer [57], while full-length *KpBlrP1* is dimeric [56]. A crystal structure is now available for *KpBlrP1*, and biochemical investigation reveals that photon absorption by the BLUF domain of one subunit of the antiparallel homodimer activates *in trans* the phosphodiesterase activity of the EAL domain of the second subunit *via* allosteric communication, transmitted through conserved domain–domain interfaces [56]. Interestingly, in the full-length protein, dimerization does not occur *via* BLUF–BLUF interactions, but rather *via* BLUF–EAL interactions *in trans* and mostly mediated by α_4 , which is in turn clamped on the BLUF domain β -sheet [56].

Summarizing the data discussed in Sections 53.3.1 and 53.3.2 for LOV and BLUF domains, we can state in both cases (a) the β -sheet undergoes light-driven conformational changes, directly conveyed by interactions with the flavin chromophores; (b) the β -sheet can mediate dimerization, but is also able to interact, more or less tightly, with helical regions flanking the photosensing LOV or BLUF core and, most probably, directly interacting with an effector domain [93,100]; (c) the sequences flanking the photosensing LOV or BLUF core can in turn mediate an alternative dimerization and interactions with effector domains, thus mediating light-driven activation of the latter. Unfolding of the J α -linker in phot might represent a limited case of a general β -sheet/helical cap mechanism [57].

53.3.2.3 Cry Proteins

AtCry1 has been reported to form homodimers in solution, mediated by the PHR core, and that dimerization is required for *AtCry1* activity *in vivo* [5,146]. The same holds for *AtCry2* [123]. A dimeric crystal structure also characterizes *AtCry3*, which is instead monomeric in solution [147]. This agrees with the fact that the interface is mostly polar and prone to dissociation in aqueous solution. It is thus likely that the crystallographically observed dimer of *Atcry3* is not representing an oligomer that is relevant *in vivo*.

53.3.3 Delivering Signals: Partners of BL Receptors during Signal Transduction

53.3.3.1 LOV Proteins

Up to now, much effort has been focused on elucidating the primary mechanisms underlying LOV proteins activation by light, but the downstream signaling processes remain largely elusive. Yet several targets have been identified, and in the following section some examples will be presented.

Several phot-interacting proteins have been identified. Phot1 from *Vicia faba* and *A. thaliana* has been shown to bind to 14-3-3, a family of conserved regulatory molecules expressed in all eukaryotic cells [84,110,148,149]. The binding to a defined 14-3-3 seems to be specific for phot1 and not phot2 [110]. The most prominent paradigms involving 14-3-3 proteins in plant regulatory events include regulation of plasma membrane H⁺-ATPase activity, nitrate reductase, and sucrose phosphate synthase [150]. One of the targets for 14-3-3 family members is NONPHOTOTROPIC HYPOCOTYL-3 (NPH3), a phot1-interacting protein essential for phototropism [151]. Other phot1-interacting proteins include ROOT PHOTOTROPISM-2 (RPT2) that is closely related to NPH3 and mediates both phototropism and stomatal opening [152], and to phytochrome kinase substrate 1 (PKS1) that influences phototropic curvature [153]. Furthermore, PKS1 interacts with phot1 and NPH3 *in vivo* at the plasma membrane and *in vitro*, indicating that the PKS proteins may function directly with phot1 and NPH3 to mediate phototropism. We note that PKS proteins may provide a molecular link between these BL and red-light photoreceptor families and explain why phytochrome influences phototropism [153]. However, none of these three proteins is required for all the phot responses that were tested, for example, NPH3 is required for phototropism, but is dispensable for chloroplast positioning and stomatal opening (reviewed in [4]). A second example illustrating rapid branching in phot1 signaling is given by the rapid increase of cytosolic Ca₂ upon BL irradiation, required for phot1-dependent inhibition of hypocotyl elongation, but not for phototropism [154]. Growth responses such as phototropism require auxin and brassinosteroids but these two factors have been shown to be not involved in the control of chloroplast movements. Also, gene expression changes are essential for phototropism and are most probably induced following the asymmetric distribution of auxin that is required for directional growth [155].

Besides the indirect control of gene expression carried out *via* complex pathways by phot [4], some LOV proteins are equipped with effector modules predicted to directly interact with target genes [8,156], and at least for one class of them, the AUREOCHROMES (AUREO) from photosynthetic stramenopiles algae, such interaction has been demonstrated [157,158]. AUREO are built of an N-terminal, DNA-binding basic leucine zipper (bZIP) motif and a C-terminal LOV domain (Figure 53.4). BL treatment of AUREO1 from *Vaucheria frigida* triggers an LOV-type photocycle (Figure 53.3) and enhances binding of AUREO1 to its target DNA sequence, implying that AUREO1 functions as a BL-regulated transcriptional factor [157].

In the ZTL/LKP2/FKF1 family, the LOV domain is linked to an F-box and six Kelch (beta-propeller structures) repeats [159], suggesting that they may act in BL-regulated protein degradation, but interactions with components of ubiquitin-mediated protein turnover are not dependent on the LOV domain [4,160–162]. The main partner of ZTL and LKP2 is GIGANTEA (GI) that interacts directly with the LOV domain in a light-dependent way, ultimately leading to regulation of *CONSTANS* (*CO*) gene expression, which is necessary for day-length discrimination and photoperiodic flowering [163,164]. FKF1 binds to GI upon BL perception, forming then a complex with CDF1, a *CO* repressor. GI, FKF1, and CDF1 proteins associate with *CO* chromatin. The FKF1–GI complex forms on the *CO* promoter in late afternoon to regulate *CO* expression, providing a mechanistic view of how the coincidence of light with circadian timing regulates photoperiodic flowering [163]. The level of ZTL protein in plant cells oscillates in time, and GI is essential to establish and sustain oscillations of ZTL by a direct protein–protein interaction that stabilizes ZTL. This interaction is enhanced by BL. Because the regulation of GI transcription is clock-controlled, consequent GI protein cycling confers a post-translational rhythm on ZTL protein [164].

For bacterial LOV proteins, we only have (limited) information. Yet, the best characterized protein function was found for *B. subtilis* YtvA [30]. The fused STAS domain shows light-modulated GTP binding *in vitro* [100,165]. During the environmental stress pathway, YtvA upregulates the alternative transcription factor σ^B through a cascade of Rsb proteins, organized in stressosomes, in a BL-regulated way [166–168]. This ability strictly depends on signal propagation from the LOV domain to the GTP-binding cavity on the STAS domain [100,101], demonstrating that nucleotide binding is physiologically relevant (see Figure 53.5 for details).

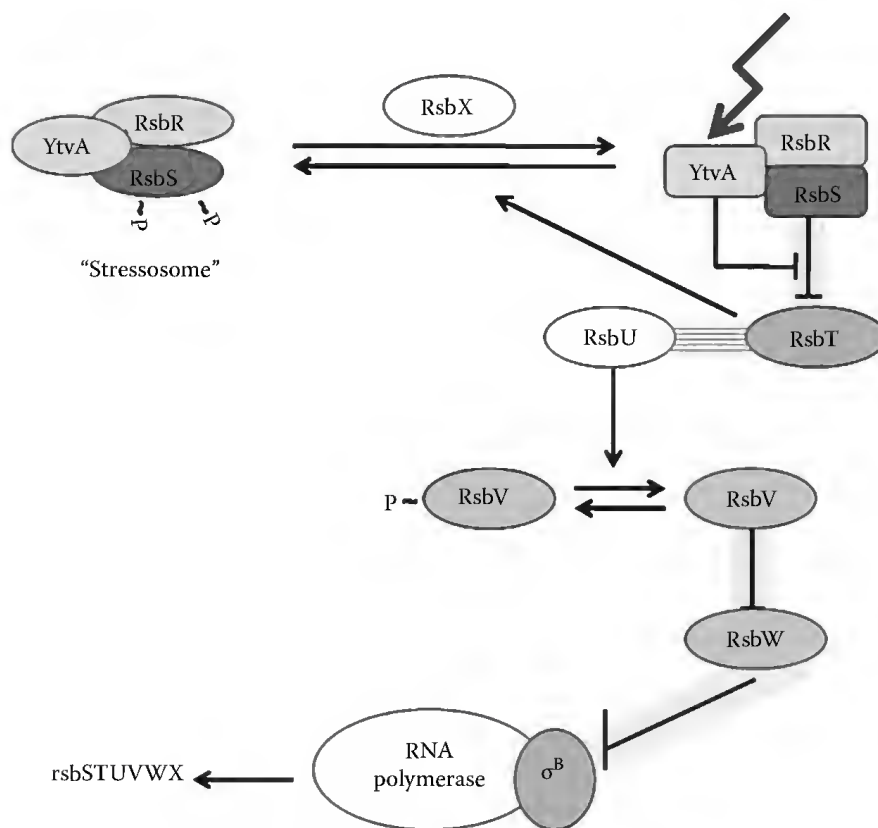

FIGURE 53.5 An example of a BL-regulated reaction pathway in a prokaryotic cell. *BsYtvA* (*Bs*, *B. subtilis*), located in the stressosome, integrates a light signal in the environmental stress response centered on the alternative transcription factor σ^B and the kinase RsbT. Upon light stress, YtvA stimulates RsbT to phosphorylate RsbS. This releases RsbT that in turn stimulates the phosphatase RsbU to dephosphorylate RsbV. RsbV can now sequester RsbW, thus setting free σ^B . As a result, the RNA polymerase- σ^B complex transcribes the σ^B regulon *rsbSTUVWX*. The phosphatase RsbX is used to reset the system to a "prestress" status. YtvA bears a photoactivable LOV domain linked to a STAS domain. (Modified from van der Horst, M.A. et al., *Trends Microbiol.*, 15, 554, 2007; Losi, A. et al., *Biophys. J.*, 82, 2627, 2002. With permission.)

53.3.3.2 BLUF Proteins

The *E. coli* YcgF protein (Figure 53.4) carries an EAL domain, until recently being postulated to catalyze c-di-GMP hydrolysis in a light-regulated way [70,114,116]. Actually, it could be shown that YcgF does not hydrolyze or bind c-di-GMP, but rather acts by protein-protein interaction [115]. YcgF directly binds to the repressor YcgE, releasing it from its operator DNA upon BL irradiation. As a consequence, a distinct regulon of eight small proteins involved in biofilm formation is induced. Furthermore, BL and other stress signals are integrated at the level of the YcgF-YcgE system that is strongly induced at low temperature and starvation conditions, and may thus modulate biofilm formation when *E. coli* has to survive in an extrahost aquatic environment [115]. This work not only elucidated the molecular pathway leading to a BL response in *E. coli* via a BLUF protein, but also showed that in a protein possessing a degenerate EAL domain [111], BL can activate a function other than an enzymatic one. We should not forget that in the protein *KpBlrP1* from *K. pneumonia* (ortholog to *E. coli* YcgF, i.e., identically built with a BLUF+EAL architecture), the EAL domain shows a light-activated phosphodiesterase activity [56].

The way how YcgF works is reminiscent of AppA (Figure 53.4), one of the other few complex bacterial BLUF proteins (the majority of which (ca. 87%) are "short-BLUF" without a fused effector domain) [8,68]. Present in the facultative photosynthetic bacterium *R. sphaeroides*, AppA binds, at low oxygen tension,

constitutively the repressor protein PpsR, whereas under fully aerobic conditions PpsR is released from AppA and binds to the promoter of certain photosynthesis genes, repressing their transcription. These responses are light independent, but at intermediate oxygen concentration (~50% oxygen saturation) light determines whether AppA releases the repressor PpsR [170,171]. Thus, AppA integrates and transmits both redox and light signals, the former thanks to the heme-binding sensor containing heme instead of cobalamin (SCHICH) domain [172] and probably to a C-terminal cysteine-rich sequence. The function of the AppA/PpsR system is fully coordinated by the PrrB/PrrA system (based on bacteriochlorophyll absorbers) that, at low oxygen concentration, activates photosynthesis gene expression [171,173]. The work of these systems in *R. sphaeroides* is obviously aimed to the maximization of photosynthesis efficiency in conditions when oxidative heterotrophy is impaired, and to minimize waste of energy for the building of photosynthesis complexes and also to reduce photooxidative damages.

53.3.3.3 Cry Proteins

The signaling mechanism of Cry in *A. thaliana* is mediated through negative regulation of the constitutive photomorphogenic-1 (COP1) protein by direct CRY–COP1 interaction through the Cry C-terminal tail, with dimerization being an important factor of Cry functioning (Section 53.3.2) [5,174]. The COP1 protein is conserved in both higher plants and vertebrates. In plants, COP1 acts as an E3 ubiquitin ligase to repress light signaling by targeting photoreceptors and downstream transcription factors for ubiquitylation and degradation. In the dark, COP1 specifically targets the transcription factor HY5 for degradation through a 26S proteasome-dependent pathway. Upon BL activation, Cry proteins repress COP1 activity through a direct protein–protein contact, and this direct regulation is primarily responsible for the Cry-mediated BL regulation of seedling photomorphogenic development and genome expression profile [175,176]. Another transcription factor, HFR1, is required for both phytochrome A-mediated far-red and Cry1-mediated BL signaling. HFR1 is a short-lived protein in darkness and is also degraded through a 26S proteasome-dependent pathway, for which COP1 is required [177]. Light, blue or red, enhances HFR1 protein accumulation by promoting its stabilization. Light enhances HFR1 protein accumulation by abrogating COP1-mediated degradation of HFR1, which is necessary and sufficient for promoting light signaling [177]. For further information and other components of the signaling cascade, refer to recent reviews [3,178–180] (for Cry proteins that are able to repair and bind to DNA, see Section 53.4.1).

53.4 Physiological Photoresponses Mediated by Cry, LOV, and BLUF Proteins

Phototropism, photomorphogenesis, and circadian rhythms entrainment in plants have important counterparts in BL-regulated growth patterns and BL/redox regulation of photosynthesis or of infectivity in bacteria, and even in BL killing of pathogens.

53.4.1 Cry: From Photomorphogenesis to Single-Strand DNA Repair

Cry proteins regulate a variety of growth and adaptive processes in organisms from bacteria to humans [6,48,181]. In *A. thaliana*, AtCry1 and AtCry2 are nuclear proteins that mediate light control of stem elongation, leaf expansion, photoperiodic flowering, and the circadian clock by interacting with proteins such as phytochromes, COP1, and clock proteins, or/and chromatin and DNA [5]. Recently, it was shown that although phot and Cry mediate largely distinct responses, there exist some interactions among their regulated pathways [182]. For example, Cry exert a positive effect on phototropic curvature under long-term irradiation conditions, and phot exert a small promotive effect on such Cry-mediated responses as hypocotyl elongation and anthocyanin accumulation. Also, Cry exert a negative regulatory effect on phot1 levels [182].

The so-called Cry-DASH subclade includes the majority of bacterial Cry but is spread throughout the living world [39,183]. The Cry-DASH protein sll1629 from *Synechocystis* has been proposed to function as a transcriptional repressor [40]; VcCry1 from *Vibrio cholerae*, another Cry-DASH protein, acts as a specific PL for the repair of single-strand DNA lesions [184]. The ortholog protein AtCry3 from *A. thaliana* has been extensively studied from the structural and biochemical point of view [45,147,185], but its precise role *in vivo* remains elusive: AtCry3 is able to repair both single- and double-stranded DNA, although the interaction with cyclobutane pyrimidine dimers is not as optimal as for PL [186], and its N-terminal sequence mediates import of Cry3 into chloroplasts and mitochondria [187].

Finally, CryB from *R. sphaeroides*, an unusual protein with low sequence similarity to other Cry/PL, might have some role in photorepair of DNA and downregulates the expression of photosynthesis genes in a light-dependent way [47]. Last, but not least, the PtCPF1 protein from the marine diatom *Phaeodactylum tricornutum* shows BL-driven DNA repair activity and can act as a transcriptional repressor of the circadian clock and seems to have a dominant role in BL-regulated gene expression in diatoms. The protein might therefore represent a missing link in the evolution of the Cry/PL family [188].

53.4.2 LOV Proteins: From Phototropism to Infectivity Regulation

In eukaryotes, the major LOV protein groups are formed by phot and the ZTL/FKF/LKP2 family in plants [3,4], by WC-1 [189–191], VIVID [192,193], and ENVOY [194] in fungi, and by the recently discovered AUREO in stramenopiles [157,158]. In the following, we will focus on plant, stramenopiles, and bacterial receptors.

Phot act as BL-driven regulators for processes that aim to the optimization of photosynthesis, growing of plants under dim light conditions and minimization of photodamage [2,4]. In *A. thaliana*, two phot (phot1 and phot2) act redundantly during many responses (phototropism, stomatal opening, leaf expansion, and chloroplast accumulation at low light intensity), but are specifically active for others, for example, phot1 inhibits hypocotyl growth during photomorphogenesis while phot2 is responsible for chloroplast avoidance movement at high light intensities (see [2,4] and references therein).

Phototropism, or curvature response to directional light, has been recently reviewed [195]. The phenomenon is very easily observed in coleoptiles of a dark grown plant seedling exposed to unidirectional light: the curvature toward light is actually due to an accumulation of auxins phytohormones in the shadowed area. This lateral movement of hormones is possible with the aid of transporter proteins. Besides auxins, phototropism requires brassinosteroids [4]. The formed auxin gradient initiates function for another class of proteins (e.g., the transcription activator complex NPH4/ARF7), by which differential growth is promoted (see [2,4,195] and references therein). Under low fluence rates, phot1 is the principal photoreceptor regulating phototropism, whereas under high fluence rates, phototropism is regulated redundantly by phot1 and phot2 [196]. Stomatal opening and leaf flattening/positioning are also phot1–phot2 coregulated responses, whereas chloroplast accumulation under dim BL and avoidance under high BL are distinctly mediated by phot1 and phot2, respectively [4].

In the green alga *Chlamydomonas reinhardtii*, however, only one phot is present. This BL photoreceptor regulates the algal sexual lifecycle, namely, it is essential for the light-dependent step in gamete differentiation [197]. Furthermore, it modulates the expression of several photosynthesis genes [198]. Broadly speaking, the two-LOV-domain phot proteins regulate movements, growth, development, and reproduction patterns.

Proteins belonging to the ZTL/FKF/LKP2 family act mainly *via* their interaction with GI (see Section 53.3.3). ZTL and FKF1 form a complex with GI upon light activation, leading to derepression of CO expression, a central element of day-length-regulated flowering. Both proteins influence flowering time by affecting circadian rhythm-controlled gene expression, i.e., they are BL sensors that posttranslationally regulate the circadian clock and photoperiodic flowering [162]. The precise role of LKP2 is still to be clarified, but it is certainly involved in the circadian regulation of the central clock [4,161].

The LOV-bearing AUREO from the stramenopile *V. frigida* not only binds to target DNA as predicted from its domain organization, but also regulates gene expression in a BL-dependent way; in other words, it is a (directly) BL-regulated transcription factor. The physiological response regulated by AUREO1 is a photomorphogenetic growth pattern, namely, BL-induced branching, elegantly demonstrated by means of interference RNA experiments [156,157]. AUREO2 may instead act as a subswitch to initiate development of a branch.

Despite the large spread of LOV proteins in the prokaryotic world, including Archaea [88,89,156,199,200], only for few of them a biological role has been established. YtvA from *B. subtilis* binds GTP and ATP within its C-terminal STAS domain. This nucleoside-5'-triphosphate (NTP)-binding capability is of special interest, since it has been shown that ATP and GTP are important signaling compounds during the sporulation process and nutritional stress responses of *B. subtilis* [201–203]. It has also been demonstrated that YtvA acts as a positive regulator for the general stress transcription factor σ B, specifically within the environmental branch, apparently in a BL-regulated way [101,166–168]. BL upregulation of the stress pathway is suppressed by mutations that affect NTP binding or light-induced conformational changes within the NTP-binding site, thus establishing a link between *in vitro* and *in vivo* data [100,101].

Recently, a link has been established between an LOV kinase and the photoregulation of bacterial pathogenesis of the Gram-negative pathogen *Brucella abortus*: the LOV kinase is required for BL-dependent cellular proliferation in macrophages [86]. A similar LOV kinase modulates the capacity for cell adhesion in a BL-dependent way [85]. Since the ability of bacterial pathogens to adhere to host cells is often a critical determinant of virulence, this observation might represent an important feature during infection. Bioinformatic analysis of over 600 bacterial genomes reveals that at least one LOV domain protein is present in 13% of species, including a number of pathogens. However, the relation between BL receptors and pathogenicity cannot yet be considered as a general one [8,204].

53.4.3 BLUF Proteins: From Phototaxis to Biofilms

There are still few examples where physiological functions could be unambiguously ascribed to BLUF proteins. Important information has been collected for the PAC proteins of *E. gracilis*. PAC- α and PAC- β are large proteins, comprising each ca. 1000 aa. Each protein (α and β) consists of two BLUF-cyclase motifs arranged in tandem. They function in a PAC- α /PAC- β heterodimeric complex as BL-regulated adenylate cyclases, responsible for step-up (but not step-down) photophobic responses as well as both positive and negative phototaxis [205,206]. PAC proteins are conserved among euglenoids [207], but to our knowledge, BLUF proteins are not present in other eukaryotic phyla.

Also in bacteria, functional information for BLUF proteins is still sparse, with the notable exception of AppA from *R. sphaeroides*, whose role and photocycle have been described [67], and of YcgF from *E. coli*. AppA is a light and redox regulator for the expression of photosynthesis genes, built of a light-sensing BLUF module [67,208] and a redox sensing C-terminal domain, shown to bind heme (see also Figure 53.4) [172,209]. This light-dependent regulatory function of AppA is accomplished only at intermediate oxygen concentration (see Section 53.3.3), when BL excitation induces the release of the transcription factor PpsR [171]. Interestingly, a BLUF domain from a Euglena PAC protein fused to the C-terminus of AppA is fully functional in regulating light-dependent gene expression in *R. sphaeroides* [210]. This finding implies that a BLUF domain can convey signals to completely different output domains, and that a eukaryotic light-sensing module can fully replace its homologue in a prokaryotic cell, although the sequence similarity between PAC-BLUF and AppA-BLUF is lower than 30%.

YcgF from *E. coli* (Figure 53.4) carries out BL regulation of biofilm formation [115]. The EAL domain in YcgF neither hydrolyzes c-di-GMP nor binds it, but is rather active in protein–protein interaction. The molecular pathway leading to light-induced upregulation of a biofilm matrix component (colanic acid) and acid resistance genes, and to the downregulation of adhesive curli fimbriae has been illustrated in Section 53.3.3. The Slr1694 short-BLUF protein from *Synechocystis* sp. PCC 6803 has been identified to be involved in phototaxis [211,212], but its action appears to be integrated with that of other photoreceptors and its precise function remains elusive [213].

53.4.4 BL, a Dangerous Beauty?

At first glance, it is surprising to find a large number of positive hits for BL photoreceptor genes from GenBank surveys. In fact, ca. 13% of fully sequenced bacteria possess at least one LOV or a BLUF protein [8]. Obviously, BL represents an important environmental factor that penetrates deepest into a water column, compared to all other spectral ranges [11]. It is also potentially harmful photochemical reactions which have to be efficiently counteracted, making the initiation of physiological responses upon the detection of BL essential for survival. This assumption also explains the variation in signaling domains for one and the same detector domain in several microorganisms (e.g., *Erythrobacter litoralis* exposes three histidine kinases fused to LOV domains and one helix-turn-helix (HTH)—motif), allowing a wider set of BL-regulated physiological responses [7,8,86,169]. Alternatively, microorganisms are found (well studied in *B. subtilis*) where several stress factors are integrated in a “stressosome” to initiate a more stereotypical response, for example, activation of the σ^B regulon (Figure 53.5) [166,167]. BL represents an attracting light range allowing activation of the photosynthetic apparatus, and also it is essential for the function of light-activated DNA-repairing enzymes (PL, *vide supra*). On the other hand, porphyrinic compounds that are ubiquitous, for example, as cofactors in cytochromes, exhibit a strong absorption (ϵ_{\max} ca. $10^5 \text{ M}^{-1} \text{ cm}^{-1}$) in the blue region of the visible spectrum [214]. These compounds usually function *via* an iron atom bound in the center of the tetrapyrrole ring structure. In case, however, the central metal ion is absent, the porphyrins exhibit a high tendency to form triplets from their excited singlet state [12,214]. Triplet state porphyrins, in turn, convert with high yield the ever present triplet oxygen into its singlet state [12], which is outstandingly reactive and readily causes deleterious damage in its direct surrounding, eventually even causing cell death by photooxidative stress [214]. This photosensitization effect is presently being exploited in the photodynamic therapy of cancer [214], and as a potential killing device for bacteria: for example, antibiotic resistant *Staphylococcus aureus* can be killed, *in vitro*, with 470 nm light [215]. Interestingly, one finds in several cases genes encoding BL photoreceptors in vicinity to genes of the iron metabolism (e.g., encoding Fe chelataes and iron scavengers). Such increase in biosynthesis of iron scavengers (pyoverdins), which is upregulated selectively by BL, has recently been demonstrated for *Pseudomonas putida* [216].

In an aerobic environment, the deleterious oxidative effects rely on the same BL bio-absorbers that optimize both respiration and photosynthesis, that is, porphyrins and flavins, but living organisms have learnt how to take advantage of O_2 and BL, at the same time minimizing photodamages. One of the organisms that has best exploited this interplay between O_2 and BL is *R. sphaeroides*, a member of the cosmopolitan α -proteobacteria family (see Section 53.3.3). *R. sphaeroides* can switch between photosynthesis and aerobic respiration *via* a complex regulation mechanism that includes the AppA protein [171]. At high pO_2 , photosynthesis genes are not expressed, no matter if BL is present: it would be useless, costly, and potentially dangerous. The contrary is true under anaerobic conditions. At low pO_2 , it is BL that promotes the transcription of photosynthesis genes by triggering AppA photocycle [217].

53.5 Novel “Blue” Trends

BL flavo-photosensors definitely present novel concepts and can be exploited and engineered for a variety of biological and biomedical applications, notably for cellular studies and for the light-controlled level of important metabolites. One of the most discussed topics is the role of Cry proteins in magnetoreception and its connection with their role as photosensors. Besides these two aspects, BL photoreceptors are being explored within the emerging field of metagenomics.

53.5.1 Cry as “Photomagnetoreceptors”

This issue has its roots in the “radical-pair” model for magnetoreception in birds, suggesting that magnetoreception is based on spin-chemical processes in specialized photopigments [44,218,219], representing an alternative to magnetite-based receptors. Cry proteins have been proposed as good candidates

for accomplishing this role (reviewed in [220]). Basically, this model implies the formation of RP upon light absorption [218]. These RP may be in the singlet (^1RP) or in the triplet state (^3RP), with the portion of each state, and its products depending, among other circumstances, on the alignment of the molecule in the external magnetic field. Birds must be able to compare the amount of singlets or triplets in various spatial alignments. One prediction of this model is that oscillating magnetic fields in the MHz range would interfere with the singlet–triplet interconversion and thus should disrupt magnetic compass orientation [218,221]. This was experimentally confirmed for a variety of cases, also showing that this photo-magnetoreception is taking place in the eyes of migratory birds [220]. Two types of responses can be distinguished in birds: (1) compass orientation controlled by the inclination compass, a response restricted to a narrow functional window around the total intensity of the local geomagnetic field that requires light from the short-wavelength part of the spectrum. The compass is based on RP processes in the right eye and is observed under “white” and low-level monochromatic light from ultraviolet (UV) to about 565 nm. This observation would imply that a RP with the flavin in the semi-reduced state (Scheme 53.1) can accept a second photon in the green spectral region and (2) “fixed direction” responses occur under artificial light conditions and in total darkness mediated by iron-based receptors located in the beak. The influence of light conditions on the two types of response suggests complex interactions between magnetoreceptors in the right eye, those in the upper beak and the visual system [220].

Quite surprisingly, evidence supporting the Cry hypothesis has been obtained from a report of magnetic field responses in *A. thaliana*. Enhanced Cry-mediated inhibition of hypocotyl elongation in a 500 μT magnetic field, relative to controls in the ambient magnetic field (approx. 40 μT), was observed under BL irradiation, but not under red light or in total darkness. Also, no magnetic field effects were found in Cry1/Cry2-deficient Arabidopsis mutants [222]. Also other Cry-mediated responses were enhanced at 500 μT , that is, BL-induced degradation of Cry2 and BL-dependent anthocyanin accumulation, consistent with a magnetic field-induced increase in the sensitivity of the seedlings to BL. This was interpreted as the formation of a photoinduced flavin–Trp RP [46]. However, these data could not be reproduced by another group that argued “that plant growth responses to the imposed magnetic field treatments are highly variable” [223]. These authors also state on the basis of their own unpublished results that the magnetic responses of various members of the PL/Cry family *in vitro* are strongly dependent on experimental conditions, including solvent viscosity, suggesting that the protein molecules must be both immobilized and aligned in order to show the anisotropic magnetic field effects essential for a compass detection mechanism [218,223].

53.5.2 BL Sensors as Tools for Cellular Studies: From Reporters to Engineered Regulators

The employment of flavins as chromophores in BL photoreceptors distinguishes these chromoproteins as promising tools for biotechnological applications. Whereas flavins are ubiquitous in practically all cell types (either endogenously generated or provided *via* dietary supplementation), chromophores for other photoreceptor types have to be added. In particular, the high fluorescence quantum yield of the LOV domain (in its dark state) makes applications possible such as those now common for the various green fluorescent protein (GFP) derivatives [224]. As fluorescence is lost upon the photochemical formation of the “signaling” photoadduct state, this process can be annihilated by exchanging the covalent bond-forming cysteine residue for an alanine or serine, yielding a permanently fluorescent molecule [225]. In fact, compared to GFPs, where the fluorescent chromophore forms *via* an intramolecular condensation of three amino acids, however, requiring the presence of oxygen, the LOV domains are advantageous for selected applications in anaerobic or microaerobic environments, where they outperform GFP since they exhibit an endogenous fluorescence [225,226].

Beyond the inherent properties of the LOV domains, their combination with various signaling domains, as found by genome surveys (Figure 53.4) [8,88], has led to the emergence of an entirely new field of biomedical applications. The possibility to regulate intracellular physiological processes simply

by an external irradiation is definitely an intriguing aspect and has experienced an explosion in applications. Initially, retinal (vitamin A aldehyde)-based photoreceptors have opened this research field [227–229]; however, the earlier discussed PAC from *E. gracilis* (carrying as functional elements a combination of a BLUF and an adenosine monophosphate (AMP) cyclase) has made possible “optogenetic” research [230,231]. This function is based on the light-regulated cAMP-mediated activation of certain neurons upon functional expression of PAC, yielding light-induced changes in behavior *via* the BLUF domain activation of the cyclase [230,231]. The fast increase in cAMP in turn regulates, *via* a phosphorylation cascade, gene expression in eukaryotic cells; accordingly, this research has been coined as “optogenetics.” Additional applications are expected to come including also the activation of other second messengers, for example, the specificity conversion of an AMP- into a GMP cyclase function by site-directed mutagenesis [232]. Recently, the first 3D structure for a GMP cyclase with an overall high similarity to the AMP cyclase has been published, making also this regulatory pathway a target for light-controlled activity [233].

One step further in this direction has been made by the combination of BL-sensing domains (LOV and BLUF) with enzymatic or regulatory functions from other proteins. The kinase domain of phot2 is constitutively active toward the heterologous substrate casein [234]. Adding *in vitro* the phot2-LOV2 domain enables a light control of this kinase activity, even in the absence of a covalent LOV2–kinase interaction [234]. Employing the building principle of many LOV domain proteins being fused to histidine kinases, the LOV domain of YtvA was fused to a histidine kinase from an oxygen-sensing pathway [109]. A direct light-regulated DNA binding was accomplished by a hybrid protein consisting of an LOV2 domain from *A. sativa* phot1 and the *E. coli* trp repressor [235]. These authors made use of the property of LOV2 to interrupt upon irradiation the interaction of the LOV core with its C-terminal extension (α -helix). Only in the light-activated, non-interacting state of the LOV domain, the trp repressor could form the active DNA-binding homodimer [235]. Extending this principle with transcription factors of different selectivity would open the path toward an irradiation-controlled gene expression. Recently, exciting results have been published, whereby Rho-like GTPases, Rac and Cdc42, caged with an LOV domain have been engineered: the proteins are activated upon irradiation, repeatedly and reversibly, in living cells to produce protrusions, filopodia, etc., and to probe signaling pathways [236].

53.5.3 From the Lab to Real World: The Wonder of Metagenomics in the BL World

The broad distribution of LOV domains in many prokaryotic genomes, documented by ongoing GenBank surveys [8], has initiated a novel activity to investigate even uncharacterized material for the presence of BL photoreceptors [237,238], assuming that the presence of BL photoreceptors would be similarly high as in genome-classified organisms. The rationale for such an approach is the expectation that searching exotic or extreme environments, proteins with novel and unusual properties might be found. Such studies are readily performed on a sequence-based setup: assuming a distribution of LOV domains in metagenome material similar as in sequenced genomes, a set of oligonucleotides, encoding representative LOV domain regions within a highly conserved, canonical sequence region, is covalently attached to a solid support material (a glass or plastic slide or an electronic chip). This DNA microarray serves as bait for hybridization with fluorescence-labeled, unknown DNA (potentially cloned into bacterial artificial chromosome (BAC), plasmids, or cosmids). It will give rise to a positive fluorescent signal at positions, where hybridization to an oligonucleotide with known sequence took place. Moving out from the known sequence motif into the unknown DNA then allows to “harvest” the full-length gene encoding a novel protein. The intermediate cloning step of uncharacterized DNA even allows, after identification of the full-length gene, a heterologous expression and a functional characterization of the gene product [200]. Such approach reveals only sequences with a relatively high degree of similarity to the oligonucleotides used as bait. A function-based investigation, however, would enable us to identify a protein function irrespective of

the sequence. In case of LOV domain proteins, the recovery of the fluorescent parent state (LOV₄₄₅) could readily be followed in a high-throughput heterologous expression approach.

Also entirely in-silico-based investigations have recently been reported for both BLUF and LOV domains [237,238]. These studies, again based on sequence comparisons, revealed the presence of BLUF and also LOV domains in practically any environment, deriving from many locations in various oceans (Sargasso and Global Ocean Sampling Project), or from wastewater treatment plants or mine drainage.

The last decade has seen an enormous growth in our understanding of the function of BL photoreceptors, both with respect to their inherent photochemical reactivity and also related to their role in regulating physiological functions. This knowledge is now starting to be extended by investigations on the role of (blue) light as an important and regulatory function in environmental research and microbial communities, including screening data bases and metagenomes. Based on these developments, one can expect in near future that novel research directions, for example, the regulation of physiological processes by BL domains in naturally occurring photoreceptors or as parts of hybrid proteins will become a rapidly growing research area.

List of Acronyms and Abbreviations

AUREO	AUREOCHROME, a LOV protein from Stramenopiles
BL	blue light
BLUF	blue light-sensing using FAD (protein domain)
c-di-GMP	bis-(3',5')-cyclic dimeric guanosine monophosphate, a second messenger
Cry	cryptochrome
FAD	flavin-adenine dinucleotide
FKF1	flavin-binding Kelch F-box1, a LOV protein from plants
FMN	flavin mononucleotide
GGDEF, EAL	protein domains named after conserved sequences, involved in the turnover of c-di-GMP
HB	hydrogen bond
LKP2	LOV Kelch protein 2, a LOV protein from plants
LOV	light oxygen voltage, FMN binding photosensing protein domain
NTP	nucleoside triphosphate (e.g., ATP, GTP)
PAC	photoactivated adenylate cyclase, a BLUF protein from Euglenoids
PAS	PerArntSim (protein domain)
phot	phototropin, a plant LOV-kinase
PL	photolyase, a BL-activated protein for DNA repair, related to Cry
RB	riboflavin
RP	radical pair
RR	response regulator, a protein domain involved in signal transduction
SPOIIE	Stage II sporulation protein E
STAS	Sulphate Transporter/Anti-Sigma factor antagonist (protein domain)
VIVID	fungal LOV protein
YtvA	a LOV protein from <i>Bacillus subtilis</i>
ZTL	Zeitlupe, a LOV protein from plants

54.1 Introduction

Bioluminescence, the emission of visible light by living organisms, has called the attention of humanity since ancient times. In a broad sense, bioluminescence includes all kinds of light emissions by living organisms, including biofluorescence, delayed luminescence, and ultraweak chemiluminescence. However, strictly speaking, bioluminescence is defined as an efficient enzyme-catalyzed chemiluminescence for biological purposes.

It occurs in a wide variety of organisms including bacteria, fungi, algae, coelenterates, mollusks, annelids, arthropods, and fishes (Harvey 1952), being used mainly for communication purposes. It results from the efficient conversion of potential energy of chemical bonds into photons of visible light, during exothermic oxidation of organic substrates generally called luciferins by oxygen or one of its derivatives, in reactions catalyzed by enzymes called luciferases (Scheme 54.1; Wilson and Hastings 1998). A special class of luciferases, in which the emitter is stably bound to the protein, are termed photoproteins because they apparently can emit light just once (Shimomura 2006). However, under specific conditions, photoproteins can also release the products, turning over like enzymes. Despite the fact that the chemical mechanism of bioluminescence is reasonably similar in most cases (Hastings 1983, 1995), the biochemical components of the bioluminescent systems in different organisms involve distinct and evolutionarily unrelated luciferases, luciferins, and cofactors (Table 54.1). Currently, the luciferases from bacteria, dinoflagellates, coelenterates, crustaceans, and beetles have been cloned, their primary sequences determined (Viviani 2007), and more recently their 3D structure was solved bringing new insights on the relationship between structure and function in this interesting class of enzymes.

SCHEME 54.1 Classical luciferin–luciferase bioluminescence reaction.

Many of these luciferases and the respective luciferins are currently used for bioanalytical purposes and their genes are used as efficient reporter tools in a wide range of biotechnological applications (Roda et al. 2009). In this chapter, my aim is to give a general overview of the field of bioluminescence, and it is not intended to make an in detail review of its several aspects; for such purpose several specialized reviews are recommended.

54.2 Biological Chemiluminescence: Light as a By-Product of Biochemical Reactions

Bioluminescence is the reverse process of photobiology. During photosynthesis, photons of visible light are absorbed by chlorophyll molecules, and their energy is ultimately stored as potential energy in the chemical bonds of reduced organic molecules. Eventually, this energy may leak again as photons of visible light during the breakdown of these bonds in reactions such as radical ion pair annihilation and peroxides cleavage, resulting in a variety of chemiluminescent processes. Although true bioluminescence is a rather rare phenomenon, all living cells, especially aerobic ones, produce an ultraweak chemiluminescence, which results from the generation of excited species during oxidative processes such as lipid peroxidation, generation of singlet oxygen, and organic molecules oxidations (Lee 1989). Generally, such excited species deactivate preferentially by other nonradiative mechanisms such as thermal inactivation and photobiochemistry (Figure 54.1). Thus, such processes produce a luminescence of the order of a few to thousand photons/s, which is not visible to most animal eyes, and therefore is not functional at least for communicative purposes. Although ultraweak chemiluminescence is considered a by-product of oxidative metabolic reactions, nevertheless it could be considered an interesting indicator of physiological state of living organisms. Attempts to use chemiluminescence to probe physiological condition is not new (Campbell 1988), but has been hampered by the lack of sufficient knowledge of the specific mechanisms underlying these reactions and by the lack of sensitive and convenient equipments for their measurement. More recently, however, with the development of very sensitive light detecting equipments for *in vivo* imaging, the use of chemiluminescence may become a reality.

54.3 Mechanisms of Bioluminescence

What differentiates bioluminescence from biological chemiluminescence is the efficiency and the intensity of such processes: in ultraweak chemiluminescence, the light efficiency is under 0.1 and the intensity is well below the detecting capacity of eye photoreceptors, whereas in bioluminescence the efficiency approaches the unity and intensity is of the order of 10^7 photons/s, being visible in dark environments. The basic requirements for an efficient bioluminescent reaction are as follows: (1) an exergonic reaction providing enough energy to yield a photon of visible light (38–71 kcal/mol for photons in the red–violet range of the spectrum); (2) a particular mechanism to channel the available chemical energy into visible photons, in the so-called chemiexcitation step; (3) an efficient radiative deactivation of the excited product. These requirements define the quantum yield of bioluminescence ($\theta_{\text{BL}} = \theta_{\text{C}}\theta_{\text{EX}}\theta_{\text{FL}}$), which is quite high for all bioluminescent reactions, ranging from 3% to 61%. The two first requirements are provided by the oxidation of organic compounds called luciferins and the intermediacy of peroxides, usually dioxetanones, whose cleavage yields electronic excited states with high efficiency (Wilson and Hastings 1998; Figure 54.2). The efficient emissive deactivation depends on the structure of the emitter, known as oxyluciferin, which is usually a fluorescent compound that provides preferential production of singlet excited species, which decay emitting fluorescence. Usually, the oxidation and cleavage of

TABLE 54.1 Biochemical Properties of the Main Bioluminescent Systems Investigated

Organism	Type	Function	MW (kDa)	Length (Residues)	Luciferin	Co-Substrate (Co-Factor)	λ_{\max} (nm)	Φ_{BL}

dioxetanones of aliphatic compounds produce high yield of triplet-excited species (Cilento and Adam 1988). Despite being potentially emissive in the absence of quenchers, the long lifetime of triplet-excited species provides a nonradiative route of deactivation through photochemical dark side reactions that compete with light emission. This is particularly important for triplet ketones, which are quenched by molecular oxygen. Nevertheless, triplet species are very important in biological systems for activating photobiochemical reactions in the absence of light. On the other hand, efficient production of excited singlet species can be achieved through the oxidation of cyclic peroxides with electron donating substituents. The mechanism of chemically initiated electron exchange luminescence (CIEEL; Figure 54.2b) was proposed to explain the efficient production of singlet species (Koo and Schuster 1978). According to this mechanism, the cleavage of the dioxetanone ring is activated by electron transfer from the electron donating substituent, followed by the cleavage and formation of radical ion pair. The back electron transfer from the radical anion intermediate results in the formation of the excited product, predominantly in the singlet state. Despite still considered an attractive mechanism, the involvement of CIEEL in bioluminescence has been subject of discussion (Tu and Mager 1995; Wilson and Hastings 1998). Luciferases may bring together all these three requirements: they are oxygenases providing favorable environments for the peroxides decomposition and excited state formation. Although the quantum

yields of bioluminescence are generally very high (0.05–0.61; Table 54.1), what turns a luciferase and its bioluminescence reaction so bright is the reaction rate. Light must be produced at a reasonable intensity to be detected by other organism. Therefore, luciferases function is to increase the rate of photon production to detectable levels through their catalytic activities.

54.3.1 Bioluminescence Colors

One of the most biologically relevant physical properties of bioluminescence is its spectrum or color. The bioluminescence color depends on the structure of the emitting molecule, oxyluciferin, its micro-environment affecting the energy gap between ground and excited states, and the presence of external factors such as the presence of filters and fluorescent acceptors that may modify the chromaticity of the primary emission.

Bioluminescence is thus classified in two groups according to the mechanism of emission (Figure 54.1): (1) the direct type, where the primary excited product formed during the luciferin–luciferase reaction is the actual emitter and (2) the type II or sensitized, where the excited product formed in the primary bioluminescence reaction transfers its energy via resonance to a fluorescent energy acceptor, which emits in another wavelength (Campbell 1988; Figure 54.1). The latter is well exemplified by green fluorescent protein (GFP) bioluminescence resonance energy transfer (BRET), which naturally occurs in jellyfish systems (Campbell 1988). In order for BRET to occur, the primary emitter and fluorescent acceptor in BRET must be in very close spatial proximity ($<15 \text{ \AA}$) and must display considerable emission and absorption spectral overlap.

The variety of luciferins and therefore oxyluciferin structures is followed by a wide range of colors spanning the entire visible spectrum. Coelenterazines usually emit in the violet–blue region, flavins emit in the green region and benzothiazolic luciferin usually emit in the yellow–green regions. But these spectra may also be considerably affected by the microenvironment in which the emitter is produced, through specific and nonspecific interactions with the excited molecule. Depending on the pH, the ionic forms of coelenteramide and firefly oxyluciferin can change their spectra. The most dramatic example of how the microenvironment can affect the bioluminescence color is provided by the active site of beetle luciferases that, although using the same biochemical reaction, can produce different colors ranging from green to red as well exemplified by railroad worms (Figure 54.3; Viviani 2002). The presence of filters narrowing down the spectral band is also found in several fishes (Haddock et al. 2010) and even insects (Viviani and Bechara 1997). Finally, fluorescent acceptors changing the color of light emission of a primary bioluminescent reaction is very well exemplified by fluorescent proteins, such as GFP in coelenterates and blue fluorescent protein (BFP) and yellow fluorescent protein (YFP) in some bioluminescent bacteria (Wilson and Hastings 1998).

54.4 Diversity, Biological Functions, and Ecology of Bioluminescence

54.4.1 Biodiversity

Bioluminescence is found among bacteria, fungi, and several animal phyla, being absent in plants and higher vertebrates.

54.4.1.1 Marine Organisms

Bioluminescence is predominantly found in the marine environment, being found in bacteria, algae, Porifera, Cnidaria, Ctenophora, Nematoda, Annelida, Mollusca, Arthropoda, Echinodermata, Urochordata, fishes, and even sharks (Haddock et al. 2010; Figure 54.4). In the depths of the ocean, about 70% of the species and 95% of individuals were found to be luminescent (Herring 1987). Luminous bacteria are found in the genera *Vibrio*, *Photobacterium*, *Photorabdus* (*Xenorhabdus*), and *Shewanella* (Watanabe 2005). They are found in the environment either as endosymbionts in the light organs of some organisms like fishes and mollusks or as free living organisms. Dinoflagellate bioluminescence occurs in species of *Lingulodinium* (formerly *Gonyaulax*), *Noctiluca*, and *Pyrocystis*. In coelenterates, bioluminescence is found among Ctenophora, Hydrozoa (jellyfishes), and Anthozoa.

FIGURE 54.4 (See color insert.) Some marine bioluminescent organisms: (a) *Vibrio fischeri* bioluminescent bacteria, (b) sea firefly *Vargula hilgendorfii* (ostracod), and (c) firefly squid *Watasenia scintillans*.

Mollusks show various examples of luminescent species, such as the bivalve *Pholas dactylus*, the firefly squid *Watasenia scintillans*. Annelids have luminescent representatives in Polychaeta such as the tubeworm *Chaetopterus variopedatus*. Among marine arthropods, ostracods and decapods are found. Echinoderms (brittle stars) are also common. Finally, fishes include many representatives, either in shallow waters or in the depths.

54.4.1.2 Terrestrial Organisms

In the terrestrial environment, bioluminescence is apparently less common than in the marine environment, occurring in bacteria, fungi, nematodes, annelids and arthropods (Figure 54.5). Among bacteria, *Xenorhabdus luminescens* has been found infecting nematodes and insects, and eventually human wounds (Hosseini and Nealson 1995). In fungi, luminescence is found in the order Basidiomycetes, with 42 luminescent species in the genera *Armillaria*, *Mycena*, *Plerotus*, *Omphalotus*, and *Panellus* among others (Desjardin et al. 2008). Bioluminescent fungi or “foxfire” (Figure 54.2) are found over decayed logs and leaves in humid tropical and temperate forests around the globe. The bioluminescence is usually green and is emitted by the mycelium, pileum, and gills.

The arthropods constitute the richest group, with bioluminescent species being found in the classes of diplopods (millipides) and insects. In insects, luminescent species are found in Collembola, Diptera, and mainly Coleoptera (Viviani 2002) with around 2000 described species around the world in the superfamily Elateroidea, which includes fireflies (Lampyridae), click beetles (Elateridae), and railroad worms (Phengodidae) (Figure 54.5). Luminescent insects are found predominantly in tropical forests and temperate zones. Some species such as fungus gnats (Diptera: Mycetophilidae) are found in caves and along river banks in temperate regions (Viviani et al. 2002). Freshwater species are extremely rare; the only known organism is the freshwater snail.

FIGURE 54.5 (See color insert.) Some bioluminescent beetles (a) *Cratomorphus concolor* firefly, (b) *Pyrophorus divergens* click beetle, and (c) *Phrixothrix* railroad worm.

54.4.2 Anatomy and Physiology

Bioluminescence can be produced by single-celled organisms such as bacteria and algae, secreted as in copepods and squids, or generated by complex light organs called photophores such as in several mollusks, fireflies, and fishes (Hastings 1983). Although the biochemical components are produced inside cells, bioluminescence can be intracellular or extracellular.

In single-celled organisms, bioluminescence can be produced in the cytoplasm or in specific organelles. Dinoflagellates have specific organelles called scintillons, which contain luciferin and luciferase, which react upon pH trigger. Fireflies have luciferase and luciferin inside peroxisomes (Gould et al. 1987).

Several organisms may secrete the bioluminescence components, which react outside of the body producing light. Bioluminescence in such cases can be produced as slimes and exudates, like in some annelids and diplopods (Shimomura 2006), or by ejection of luciferin and luciferase outside the body producing luminescent clouds like in some squids and ostracods (Haddock et al. 2010).

Light organs may assume variable degrees of complexity, from single cells to highly specialized photophores. In several cases, bioluminescence is neurally controlled, through the access of oxygen and the activation of photocytes. The simplest neural control is found in coelenterates. Some organisms like mollusks, fireflies, and fishes have more specialized light organs constituted by the photogenic tissue, reflector layers, lens, and developed neural control. Fireflies and other beetles exemplify such complexity at its utmost (Figure 54.6), with lanterns constituted by rosettes with thousands of photocytes, tracheolar end cells that control the access of oxygen upon neural control and an upper reflector layer (Ghiradella 1998).

54.4.3 Biological Functions

Bioluminescence is used mainly for communicative purposes, being divided in two main groups: interspecific and intraspecific functions. Among interspecific functions, bioluminescence may be used for defensive and for prey attraction purposes, whereas among intraspecific function, sexual attraction, group cohesion, and territoriality are the main functions.

54.4.3.1 Courtship

Among intraspecific functions, sexual attraction is especially common, being found in squids, polychaetes, ostracods, insects, brittle stars, and fishes like the lanternfish. Fireflies use an elaborate communication system where males and females emit species-specific signals during courtship. Formerly, two main communicative systems have been described (Lloyd 1978): In system I, females are stationary in the grass, broadcasting a specific signal that flying males recognize and answer. In system II, flying males broadcast a specific signal to which females in the grass answer. However, other communication systems are currently described (Branham and Wenzel, 2003; Lewis, 2010; De Cock 2010). Bioluminescence may also be used to advertise populational densities, to keep the integrity of groups, territoriality such as in fishes.

54.4.3.2 Defense

Among interspecific functions, defense against predators and attraction of preys are especially important. Usually sudden flashes may repel predator attacks by an effect of startling or frightening. Defense may assume different forms. In some fishes bioluminescence can be used for counter-illumination, turning the organism invisible against environmental background light (Haddock et al. 2010). Dinoflagellates may use their flashes as burglar alarm, advertising the presence of a predator to a higher rank predator. Some ostracods and squids secrete clouds of bioluminescent material, which may confuse a predator. Click beetles, as well as some bioluminescent beetle larvae, may display false eye-like spot lanterns upon touch, frightening potential predators. Luminescence can also be used as aposematic signals.

FIGURE 54.6 Firefly photophore: anatomical complexity at its utmost according to Ghiradella 1998. Oxygen access controlled by: (a) increased fluid length when lantern is off and (b) decreased fluid length when lantern is emitting. *Note:* P=photocytes; NE=nerve; T=trachea; t=tracheole; TF=tracheolar fluid; TEC=tracheal end cell. (From Ghiradella, H., The anatomy of light production: the fine structure of the firefly lantern, in *Microscopic Anatomy of Invertebrates*, eds. F. W. Harrison and M. Locke, Wiley-Liss, New York, 1998, pp. 363–381. With permission.)

Larval beetles such as glowworms and railroad worms may use their luminescence to advertise distastefulness to predators such as frogs and birds (Sivinsky 1981; DeCock 2004).

54.4.3.3 Prey Attraction

Continuous emissions may have the opposite effect of flashes, attracting the attention of other organisms. Several organisms such as siphonophores and the deep sea fishes such as the anglerfish use their lanterns as luminous traps to attract preys. Such behavior is also well known in the terrestrial mycetophilidae

larvae (fungus gnats) *Arachnocampa* spp. in New Zealand caves and *Orfelia fultoni* in the Appalachian stream banks in the United States, using their blue–green bioluminescence to attract flying insect preys in the caves and stream banks (Viviani et al. 2002). The larval click beetle *Pyrearinus termitilluminans* displays the wonderful phenomenon of luminous termite mounds in central Brazilian savannas, using its greenish-blue bioluminescence to attract flying insects (Bechara 1989).

54.4.3.4 Dispersion

The biological function of bioluminescence in bacteria and fungi is quite controversial because luminescence has no obvious intraspecific communication function. It has been suggested that their continuous luminescence plays an important role for the propagation and dispersal of species, by attracting positive phototropic organisms that feed on them, dispersing the species.

54.4.3.5 Illumination

Some organisms may also use their own light as a lantern to probe the environment during the search for preys. Such kind of behavior is found in the flashlight fish and dragonfishes and is apparently found in railroad worms, which use their head red bioluminescence to illuminate the environment during the search for preys (Sivinsky 1981; Viviani and Bechara 1997), in some fireflies and click beetle that use their abdominal lanterns during landing to illuminate the grass in front of them (Lall et al. 2009).

54.4.3.6 Physiological Functions

Another still poorly considered class of biological functions for bioluminescence is the physiological one. It is known that all bioluminescent systems require oxygen or one of its active species. It was originally suggested that bioluminescence systems evolved from such biochemical systems involved in removing or detoxifying oxygen (Seliger and McElroy 1965). Although unlikely in most cases, it is possible that at least in a few of them bioluminescence may aid in the removal and control the oxygen availability that may ultimately lead to reactive oxygen species (ROS) production, damaging the biological systems (Bechara 1989; Rees et al. 1998). This possibility has been proposed for bacteria, and also for bioluminescent click beetle larvae (Barros and Bechara 1998). Photobiochemistry mediated by bioluminescence is another possibility. In bacteria, bioluminescence was proposed to be used for the photoreactivation and repair of DNA damage caused by UV light, based on experiments in which UV damaged bacteria exposed to blue light, or bioluminescent bacteria, show higher rate of DNA repair (Czyz et al. 2003). Considering the photobiochemical reactions, it is even possible to wonder whether bioluminescence could play a role in photoactivating certain metabolic pathways. Of course, it is hard to conceive such a hypothesis when considering organisms exposed to exceedingly higher environmental light doses, however, it could be a real possibility for organisms living in the darkness or for opaque tissues.

54.4.4 Photoecology

Thus, bioluminescence is adapted and optimized for specific biological functions under specific photic environments. In the marine environment, blue bioluminescence is predominant, because at depths below 10 m, most sunlight wavelengths have been absorbed and only blue light passes (Haddock et al. 2010). Therefore, the photoreceptors of most organisms are adapted to blue light. On the other hand, in the terrestrial environment, the incident sunlight has wide spectral range whereas the predominant reflectance color is green reflected from the foliage and blue from the skylight, therefore most visual systems are adapted to green and eventually blue (Lall et al. 2009). Indeed, most visual photoreceptors in terrestrial organisms display bands in the blue and green regions. Not surprisingly, the most predominant bioluminescence color among terrestrial organisms is green. Bioluminescent beetles usually emit light in the green–yellow range of the spectrum, though orange is also found, although much less common (Lall et al. 2009). Only the dipterans *Arachnocampa* spp. and *Orfelia fultoni* are known to produce blue bioluminescence (Viviani 2002). Even rarer is red

light, which is produced only in *Phrixothrix* genus and a few other railroad worm species (Viviani and Bechara 1997). In such cases, light is produced by head lanterns, which are likely to be used to illuminate the environment during the searching for preys. Although the function is not clear, red light in the case of railroad worms could be an adaptation to the reflectance of the soil where they live most of the time buried. In the case of blue light, bioluminescence could be an adaptation to blue skylight, attracting lost flying insects in the darkness.

The intensity and chromaticity of environmental light are important to modulate the activity of bioluminescence species. Fireflies and bioluminescent beetles become active at very specific times, usually at the twilight and during the night, which are triggered by the background environmental light (Lall et al. 2009). Full moon has been shown to affect the activity of bioluminescent organisms such as fireflies and scaleworms. Therefore, artificial night-lighting near urban areas may have disruptive effect on the occurrence of bioluminescent species. The impact of artificial illumination on bioluminescent species is just starting to be investigated in fireflies (Lloyd 2006), but it is almost unstudied for marine environment, where most of the bioluminescent diversity is found. Bioluminescent organisms, upon their dependence on light production for survival, could be good bioindicators of the impact of artificial night-lighting on nocturnal environment.

54.5 Biochemical and Molecular Diversity

Bioluminescent systems can be classified in several biochemical classes depending on the chemical nature of the luciferin. Luciferins have a wide variety of structures: bacterial luciferin is a flavin nucleotide, coelenterazine and cypridina luciferin are imidazolpyrazines, dinoflagellate and shrimp luciferin are a linear tetrapyrrolo structurally similar to chlorophyll, some annelid luciferins are aldehydes, and firefly luciferin is a benzothiazole. Bioluminescence systems can also be classified in two basic subtypes depending on the protein responsible for light emission: classical luciferin–luciferase systems and photoprotein systems. Even within each of these two classes, the systems can be further split in different types according to the nature of the enzymatic reaction. In the case of most luciferin–luciferase systems, the luciferases are functionally classified as monooxygenases, which catalyze the insertion of an oxygen atom in the substrate and another in water or CO₂. In some cases, luciferases can be peroxidases (Viviani 2005), in which a transition metal within the protein, such as Fe²⁺ or Cu²⁺ or perhaps a heme group, catalyzes the abstraction of a labile proton from the substrate and use hydrogen peroxide as oxidizing agent, leading to the emissive step (Scheme 54.2). Peroxidase-like systems are found in bivalves and some annelids. Despite being isolated from a nonbioluminescent organism (horseradish), the widely used in immunoassays horseradish peroxidase (HRP) exemplifies well the chemiluminescence mechanism of a peroxidase.

In the following sections, the main bioluminescent systems studied, those of bacteria, dinoflagellates, coelenterates, and beetles will be introduced and an overview of the other bioluminescent systems under investigation will be given.

54.5.1 Bacteria

The bioluminescent system of bacteria is one of the most well studied (Tu and Mager 1995; Watanabe 2005; Tu 2007). The luciferase is a flavin mononucleotide (FMN)-monooxygenase that co-oxidizes FMNH₂ and a long-chain aldehyde (>C8) using molecular oxygen (Scheme 54.3; Figure 54.7) producing blue–green bioluminescence ($\lambda_{\text{max}} = 490\text{--}495\text{ nm}$; Tu 2007). The reaction comprises the oxidation

SCHEME 54.2 Peroxidase-catalyzed bioluminescence reaction.

SCHEME 54.3 Bacterial bioluminescence reaction.

FIGURE 54.7 Bacterial bioluminescent reaction according to Tu (2007). (From Tu, S.C., Bacterial luciferase: structure-function relationships and protein engineering, in *Luciferases and Fluorescent Proteins: Principles and Advances in Biotechnology and Bioimaging*, eds. V. R. Viviani and Y. Ohmiya, Transworld Research Network, Kerala, 2007, pp. 1–18. With permission.)

of FMNH₂ forming a linear peroxide (intermediate II) which in the presence of a long-chain aldehyde forms a peroxyhemiacetal between the aldehyde and semi-reduced Flavin MonoNucleotide (FMNH) (intermediate III), which undergoes heterolytical cleavage forming excited 4a-hydroxy-FMNH intermediate, the light emitting species (Figure 54.7). Ground-state intermediate IV then suffers dehydration yielding FMN and thus completing the enzymatic cycle. FMN oxidoreductases participate on the reduction of FMN for luciferase reaction (Tu 2008). Accessory fluorescent proteins that modify the original emission into more blueshifted (BFP) or redshifted (YFP) colors and affect the rate of the reaction may participate in the reaction of some bacteria.

Bacterial luciferase is a heterodimer consisting of homologous α and β subunits with ca. 350 residues and ca. 40 kDa each, encoded by *Lux A* and *Lux B* genes of the operon *Lux* (Tu 2007), having a similar structure to triose phosphate isomerase consisting of a $(\beta/\alpha)_8$ barrel structure (Figure 54.8). Although the dimer is the active form, both subunits display orders of magnitude lower catalytic and bioluminescence activities than the dimer. The active site was proposed to be located in a pocket in the α subunit next to the C-terminal end of the β barrel. The loop between the residues 257–291 in the α subunit shields the catalytic intermediates and the emitter, providing a hydrophobic environment favorable for emissive decay (Tu 2007). The residues, α R107 interact with FMNH₂ phosphate group; α W250 with flavin isoalloxazine ring and aldehyde; and α H45 and α H44 are important for the formation of the catalytically active intermediate II and as a catalytic base participating in the proton abstraction from intermediate III.

FIGURE 54.8 (See color insert.) 3D structures of luciferases and photoproteins: (a) bacterial luciferase according to Tu (2007), (b) firefly luciferase (*Photinus pyralis*), and (c) Obelin (coelenterate photoprotein) according to Vysotski and Lee (2004). (From Vysotski, E. and Lee, J., *Acc. Chem. Res.*, 37, 405, 2004. With permission.)

The operon Lux consists of the genes *ICDABEG* that code for proteins involved in the bioluminescent system and its regulation: gene *I* codes for the protein involved in production of autoinducer, homoserine lactone, the genes *C*, *D*, and *E* code for proteins involved in the luminescence-specific fatty acid reductase system. Once the autoinducer reaches a threshold level around 40 molecules/cell, gene expression is induced through the interaction with Lux R protein forming a complex, which facilitates association of RNA polymerase with the Lux operon activating transcription (Watanabe 2005). This autoinduction system, first discovered in luminous bacteria has been called “quorum sensing” to indicate a minimal population necessary to sense cell-to-cell communication.

54.5.2 Dinoflagellates

Their bioluminescent system contains a linear tetrapyrrolic luciferin, a 140 kDa luciferase and, in some species, a luciferin binding protein (LBP; Dunlap and Hastings 1981). The components of the bioluminescence occur inside organelles called scintillons. The reaction (Scheme 54.4) is triggered by pH changes: at acidic pH, the bioluminescent reaction is triggered whereas at alkaline ones the reaction is suppressed. The full-length luciferase displays maximum activity at pH 6.3 and no activity at pH 8. The LBP releases luciferin at acidic pH and sequesters it at pH 8. *Lingulodinium polyedra* luciferase has a 111 residue long *N*-terminal, followed by three conserved domains termed D1, D2, and D3, each one with proper catalytic activity (Liu et al. 2004). The individual domains are more conserved among different species than among themselves in the full-length luciferase, supporting their divergence by a gene duplication event prior to speciation. It was suggested that such repeated domains may result from a new evolutionary way to increase the catalytic efficiency of an enzyme. The full-length luciferase, as well as the independent domain luciferases, display maximal activity at pH 6.3 and no activity at pH 8. The removal of 50 *N*-terminal residues from each of the domains resulted in an increase of activity at pH 8. Site-directed mutagenesis showed that four conserved histidines are important for pH activity regulation (Liu et al. 2004):

SCHEME 54.4 Dinoflagellate bioluminescence reaction: LBP and luciferin (LH₂).

54.5.3 Coelenterate Photoprotein System (Hydrozoa)

In the jellyfishes, the bioluminescent system includes coelenterazine, an imidazolpyrazine, as the luciferin, a photoprotein and calcium ion (Shimomura 2006). Some systems such as the jellyfish *Aequorea* may also contain a third component, a GFP that serves as an excitation energy acceptor from the primary bioluminescent product turning the bioluminescence color into green. The coelenterate photoproteins are calcium-binding proteins. Under reducing conditions, the apoprotein binds coelenterazine and oxygen forming a stable endoperoxy intermediate (Scheme 54.5). Upon calcium binding, the photoproteins undergo a conformational change leading to the breakdown of the peroxy-intermediate producing carbon dioxide and excited coelenteramide, which decays emitting a photon of blue light ($\lambda_{\text{max}} = 464\text{--}495\text{ nm}$) (Figure 54.9). Coelenteramide remains tightly and noncovalently bound to the active site of the photoprotein turning it into a temporary fluorescent protein. However, under reducing conditions, the coelenteramide product is released. The photoproteins aequorin, obelin, mitrocomin, and clytin are small polypeptides of 21–27 kDa homologous to other calcium-binding proteins such as calmodulin, parvalbumin, and troponin, displaying helices E and F (EF) hands calcium-binding sites (Vysotski and Lee 2007; Figure 54.8). The active site is highly hydrophobic, with the hydroperoxycoelenteramide intermediate being stabilized by hydrogen bonds with Y190 hydroxyl and other residues (Figure 54.9). Comparison between aequorin and obelin (Vysotski and Lee 2007) and site-directed mutagenesis studies showed that hydrogen bonding of coelenteramide hydroxyl groups with surrounding residues determine bioluminescence spectra. Fluorescence studies with coelenteramide and its analogues have also shown that differences in bioluminescence spectra among photoproteins are due to the activation of different ionic species in the active site: the neutral form has a fluorescence maximum at 400 nm, the monoanion at 450 nm, the phenolate between 465 and 495 nm, and the pyrazine-N(4) with a maximum between 530 and 565 nm.

54.5.4 Beetles

The bioluminescent system of beetles involves the ATP-activated oxidation of a benzothiazolic luciferin (McElroy and DeLuca 1978; Wood 1995; Figure 54.10). Beetle luciferases are bifunctional enzymes, catalyzing a two step-reaction. In the first step, D-luciferin is activated by adenylation at expenses of ATP releasing pyrophosphate. The second step involves the addition of dioxygen to luciferyl-adenylate, followed by release of adenosine monophosphate (AMP) and concomitant formation of a dioxetanone, whose cleavage results in excited singlet oxyluciferin and carbon dioxide. The decay of excited oxyluciferin generates a photon usually in the green–yellow range of the spectrum with a reported efficiency of 15%–61% (Ando et al. 2008). Firefly luciferase can also catalyze the thioesterification of L-luciferin to Coenzyme A (CoA) but not of D-luciferin under aerobic conditions.

Despite extensive studies, the nature of the emitters involved in different bioluminescence colors is still unknown. It was originally proposed that the keto form of excited oxyluciferin was the red emitter and the enol form the green emitter (White et al. 1969): a tautomerization equilibrium under influence of a basic active site residue influencing the ratio between green and red emitters (White and Branchini 1975). However, recent studies (Branchini et al. 2004) showed that the polarization around the carbonyl and phenolate groups being major factors influencing the emission spectrum (Orlova et al. 2003; Hirano et al. 2009). Thus, three basic mechanisms have been proposed to explain bioluminescence color modulation by beetle luciferases: (1) nonspecific effects including the solvent effect and orientation polarizability (Ugarova and Brovko 2002); (2) specific interactions between active site residues and oxyluciferin functional groups, mainly acid–base and electrostatic interactions (Branchini et al. 2004; Hirano et al. 2009); and (3) the degree of rotational freedom of oxyluciferin thiazinic rings

FIGURE 54.10 Beetle bioluminescence reaction.

under influence of active site geometry (McCapra et al. 1994); the two former hypothesis being supported theoretically and experimentally.

Bioluminescence colors in beetles are determined by different luciferases. Beetle luciferases can emit different colors using the same D-luciferin: firefly (Lampyridae) luciferases emit in the green–yellow region (545–575 nm); click-beetle (Elateridae) luciferases emit in the green–orange region (534–593 nm), and railroad worms (Phengodidae) in the green–red region (546–628 nm), the *Phrixothrix* railroad worms (Figure 54.8) being the only known terrestrial organisms to produce true red bioluminescence (Viviani and Bechara 1997).

Beetle luciferases are 542–550 long polypeptides with ca 60 kDa and a C-terminal peroxisomal targeting peptide, Ser–Lys–Leu, which drives them into peroxisomes (Gould et al. 1987). Beetle luciferases are homologous to the family of AMP-ligases, which include fatty acid CoA synthetases, aromatic acid CoA synthetases, coumarate CoA synthetases, and peptidyl synthetases (Schroeder 1989; Wood 1995; Viviani 2002).

The 3D structure of firefly luciferases show a main N-terminal domain bound by a hinge to a smaller C-terminal domain (Figure 54.8) (Conti et al. 1996; Nakatsu et al. 2006). The active site is located in a cavity in the N-terminal domain facing the C-terminal domain and consists of a luciferin and ATP binding sites. The C-terminal domain was found to play an essential role for efficient catalysis of the oxidative reaction and bioluminescence color (Branchini et al. 2004). Several mutations were found to affect the bioluminescence color of beetle luciferases. They fall into two main classes: those directly involved in the active site, probably affecting the microenvironment around the excited oxyluciferin, and those that affect the enzyme conformation indirectly affecting the active site microenvironment (Viviani et al. 2008). The pH-sensitive firefly luciferases were found to be especially prone to be affected by mutations outside the active site whereas the pH-insensitive ones were more resistant (Viviani et al. 2008).

54.5.5 Other Bioluminescent Systems

Several other bioluminescent systems that differ in their biochemistry (Table 54.1) and, therefore, in their evolutionary origin are partially investigated. In marine environment, most bioluminescent systems use imidazolpyrazines derivatives as luciferin, coelenterazine being the most common luciferin found in such environment. Coelenterazine can be acquired either from the diet, as in the case of fishes, or synthesized (Haddock et al. 2010). Differently from the jellyfish photoprotein systems of hydrozoans, anthozoans employ a typical luciferin–luciferase system with coelenterazine as luciferin, a luciferase which is unrelated to photoproteins, and, noteworthy, LBP which are calcium-binding proteins evolutionarily related to the jellyfishes' photoproteins (Hastings and Wood 2001). Mollusks have a variety of bioluminescent systems: bivalves employ two proteins, pholasin that binds coelenterazine and displays weak chemiluminescence properties, and a peroxidase-like luciferase, which acts on pholasin to produce intense light; squids use a luciferase, coelenterazine disulfate and ATP activation; annelids may use photoprotein systems like in tubeworm *Chaetopterus variopedatus* (Shimomura 2006), peroxidase-like system involving aldehydes as luciferin such as in earthworm *Diplocardia longa*, and ATP-activated system. Marine crustaceans such as the copepods *Vargula* and *Gaussia* have luciferin–luciferase system with a glycosylated luciferase, which is secreted and cypridina luciferin, which is an imidazolpyrazine, or a porphyrin luciferin such as in decapods. Fishes may import their bioluminescent system from symbiotic bioluminescent bacteria, or have their own bioluminescent system, in the last case coelenterazine is the luciferin.

Terrestrial organisms are also quite diverse in their biochemistry. In fungi, the bioluminescence system has some resemblances with the bacterial system, including a nicotinamide adenine dinucleotide (NADH)-dependent reductase involved in reducing the luciferin. Although an enzymatic complex involving soluble and nonsoluble enzymes was found (Oliveira and Stevani 2009), no luciferase was

isolated yet. Furthermore, although several compounds have been correlated with fungal luciferin, its true identity is still unknown (Desjardin et al. 2008).

In arthropods, the millipede *Luminodesmus sequoiae* employs an ATP-activated photoprotein system. In insects, at least three different systems are known: the classical firefly luciferin–luciferase system, and two morphologically and biochemically distinct systems in Diptera: the system of *Arachnocampa*, which employs an ATP-activated luciferin–luciferase system, and the *Orfelia*'s bioluminescent system, which employs an unrelated dimeric luciferase, an LBP and a very unstable luciferin (Viviani et al. 2002). The system of Collembola and Staphylinid beetles remain unknown. *Latia neritoides*, the only freshwater snail uses an aldehyde as luciferin.

54.6 Origin and Evolution of Bioluminescent Systems

One of the most intriguing questions about bioluminescence is how such exotic processes originated during evolution. Bioluminescence may have arose about 40 independent times during the evolution (Haddock et al. 2010). It arose from the fortuitous encounter of a chemiluminescent substrate (luciferin) and an enzyme able to catalyze its chemiluminescent oxidation. The biosynthetic origin and functions of many luciferins remain unknown. In bacteria, the FMN is clearly involved in electron transport; in dinoflagellates luciferin may result from chlorophyll metabolism; in the case of coelenterazine, its imidazolpyrazine structure suggests it may arise from histidine biosynthetic pathway, its widespread occurrence in the marine environment and its antioxidant properties suggested that it may have played an antioxidant role analogous to α -tocopherol (Rees et al. 1998); in beetles, luciferin benzothiazoline ring may have originated from cysteine and quinone fusion, but its original function remains unknown.

Early reports suggested that bioluminescence arose as an accidental by-product of oxygen detoxification when photosynthetic oxygen started to rise in the atmosphere (Seliger and McElroy 1965). According to such a hypothesis, luciferases evolved from accidentally luminescent oxygenases, involved in the removal of the increasingly toxic oxygen. Later, Seliger (1975) suggested that luciferases may have arisen from mixed-function oxygenases involved with the oxidation of unsaturated and aromatic compounds, accumulated during early preaerobic life history, when the levels of oxygen started to rise. The new luminescent phenotype conferred a selective advantage in their survival. Whereas the origin from an early oxygenase could be valid for bacterial luciferases, it is unlikely that such a hypothesis applies to most other taxa since most of them originated after the oxygen pressure reached the current level. However, in some cases evidences suggest that bioluminescence plays an auxiliary role in oxygen detoxification (Barros and Bechara 1998). Hastings (1983) suggested that most luciferases evolved much later after the development of vision. Oxygenases are usually metallo-proteins with prosthetic groups and no similarity with luciferases at the primary structure level (Rees et al. 1998). Thus, most luciferases did not originate from oxygenases but rather it was the accidental weak luminescent phenotype which drove the evolution of the new oxygenase functions (Hastings and Wood 2001). Indeed, recent experiments with bovine serum albumin (BSA) suggest that hydrophobic pockets of proteins increase the quantum yield of chemiluminescent reactions (Viviani and Ohmiya 2006a). In such a context, it is likely that upon the appearance of molecular oxygen in the atmosphere, several proteins providing hydrophobic pockets and even catalytic residues for oxidative reaction gave rise to protobioluminescent systems. Since bioluminescence is a specific case of the more general process of generation of excited states in biological systems, it may have evolved from other metabolic pathways generating excited species. Thus, some especially efficient reactions were selected from a milieu of chemiluminescent reactions. The recruitment of proteins for new biological functions during evolution is well exemplified by several proteins, which were independently recruited as structural proteins in invertebrate lens crystallins (Anke et al. 2000). Thus, calcium-binding proteins originated coelenterate photoproteins and LBPs, whereas AMP/CoA-ligases gave rise to beetle luciferases. The origin of many other luciferases remains unknown.

54.7 Bioluminescence Applications and Perspectives: Bioindication from the Molecular to the Global Level

Since the purification of the first bioluminescent systems almost 50 years ago, their luciferin and luciferases were used in a wide range of bioanalytical applications (Campbell 1988). Firefly luciferases have been extensively used for analytical detection and quantification of ATP, including biomass estimation, cell viability tests, enzymes assays, and signaling molecules in biological samples. Bacterial luciferases were used to measure FMNH₂ to monitor redox reactions. Coelenterate photoproteins were used as sensitive calcium indicators. With the advances of molecular biology two decades ago, the genes coding luciferases of bacteria, beetles, coelenterates, crustaceans among other organisms, and GFPs, have been cloned, sequenced, and used as reporter genes in many applications involving analysis of promoter activation and location of gene expression (Daunert and Deo 2006; Viviani 2007). Bacterial luciferases have the advantage that the full Lux operon was cloned, allowing the expression of all required components for bioluminescence without the need to exogenously provide luciferin or other cofactors. GFPs were the most popular reporter genes, due to their strong fluorescent signal and stability, allowing their use in diverse studies of gene expression *in situ* localization in biological and biomedical areas. Recently the Nobel prize was awarded to O. Shimomura, their discoverer, M. Chalfie for their heterologous expression in other cells, and R. Tsien, for their engineering, producing a variety of colors and for their application (http://www.nobelprize.org/nobel_prizes/chemistry/laureates/2008/press.html). On the other hand, luciferases as reporter genes have the desirable properties of being very sensitive and fast and not showing the disadvantage of unwanted background (Roda et al. 2009). Although luciferases are usually very unstable and for this reason they are not appropriate for *in situ* localization like GFPs, their instability associated with the high signal/background ratio make them the most versatile reporter genes for real time *in vivo* applications (Roda et al. 2009). Some of these genes are used for monitoring the progress and regress of bacterial and viral infections in animal models for drug screening purposes, for imaging brain structure and function, assessment of tumor metastasis (Figure 54.11), among others (Shinde et al. 2006). They are also used in sensitive cytotoxicity tests and in biosensors of toxic agents (Figure 54.11) and environmental disrupting agents such as heavy metals and halogenated aromatics (Feliciano et al. 2006; Roda et al. 2009). New luciferases emitting different bioluminescence colors such as *Phrixothrix* railroad worm and *Pyrearinus* click beetle luciferases, the only one that naturally produces red light, have been cloned (Viviani et al. 1999), engineered, and successfully expressed in mammalian cells (Nakajima et al. 2004a; Viviani and Ohmiya 2006b; Figure 54.11b). Dual and multicolor reporter systems employing luciferases emitting different bioluminescence colors are commercially available for simultaneously monitoring several genes expressions with the aim to better understand the cellular physiology and pathology, in studies such as circadian rhythms (Nakajima et al. 2004b). Systems involving BRET are currently available to study protein–protein interaction and agonist–receptor interactions (Shrestha and Deo 2006). Protease-sensitive biosensors have been developed to assess cellular and biochemical pathways (Shinde et al. 2006). And the range of applications keep increasing as new luciferases are cloned or engineered and new sensitive and affordable photodetecting systems are developed.

Whereas most applications of bioluminescence deal with its use as a bioindicator or biomarker at the molecular level, recently bioluminescent organisms themselves are beginning to be used as environmental indicators. Fireflies can be used as indicators of artificial night-lighting impact or to assess stream water quality, whereas bioluminescent bacteria and algae populations can be monitored by satellite giving global information about planktonic growth and oceanic currents (Figure 54.11c; Haddock et al. 2010), which are important for ecosystem assessment.

Many other bioluminescent systems such as those of fungi, Diptera, and many marine organisms remain poorly studied or not studied at all, therefore providing substrate for new scientific discoveries in the areas of biochemistry, evolution, and ecology, and the potential of new analytical tools. Bioluminescence will continue to provide important answers in different fields such as biophysics, enzymology, cell biology, evolution, and ecology.

55.1 Introduction

For millions of years, green plants have employed photosynthesis to capture energy from sunlight, to convert it into electrochemical energy, and finally to produce energy-rich (organic) compounds. Water is the key chemical component in this process: it supplies electrons to reduce carbon dioxide to carbohydrate and forms oxygen as by-product. The overall process is responsible for the majority of energy used by mankind during our evolution and is challenged only by nuclear processes highly debated by environmentalists [1–3].

Photosynthesis is deceptively a complex process and involves a large number of key photophysical, photochemical, and chemical steps. Photosynthesis (and respiration) employs catalysts that self-assemble, self-repair, use Mn, Cu, Fe, Ni, Ca (no noble metals), and operate at ambient temperature with essentially no overpotential. To a large degree, the underlying physics and chemistry are known and, in principle, could be used to devise artificial analogs suited to current energy and environmental demands. Nature has perfected the process of photosynthesis over billions of years but unfortunately it is not easily reproducible in laboratory since the natural components do not work properly outside their physiological environment. The unprecedented high degree of molecular connectivity in reaction center (RC)—antenna complexes of bacteria and plants—is well documented in the color insert. The alternative we are left with is replicating the natural parts in synthetic systems that—struggling through numerous trials and errors—aims to mimic photosynthesis. From energetic point of view, photosynthesis converts the free energy of (sun)light into redox potential, electrochemical potential of ions and protons through the membrane, and finally phosphate potential. The blueprint of a synthetic system mimicking these tasks should consist of parts that (1) efficiently absorb light and generate electron-excited states of suitable molecular moieties, (2) transfer the excitation energy to a donor/acceptor interface where it is trapped and converted into photochemical charge separation (CS), and

(3) neutralize the charges (removing excess electrons and filling holes) of the interface minimizing any wasteful internal charge recombination (CR) and eventually employ the final available free energy to (4a) generate protonmotive force (including membrane electric potential) by accumulation of charges in opposite sides of noncommunicating compartments or (4b) drive reversible proton pumps or (4c) couple the electron flow to appropriate catalysts to produce high-energy reduced species (fuels). A schematic representation of the four basic steps is given in Figure 55.1.

Plants use organic compounds that need to be continuously renewed. The D1 and D2 subunits of the RC of photosystem (PSII) of green plants (Figure 55.P2 in the color insert) exposed to strong UV-B irradiation suffer severe (photo-) damage but, depending on the degree of damage, recover very fast. By *de novo* synthesis of the subunits within short period of time (2–4 h), the function of the oxygen evolution of PSII is reestablished [4]. The effective repair mechanisms in natural systems present definite advantage compared to any man-made biomimetic constructions. Presently, much less requirements of operation of artificial systems are set as goals. Inorganic compounds are looked for that catalyze the needed reactions and are both efficient and widely available. Several artificial photosynthetic elements are designed and assembled them into energy converting systems. Carotenoid pigments and polymer polyenes can be incorporated into tetrapyrrole-based artificial RCs. In certain systems, the pigment is near 100% efficient. In more complex systems, liposome-based artificial ion pumps have been assembled that are based on Mitchellian redox loops and vectorial redox potential developed by either natural [5] or artificial RCs [6,7]. The direct conversion of light energy to chemical potential in similar biomimetic constructions will be surveyed in this work.

Synthetic photosystems have the advantage of manipulation of individual components at molecular and phenomenological levels and of direct test of theoretical considerations on thermodynamics and

FIGURE 55.1 Key processes of oxygenic photosynthesis representing potential targets to establish artificial systems. The light energy is absorbed and collected by the large array of antenna pigments (circle) that surrounds the photochemical interface (RC, rectangular box) acting similarly as a semiconductor *p-n* junction. After the excitation energy is funneled to here (dotted line), CS (production of an electron (*e*)/hole (+) pair) takes place followed by consecutive ET processes (solid lines). The electrons emerging from the water-splitting process at the *e*-donor catalytic site (producing molecular oxygen and H^+ ions) fill the holes (vacancies of electrons) and drive reductive processes at the *e*-acceptor catalytic site (producing, e.g., molecular hydrogen or methanol from carbon dioxide).

reaction kinetics. As many of the essential parameters are not readily altered in the natural systems, trials on artificial systems have been helpful in understanding the principles of natural photosynthesis [8–11].

In artificial photosynthesis, the goal is to mimic the ability of green plants and other photosynthetic organisms to convert the free energy of sunlight into other forms of free energy including electrons (redox potential), ions (ion electrochemical potential), protons (protonmotive force), and high-energy chemicals (phosphate potential) [12]. Although the complexity of the structure and function of natural photosynthesis is unlimited, a number of promising approaches to artificial realization of some selected steps of the natural processes have appeared recently based on semiconductors, membranes, liposomes, nanoparticles, and (supra)molecular systems. Figure 55.2 demonstrates how the light energy can be utilized by photovoltaic (PV), electrochemical, and photocatalytic reactions designed by partial and/or combined processes of natural photosynthesis.

The first steps of photosynthesis including the absorption and collection of solar energy and its conversion into charge-separated state can be realized in silicon-based PV modules [13]. The photon is absorbed in the bulk silicon semiconductor, and the electron-excited state migrates to a p - n junction where CS occurs. The separated charges generate electromotive force (emf) that can drive electric current in an external wire connecting the two sides of the junction. The emf is produced by high yield as the intrinsic electric field of the p - n junction helps to prevent the recombination of the charges (see the direction of the electric field in Figure 55.1). Commercially available silicon PV cells convert sunlight to electricity with 14%–19% energy conversion efficiency [14,15]. Recent silicon PVs have even higher efficiencies that approach the Shockley–Queisser limit of about 30%. Beside silicon PVs, alternative materials have been developed including dye-sensitized solar cells [16] and organic PVs [15]. Although these systems have presently significantly lower efficiency and stability compared to silicon PVs, they use lower cost materials.

Electrochemistry can be combined with PVs to convert electricity to chemical energy. If PVs is wired to a water electrolyzer, H_2 (fuel) is produced at $\Delta E^0 = -1.23$ V cell voltage according to the overall reaction of $2H_2O \leftrightarrow 2H_2 + O_2$. Typical alkaline electrolyzers operate in concentrated KOH, utilizing nickel or nickel-coated steel electrodes, and convert electricity to chemical energy in hydrogen with ~70% energy conversion

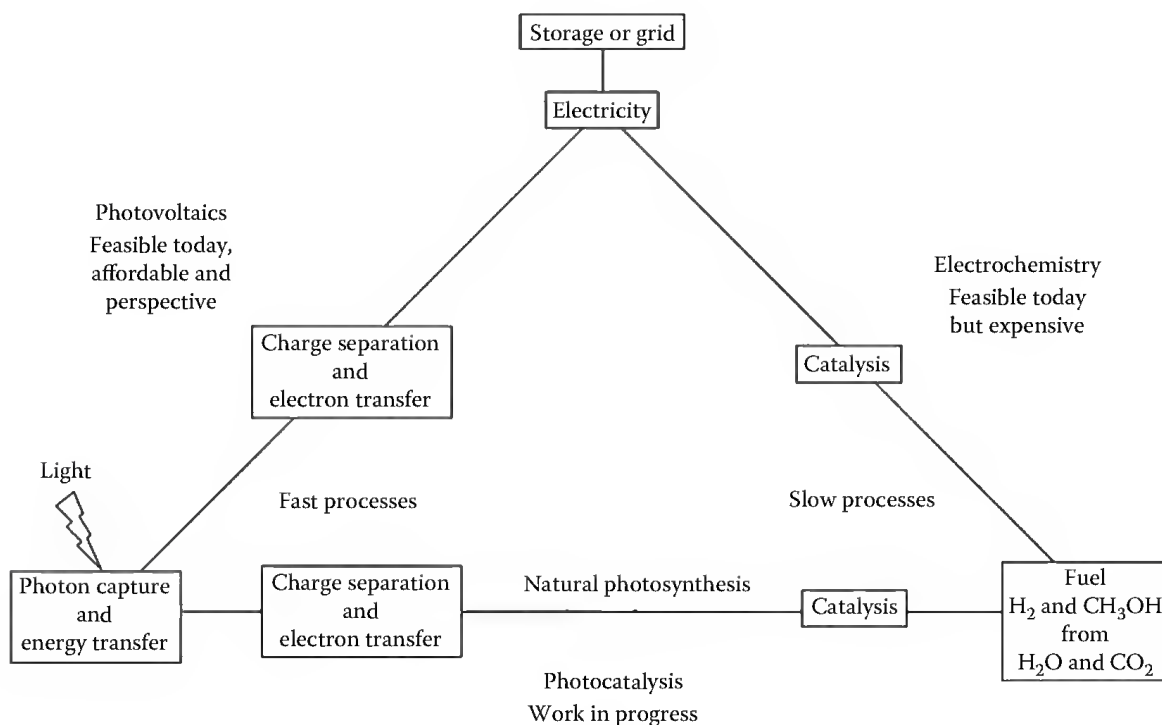

FIGURE 55.2 Possible ways of utilization of light energy in artificial photosystems based on photovoltaics, electrochemistry, and photocatalysis designed by natural processes of photosynthesis.

efficiency. Proton exchange membrane (PEM) electrolyzers operate near neutral pH, utilize noble metal catalysts, and convert sunlight to chemical energy with an energy conversion efficiency larger than 12% [17].

The photocatalytic ways of conversion of sunlight into chemical energy are implemented by the processes of natural photosynthesis. The final goal has been to develop an artificial version of photosynthesis that can be used to produce (liquid) fuels from carbon dioxide and water. The following sections will start with the introduction of the selected processes of natural photosynthesis followed by description of attempts to mimic the partial and/or overall natural reactions in artificial systems. While different manifestations of artificial photosynthesis work in the lab, they are not yet ready for mass consumption. The artificial photosynthesis should be a technology that would not only provide a green and renewable source of electrical energy, but could also help scrub the atmosphere of excessive carbon dioxide resulting from the burning of fossil fuels.

55.2 Harvesting the Light

55.2.1 Natural System

The photosynthesis is triggered by absorption of sunlight. Light harvesting is efficiently accomplished if performed by strongly absorbing and interacting molecules (usually pigments such as chlorophylls and bacteriochlorophylls *a*, *b*, *c* (Figure 55.3), *d*, and so forth, phycobilins, carotenoids). During the long-living electron-excited state of the pigment molecule, electron excitation energy can be transferred to unexcited pigments molecules before any detrimental decay processes take place. The intrinsic lifetime of the excited state of chlorophylls (τ_0) is 1–10 ns while the time required to transfer energy ($\tau = 1/k_T$) to neighboring pigment at distance of *R* is 2–3 orders of magnitude smaller (1–10 ps). This difference allows

FIGURE 55.3 Chlorosomes, the peripheral antenna of green photosynthetic bacteria. Structure of bacteriochlorophyll *c*, the building block of the chlorosomes (A). The chlorin ring can have three naturally occurring different substitutes in *R*: ethyl, propyl, or iso-butyl moieties. The hydrophobic chain is formed by an unsaturated branched alcohol (farnesol, phytol, etc.) bound to the tetrapyrrole via ester formations. For more information, see Grimm et al. [139]. Cross-section view of the rod-shaped elements (B) of chlorosome with an average length of 100 nm and a diameter of 25–30 nm. The gray polar heads represent the chlorin macrocycle of the pigment. Within each chlorosome, a number of rod-shaped elements are formed by interconnected bacteriochlorophyll *c*.

excitation to travel by a biased random walk and to reach the RC much before the electron excitation energy of the pigment would dissipate. The rate of energy transfer between two (donor and acceptor) pigments (k_T) depends on the magnitude of interaction energy between the donor and acceptor molecules. If the coupling is very weak and is approximated by dipole–dipole interaction (as a rule of thumb, $1\text{ nm} < R < 10\text{ nm}$), then the rate of energy transfer can be determined by the Förster's expression:

$$k_T = \frac{1}{\tau_0} \left(\frac{R_0}{R} \right)^6. \quad (55.1)$$

Here, R_0 is the Förster's distance (radius) at which the rate of energy transfer becomes equal to that of the intrinsic deactivation. R_0 depends upon the quantum yield of the donor fluorescence, the overlap integral between the emission spectrum of the donor and the absorption spectrum of the acceptor, the relative orientation of the donor and acceptor transition vectors, the so-called alignment or orientation factor and the refractive index of the medium. At smaller distance between the donor and the acceptor molecules ($R < 1\text{ nm}$), the electron wave functions may overlap and the Coulomb-type interactions are accompanied by several quantum effects (e.g., exchange interactions) [18]. Accordingly, the rate of energy transfer cannot be given by a simple, practical, and universal expression as [Equation 55.1](#).

In native photosynthetic systems, the pigments form discrete structural and functional units to assure efficient harvest of the light. The first description of photosynthetic units (PSU) as supramolecular aggregates with a univocal purpose dates back to the research of Arnold and Emerson in the early 1930. In two pioneering articles [19,20], Emerson and Arnold found that the green alga *Chlorella* would produce, under optimal conditions, one molecule of oxygen every 2400 molecules of chlorophylls. Given that eight photons are needed to reduce one CO_2 molecule and evolve one molecule of O_2 , the figure of $2400/8 = 300$ chlorophylls represents the average number of pigment molecules that, without performing photochemistry, is anyway connected with the light phase of photosynthesis. It is clear today that chlorophylls and other pigments are organized within protein scaffoldings, and to present knowledge, we can conceive the PSU as a two-part assembled molecular machinery composed of a central unit dedicated to the conversion of (sun)light in CS (RC) and of an ancillary unit devoted to harvest the sun(light) (antenna). The antenna is organized in a peripheral part and a core antenna closely associated with the RC. The organizations of the supramolecular aggregates are illustrated in the color insert with atomic details in photosystem II in Figures 55.P1 and 55.P2 and in photosynthetic bacteria in Figures 55.B1 and 55.B2.

Antenna proteins offer perfect structural scaffolding for the efficient energy transfer among photosynthetic pigments. However, the scaffolding is not always required as in chlorosomes of green bacteria, where an array of light-harvesting pigments is organized without proteins ([Figure 55.3](#)). The chlorosomes are attached to the cytoplasm of the green bacteria and funnel the excitation energy to the RC by means of the so-called baseplate, a protein layer containing bacteriochlorophyll *a*. Because of the unusual organization (aggregates), the chlorosome structure has not been resolved and only models, in which BChl pigments are organized into large rods and lamellar structures are proposed on the basis of freeze-fracture electron microscopy and spectroscopic constraints [21]. According to a widely accepted model, the chlorosomes are formed by vesicles shaped as cigars, with an average length of 100 nm and a cross section of 25–30 nm. Within each chlorosome, a number of rod-shaped elements with a horizontal average cross section of 10 nm are formed by interconnected bacteriochlorophyll *c*. The bacteriochlorophyll *c* molecules are self-organized by extensive networks of hydrogen and coordinative bonding and by π – π interactions forming large supramolecular aggregates containing even thousands of BChls [22,23].

The chemical design of light-harvesting aggregates has taken more than 3×10^9 years to reach the actually unmatched efficiency both in terms of light capturing and of light conversion abilities, a goal

that artificial systems struggle to reach [24]. On the opposite side, the shelf life of these macromolecular aggregates outside their physiological environment does not allow to conjecture their direct use in any sort of device. As matter of examples, the various protective and repair mechanisms developed in oxygenic photosynthesis should be referred to [25–28]. In solution, one-third of the excited chlorophyll molecules populate triplet states, which may readily interact with the similar (triplet) state of the oxygen. Without protection of the carotenoids (whose triplet states are not sensitive to the attack of oxygen), the chlorophylls in the antenna or in RC would be exposed to significant photodestruction even under moderate light conditions [29,30]. Similarly, the D1 and D2 subunits of the PSII RC are subject to (photo-)damage but the entire photosynthetic process is not jeopardize since they can undergo to a very fast turnover by *de novo* synthesis ensuring the reestablishment of a fully active RC [31]. Not well operating heat dissipative pathways causing elevated temperature can be also harmful to RC [32,33]. The valuable protective and repair mechanisms in natural systems are based on very sophisticated processes accompanied by fine-tuning regulations but unfortunately are way out of any forecast in biomimetic systems. The present approach to mimic photosynthesis is to reproduce the physical phenomena (i.e., energy or electron transfer [ET]) without being diverted from the “useless” or “complicated” metabolic frills that evolution has put forward.

55.2.2 Artificial Model

Properly organized supramolecular arrays of molecules of large extinction coefficients can be synthesized to act as light-harvesting antenna. In recent years, the development of supramolecular chemistry, photophysics, and photochemistry enabled to design and assemble several of such arrays in which each molecular component can absorb the incident light effectively, transfer excitation to a nearby (unexcited) component before radiative or nonradiative deactivation, and funnel the excitation to a key component of the array interfaced with the photoconverter (see [Figure 55.1](#)).

55.2.2.1 Self-Organized Nanostructures for Artificial Light Harvest

In chlorosomes of green bacteria, the light-absorbing pigments form light-harvesting system by self-organization and without any protein scaffold. The strong interaction among pigments reduces the exciton–phonon coupling efficiently, which is mainly responsible for the optical dephasing and the localization of excitons on single chromophores. Due to the strong coupling, long-living coherent excitonic states are established even at room temperature. The coherence can be maintained over a range of about 100 chlorin molecules with duration of a few picoseconds. In this respect, the chlorosomes are extremely interesting objects as they may serve as artificial self-organized antenna system in artificial photosynthesis. The understanding the molecular interactions which control the self-aggregation of metallochlorins (BChl *c* or *d*, [Figure 55.3](#)) and the formation of supramolecular structures in natural systems and artificial aggregates is a great challenge and expectation.

Several principal structural models of the metallochlorin aggregates were proposed: (1) The rod model contains closely stacked chlorins based on a monomer basic unit. Some of these stacks combine at a higher level to single- or to double-rod structures [22]. (2) The lamellar structure model proposed from electron microscopy data uses chlorin dimers as basic building blocks and does not contain any rod elements. (3) The model of extended lamellar structure is based on solid-state nuclear magnetic resonance experiments [34]. The building block is dimeric chlorin but the structure contains rod elements, as well.

The ligation of the metal centers in chlorins has not been clearly attributed to a syn- or an anti-conformation [35,36]. The BChl *c* is rather unstable but can be modeled by Chl *a*, the main pigments of the photosynthetic apparatus of plants and algae, to which the magnesium of the chlorin ring is substituted by a zinc. The Zn-chlorophyll molecules associate with rod-shaped assemblies spontaneously as BChl *c* molecules do, but show much higher resistance to photodegradation. The drawback of such systems is the lack of any absorption peaks in the green part of the solar spectrum that diminishes

the light-harvesting capacity. This problem can be solved by preparation of rod-shaped structure with the use of a second chromophore—the green-absorbing naphthalene bisimide (NBI)—conjugated to Zn-Chl forming a dyad with 26% higher light absorption efficiency in the solar spectrum than Zn-Chl aggregates [37]. Such dyads can form aggregates longer than 200 nm with a horizontal section of few tens of nanometer. The energy transfer from the NBI chromophore to the chlorin aggregate is close to 100% efficient. By covalently attaching a third chromophore to this system, the solar coverage increases substantially and the absorption gap is practically closed.

Chlorosome-like artificial systems have been also obtained by using fluorescent chromophores as building blocks attached to a recombinant tobacco mosaic virus coat (TMVC) protein monomer functionalized with reactive cysteines [38]. Under appropriate buffer conditions, these monomers assemble into rods or stacks of disks that reach hundreds of nanometers in length. In these rods, several hundreds of chromophores can arrange every 100 nm of TMVC rods, with a spacing between neighboring chromophores averaging 2 nm in the horizontal and vertical dimensions. Donors and acceptor, chosen on the base of their large extinction coefficients ($\sim 10^5 \text{ M}^{-1} \text{ cm}^{-1}$), have their excitation and emission maxima ranging between 495 and 612 nm, covering a large portion of the visible part of the solar spectrum. Energy transfer from donors (Oregon Green 488 and tetramethylrhodamine) to a single acceptor (Alexa Fluor 594) was observed, with an efficiency of 47%.

55.2.2.2 Dendrimers

The dendrimers (see an example in [Figure 55.3](#)) constitute a class of well-defined macromolecules exhibiting a treelike, nanometer-size architecture, reminiscent of the architecture of natural light-harvesting complexes [39]. Their structures are hence very attractive for the construction of artificial antennae since their convergent and/or divergent synthesis allows, in a few steps, the assembly of a large number of chromophores in a restricted space and with high topological control.

Photoactive units can be directly incorporated in or appended to different regions of a dendritic structure with covalent or coordination bonds or even caged into cavities formed within the structure such as void regions. Due to the proximity of the residues, the various functional groups of a dendrimer may easily interact with one another, a prerequisite for artificial antennas. The constitutive building blocks can be of different types among which porphyrins, a close analog of chlorophylls.

Photophysical investigations on porphyrin-based dendrimers have revealed [40] that (1) the singlet excited-state energy transfer from Zn-porphyrin to free-base porphyrin is extremely efficient (the yield is 95%–99%), (2) no competitive ET reactions are observed, (3) the predominant energy transfer mechanism involves through-bond communication via the linker, and (4) the energy transfer between two isoenergetic Zn-porphyrins is very fast. Hence, extended multiporphyrin arrays can be rationally designed with predictable photophysical features and efficient light-harvesting properties. By means of a modular approach and the use of an opportune linkers between aryl groups on adjacent tetraarylporphyrin macrocycles (typically ethyne groups), a variety of di-, tri-, tetra-, and pentameric porphyrin arrays have been synthesized [41]. Efficient excitation energy transfer has been shown to occur in giant dendrimer wheels (sizing about 7 nm in diameter) composed of 24 porphyrin units. In such system, the energy hopping between neighboring tetraporphyrin moieties takes place with a rate of 35 ps^{-1} [42]. Attempts to build up artificial antennae by self-assembling of porphyrin components have also been reported [22,37,43–46]. Recently, a series of dendritic multiporphyrin array systems were prepared to study singlet–singlet and triplet–triplet energy transfer from peripheral Zn-porphyrins to the focal core formed by a free-base porphyrin. In these systems, triplet–triplet annihilation has been detected [47].

The characteristics of light collection of the dendrimers dependent on morphology [48–50]. With the use of a free-base porphyrin as core, it is possible to connect up to four dendrons, originating from the four *meso* positions of the ring, generating four different shapes with different light-harvesting characteristics (see [Figure 55.4](#) for the structure of the dendron). In the most substituted case, the four dendrons

FIGURE 55.4 General topology of a dendrite formed by the building (joint, bridging, and termination) blocks shown in the table. Each dendron, indicated by the curly bracket and limited by two thick black lines, is allowed to grow for four generations starting from a common core from which two other dendrons can layer up. The branching or (joint) points (O) are metal ions, ruthenium, and/or osmium, which coordinate three bridging units (---). These building blocks have two coordinative moieties on the opposite sides of the molecule, allowing the growth of a further layer. The growth of a dendron can be stopped by the termination blocks (\\ /) having the coordinating nitrogen atoms only on one side of the molecule. A rather large void region (filled gray circle) wedging away from the core is formed between each couple of dendrons. (Redrawn from Balzani, V. et al., *ChemSusChem*, 1(1–2), 26, 2008.)

assume a star-like structure that incorporates 28 light-absorbing and interacting Zn-porphyrins able to efficiently gather light and funnel the absorbed energy to the core with a rate constant of $1.0 \times 10^9 \text{ s}^{-1}$ and 71% efficiency (Figure 55.5). In the case of monosubstitution, the conically shaped single dendron shows a 10-fold smaller rate of energy transfer with an efficiency as low as to 19%. In addition to suited morphology, the cooperative effects also improve the efficiency of the energy transfer within dendrons: the interaction increases with increasing number of chromophores but decreases with increasing conformational mobility (e.g., the efficiency of the energy transfer in a given dendron decreases with increasing temperature).

Thanks to the large number of chromophores, the suitable morphology and the compact scaffold of dendrimers they function efficiently in capture of visible photons and in transfer of the energy to the central core, mimicking natural photosynthetic systems, where energy migration within “wheels” of chromophoric groups (see Figures 55.B1 and 55.P1 in the color insert) results in an efficient energy transfer to the central RC.

FIGURE 55.5 Building blocks of light-harvesting dendrimers based on porphyrins. A free-base porphyrin is in the core (left corner) and four dendrons (ligands) each constituting of seven Zn-porphyrin units (top) can be attached to R_1 , R_2 , R_3 , and R_4 . In these dendrons (see table in Figure 55.4), the bridging block is Zn-porphyrin while the termination block is 3,5 dimethoxy benzene (circled). The dendron has grown three layers before termination, and the core is formed by a free-base porphyrin. (Redrawn from Balzani, V. et al., *ChemSusChem*, 1(1–2), 26, 2008.)

55.3 Systems for Charge Separation and Electron Transfer

55.3.1 Biological Paragon

Once (sun)light is absorbed by the antenna of the photosynthetic organisms, the excitation is funneled to the photochemical core of the PSU, the RC. Here, a shallow energy trap catches the exciton: it cannot easily escape from the RC because of the lower excited energy state of the Chl dimer of the RC (P^*) than those of the excited Chls in the antennae (Chl^*). The excited state of the dimer has two possible deactivation routes: the first is to dissipate the electron excitation energy in the environment as fluorescence and the second is to generate a photoelectron that is transferred to a neighboring pigment, generating a biological hole–electron system. Similarly to what has been described in the case of energy transfer, the first possibility is a waist of energy (although can be utilized to characterize the photosynthetic states of the organisms [51,52]), while the second is a useful process that can take place only if the CS is faster than the dissipation. In RC, this is exactly the case, as illustrated in Figure 55.6 for purple photosynthetic bacteria, where the rate of the first ET step is faster by three orders of magnitude than the radiative decay of the excitation. This rule of thumb that forward reactions are at least two orders of magnitude faster than the competing wasteful reactions is true also for the following steps of the ET, in which the electron donation to the next acceptor is significantly faster than the back reaction and the CR [53–55]. Due to the well-organized architecture of the protein scaffolding and of

FIGURE 55.6 Organization of cofactors in two branches (A and B, left) and the free energies of redox states (right) in the RC of purple bacterium *Rba sphaeroides*. (Redrawn from Feher, G. et al., *Nature*, 339(6220), 111, 1989.) The dimer (P) formed by two partially overlapping molecules of bacteriochlorophyll *a* serves as trap for excitation energy and source of electron to the A (active) branch. The electron is transferred to the secondary ubiquinone electron acceptor (Q_B) via the bacteriopheophytin (Φ_A) and the primary ubiquinone (Q_A). The bridging bacteriochlorophyll monomer (B_A) and the nonheme iron ion facilitate but do not directly participate in ET. In the presence of external donor, reduced soluble cytochrome *c* (not shown), Q_B can accept up to two electrons and upon quinol (Q_BH_2) formation, it is replaced by exogenous quinone (quinone cycle). The closest distances between two neighboring pigments are as follows: $P - B_A \sim 5 \text{ \AA}$, $B_A - \Phi_A \sim 5.5 \text{ \AA}$, $\Phi_A - Q_A \sim 9 \text{ \AA}$, and $Q_A - Q_B \sim 15 \text{ \AA}$. The larger is the distance covered by the electron, the smaller are the free energy gaps and the rates of forward ET ($A_i \rightarrow A_{i+1}$) excluding $P^+B_A \rightarrow P^+B_A^-$ [140], backward ET ($A_i \leftarrow A_{i+1}$), and CR ($P^+A_i^- \rightarrow PA_i$). A_i and A_{i+1} denote neighboring electron acceptors.

the pigment localization, as shown in Figure 55.6 the arrangement is extremely efficient: 98% of the excitons caught by the dimer will generate CS [56] and subsequently semiquinone molecule [53,57]. In the presence of exogenous electron donors, the hole can be filled [58] and the RC is ready for a second cycle that terminates with the double reduction and double protonation of the quinone (refer to Figure 55.B3 in the color insert).

The successful competition between CS reactions and CR reactions is well explained by the Marcus theory of the ET reactions [59]. This theory predicts a parabolic relationship (see Figure 55.6) between the logarithm of the rate of the ET, k_{ET} , and the driving force of the reaction, $-\Delta G_{ET}^\circ$:

$$\ln k_{ET} = -\frac{(\Delta G_{ET}^\circ + \lambda)^2}{4\lambda k_B T} + \ln k_{\max}, \quad (55.2)$$

where

$k_B T$ is the Boltzmann term

λ is the reorganization energy

k_{\max} is the maximum rate of ET

k_{\max} is the product of the electron transmission coefficient, k ($=1$ for adiabatic reaction and $\ll 1$ for nonadiabatic reactions) and the effective frequency of nuclear vibrations, ν_{nuc} ($\approx 10^{13} \text{ s}^{-1}$): $k_{\max} = k\nu_{\text{nuc}}$. In a couple formed by an electron donor and an electron acceptor, optimal conditions for forward ET are found for $-\Delta G_{ET}^\circ = \lambda_{CS}$ and the rate of charge-separated state formation corresponds to k_{\max} , graphically found on the maximum of the CS parabola (see Figure 55.7). At this value of $-\Delta G_{ET}^\circ$, the highly exergonic

FIGURE 55.7 Marcus parabolas for CS and CR derived from Equation 55.2. At the peak of the parabola (the rate is at maximum), the driving force equals the reorganization energy, $-\Delta G_{\text{ET}}^0 = \lambda$. Fast CS and slow CR are facilitated by small λ_{CS} and large λ_{CR} , respectively. The larger is the difference in reorganization energies (and in maximum rates), the wider is the range of driving force where the stabilization of the charges is effective.

and energy-wasting back ET process, found on the CR parabola in correspondence of the CS maximum, is much slower than the forward one and is shifted deeply into the inverted region of CS, leading to the formation of a charge-separated state with both high quantum yield and long lifetime.

This is the strategy adopted by natural photosynthesis. In bacterial RCs, the driving force $-\Delta G_{\text{ET}}^0$ ($\text{P}\Phi \rightarrow \text{P}^+\Phi^-$) of the donor–acceptor couple $\text{P}^+\Phi^-$ (≈ 1.2 eV) is lowered by roughly 0.2 eV compared to P^* (1.38 eV) (Figure 55.6), which matches the CS reorganization energy optimizing the forward ET, but the CR process lies deep within the Marcus inverted region making it much slower.

The driving force at which the rates of the forward and back ET are equal (crossing point of the two parabolas in Figure 55.7) is obtained by applying Equation 55.2 to CS and CR and impose that $(\ln k_{\text{ET}})_{\text{CS}} = (\ln k_{\text{ET}})_{\text{CR}}$:

$$-\Delta G_{\text{ET}}^0(k_{\text{CS}} = k_{\text{CR}}) = \sqrt{\frac{\lambda_{\text{CR}} - \lambda_{\text{CS}} + 4k_{\text{B}}T \ln \frac{k_{\text{max}}(\text{CS})}{k_{\text{max}}(\text{CR})}}{\frac{1}{\lambda_{\text{CS}}} - \frac{1}{\lambda_{\text{CR}}}}}. \quad (55.3)$$

If the actual standard free energy change for ET reaction is smaller than this limit, the rate of the forward ET will exceed that of the competing reverse reaction. The larger is the difference between the reorganization energies ($\lambda_{\text{CR}} \gg \lambda_{\text{CS}}$) and the maximum rates ($k_{\text{max}}(\text{CS}) \gg k_{\text{max}}(\text{CR})$) of the ET, the more favorable will be the CS and stabilization. The observed rate of ET is highly sensitive to the (network of) reaction pathways and consequently to the distance between donors and acceptors in proteins: a variation of 2 nm in the distance, the ET rate changes by 12 orders of magnitude [60,61]. The exact distance dependence of the rate of the ET is more complicated than that of the electronic excitation energy (Förster's expression, see Equation 55.1) but excellent empirical approximations are in use [61–63] which may serve also as ruler to determine distances between redox centers in biological systems [64].

55.3.2 Biomimetic Systems

Both artificial and natural light-harvesting systems would turn out useless in the absence of a molecular device able to induce photoelectron transfer and eventually to generate an electron–hole couple. It is hence vital the design and synthesis of artificial molecular systems provided with suitable organized electron donors and acceptors, which mimic photochemical CS and ET in photosynthetic proteins [8,65,66]. Many bioinspired systems employ photoactive transition metal complexes or chromophores with extended conjugated π -systems, such as porphyrins, which are often synthetically easier to incorporate into complex donor–acceptor systems than natural chlorophylls and bacteriochlorophylls. Porphyrins are frequently used as both donors and acceptors in these arrays, while aromatic amines and carotenoids serve as secondary electron donors. In addition, fullerenes, quinones, aromatic imides, and bis(imides) are common electron acceptors because of their low reduction potentials and stable anions. Oppositely to what happens in natural RCs, the artificial RCs do not need any further design for double ET as in the case of quinone reduction, but rather has to stabilize the photogenerated hole–electron couple as much as possible. Notwithstanding such simplification, the fight against wasteful CR reaction is much harder in bioinspired systems.

If CS occurs in a single step, the competition with CR will be extremely unfavorable. As in natural photosynthetic RC proteins, secondary electron donors and acceptors need to be attached to the artificial RC to further spatially separate the charge pair, thereby increasing the lifetime of the charge-separated state. Multicomponent donor–acceptor arrays performing multistep ET reactions are most useful for producing long-living charge-separated states. The importance of using a cascade of thermal ET steps following the initial photochemical event to increase CS lifetimes has been widely demonstrated [8,67–69].

Studies on the optimization of the free energy changes, distances, and orientations between the various donors and acceptors and minimizing the reorganization energy for ET have determined synthetic strategies for the development of novel molecular structures to tailor the CS and storage characteristics for specific applications. Relatively simple electron donor–acceptor ensembles linked by covalent and noncovalent bonds have been synthesized to attain fast CS with extremely slow CR of high-energy CS states provided by minimizing the reorganization energy of ET according to Marcus theory of ET [70,71]. Such simple electron donor–acceptor systems provide a variety of applications for photoinduced ET catalytic systems including radical coupling of radical ions produced by ET of electron donors and acceptors with the CS states and the photocatalytic hydrogen evolution.

55.3.2.1 Artificial Reaction Centers

The artificial RCs have to match the performance of the natural ones in terms of the fraction of photon energy conserved, the quantum yield of CS, and the lifetime of the photoinduced CS. In the synthesized molecule, the distance between electron donor and acceptor should not be too small in order to have much faster forward than backward ET. To follow this demand, a spacer that physically separates the donor and the acceptor should be inserted. The yield of light harvest would be increased if the spacer acted as sensitizer, as well. In addition, the introduction of secondary electron acceptors and donors would further stabilize the charge-separated state.

Figure 55.8 shows an example of an artificial photosynthetic RC formed by a molecular pentad, which is formally obtained by introducing a secondary acceptor and a secondary donor/chromophore in a triad [72,73]. The ZnP of the central dyad absorbs photons in the visible spectral range and becomes excited: $C\text{-ZnP}^*\text{-P-Q}_1\text{-Q}_2$. The excitation energy is transferred to the neighbor porphyrin forming the singlet state $C\text{-ZnP-P}^*\text{-Q}_1\text{-Q}_2$. From P, a photoelectron is shuttled toward the first electron acceptor, the quinone Q_1 , forming the electron–hole system $C\text{-ZnP-P}^+\text{-Q}_1^{\bullet-}\text{-Q}_2$. The following step is performed by the secondary electron acceptor (Q_2) and electron donor (C) to establish the final charge-separated state $C^{\bullet+}\text{-ZnP-P-Q}_1\text{-Q}_2^{\bullet-}$. The relatively high quantum yield (0.83) and energy conversion efficiency (larger than 50%) make the assembly as promising candidate of photoconverter. The main drawbacks are the

FIGURE 55.8 Molecular pentad as artificial RC. This molecule consists of a central tetraphenyl-porphyrin dyad (ZnP-P) connected by an amido group. The dyad is attached to a carotenoid moiety (C) on the ZnP side and to a diquinone moiety (Q_1 - Q_2) on the P side via amido groups. With a molecular weight slightly above 2000 g/mol, this pentad has shown very interesting similarity (see text for details) with the photochemical behavior of bacterial RCs, whose molecular weight is well above 100,000 g/mol. (Redrawn from Gust, D. et al., *Mimicking bacterial photosynthesis*, A.F. Collings and C. Critchley, Eds, Wiley-VCH Weinheim, Germany, 2005, pp. 187–210.)

high hydrophobicity of the molecules and the short-lived final state (the lifetime is 55 μ s in chloroform) that is four orders of magnitude smaller than that of the bacterial RC (see Figure 55.6).

55.3.2.2 Porphyrin–Fullerene-Based Artificial Photosynthetic Systems

Porphyrins are excellent electron donors as well as sensitizers and the most frequently employed building blocks in artificial photosynthetic models. Although the quinones are the obligatory electron acceptors of native photosynthesis and frequently used also in artificial systems, buckminsterfullerene (C_{60}) [74] covalently linked to porphyrin appeared recently as novel type of attractive electron acceptor. The following basic characteristics of fullerenes can be utilized in artificial photoconverter systems: (1) the C_{60} consists solely of 60 carbon atoms and has a moderate size (with a molecular weight of 720 g/mol and a diameter of 8.8 Å) and round shape; (2) has moderate electron-accepting abilities [$-300 \div -400$ mV vs. standard calomel electrode (SCE)] and can reversibly accommodate up to six electrons; (3) the energy levels of the first excited singlet (2.0 eV) and triplet states (1.6 eV) are comparable to those of porphyrins; and (4) has a rigid framework in the ground, excited, and reduced states and high stability under severe environmental conditions.

Various porphyrin–fullerene systems have been synthesized to elucidate the intrinsic ET properties of fullerenes [71,75,76]. The C_{60} accelerated the photoinduced CS and the ET, but slowed down the CR. This is in sharp contrast to those of conventional planar acceptors such as quinones and imides. The distinctive ET properties of fullerene result from the small reorganization energies arising from the widely delocalized π system on the spherical structure accompanied with the rigid structure. This makes the long-lived charge-separated states with high quantum yield in donor- C_{60} systems. Porphyrin–fullerene systems display stepwise ET relay, and the lifetimes of the final charge-separated state in tetrads and pentads are comparable to those of the $P^+Q_B^{\bullet-}$ couple in bacterial RCs (see Figure 55.6).

Proper coupling of functions of antenna (light absorption) and RC (CS) in one artificial system is a crucial task [77–79]. Among the several attempts reported recently, only one will be demonstrated here (Figure 55.9). The CS (and recombination) module is represented by a porphyrin–fullerene dyad linked to a phenyl ring of an hexaphenylbenzene core bearing at the other positions five light-gathering moieties formed by bis(phenylethynyl)anthracene (for details see the legend of Figure 55.9).

FIGURE 55.9 Coupling of energy and ET processes in a single biomimetic macromolecule with a porphyrin- (P) and fullerene (C_{60})-based macromolecular antenna-RC complex. The antenna moiety of the molecular system has very high extinction coefficient in the blue region of the visible spectrum ($430 \div 475$ nm), and the absorbed excitation energy is shared among the pigments (dotted open circle) with very high rate ($2.5 \times 10^{12} \text{ s}^{-1}$). The energy is funneled to the porphyrin via the ortho-, meta- and para-position of the central phenyl ring with somewhat less rates of $1.1 \times 10^{12} \text{ s}^{-1}$, $1.3 \times 10^{11} \text{ s}^{-1}$, and $2.5 \times 10^{11} \text{ s}^{-1}$, respectively (dotted arrow). Resonance (Förster-type) mechanism dominates the energy transfer but through-bond and electron-exchange mechanisms may also contribute to the very high quantum yield of the process estimated to 80% for porphyrin and to 96% for Zn-porphyrin. From the first excited singlet state of the porphyrin (P^*C_{60}), one electron is donated to fullerene (the rate is $4.0 \times 10^8 \text{ s}^{-1}$) forming the charge-separated state $P^+C_{60}^-$. The CR ($P^+C_{60}^- \rightarrow PC_{60}$) is four times slower (the rate is $1.1 \times 10^8 \text{ s}^{-1}$). ETs are shown by solid arrows.

Highly efficient photoinduced energy and ET were achieved on gold and indium tin oxide (ITO) electrodes modified with self-assembled monolayers of the porphyrin–fullerene systems [71]. The internal quantum yield for photocurrent generation of the boron dipyrrole and ferrocene–porphyrin– C_{60} triad system has reached up to 50%. Supramolecular arrays of porphyrin with fullerene were linked to gold nanoparticles or to high-surface-area nanocrystalline TiO_2 films creating dye-sensitized solar cells [80]. The dye-sensitized bulk heterojunction photoelectrochemical cells possessed both characteristics of dye-sensitized and bulk heterojunction solar cells. These encouraging results show the advantages of fullerenes as electron acceptors in artificial photosynthetic models, photonic molecular devices and machines, and organic molecular electronics including solar cells.

55.4 Great Expectations: Oxygen and Hydrogen Gas Production

55.4.1 Oxygen Evolution

55.4.1.1 Native Oxygen-Evolving System

Through water oxidation, oxygen is continuously generated by oxygenic photosynthetic organisms (i.e., plants, algae, and cyanobacteria), which maintain the level of O_2 in the atmosphere presently around 21%. This paramount task is accomplished by use of a catalyst called oxygen-evolving complex (OEC, see the e-donor catalytic site in [Figure 55.1](#)). Due to its vital role in the development and maintenance of the present terrestrial conditions for life, its importance cannot be overestimated (“the most important catalyst on Earth”). The OEC is an extrinsic subunit of the PSII consisting of a cluster of four manganese ions, one calcium ion and one chloride ion. The latter is required in the oxygen evolution but the structural and chemical details are not yet clear.

The OEC is responsible for transfer of four electrons from water to the photo-oxidized chlorophyll dimer of the D1D2-RC. The extremely highly oxidizing P^+ is rereduced by a deprotonated tyrosine residue (Tyr_Z or Y_Z) that is subsequently rereduced by the OEC (see [Figure 55.P3](#) in the color insert) in the color insert). The ET steps on the donor side of the PSII RC are very fast, much faster than the oxygen evolution. The observed period 4 damped oscillation of the oxygen evolution upon trains of saturating flashes was the first evidence that the Mn_4Ca cluster accumulated the oxidizing equivalents in five, so-called S (S_0 , S_1 , S_2 , S_3 , and S_4) states [81,82]. The values of the subscript of the S states indicate the oxidation state of the enzyme. In dark-adapted state, the OEC is found in a mixture of S_0 and S_1 states (usually in 25%–75% ratio) and, omitting the trivial waste processes of misses and double hits, the oxidation state of the enzyme increases stepwise after each saturating flashes of light (or ET steps) (Kok’s clock). Finally, the S_4 state converts to S_0 state accompanied by splitting of the two water molecules ligated to the Mn_4Ca cluster resulting the release of one oxygen molecule and four H^+ ions.

Unrevealing the chemistry and the structure–function relationship is the key point to understand the function of the chemical core of the OEC and to attempt the mimicry of such indispensable enzyme [83].

55.4.1.2 Attempts to Artificial Water Splitting

The hardest but most wanted part of mimicking natural photosynthesis is splitting the water molecules to get the electrons and protons necessary to sustain additional chemical process including the reduction of CO_2 . Under standard conditions, water can be reversibly electrolyzed at redox potential of $+0.81\text{ V} - (-0.41\text{ V}) = +1.22\text{ V}$ ([Figure 55.10](#)). As splitting water requires energy input of about 2.5 eV, the oxidation of water requires a catalyst (e-donor catalytic site). Similarly, the reduction of proton needs catalyst, as well (e-acceptor catalytic site). The catalysts react with photons to initiate the chemical reactions. The e-acceptor site catalyst must be more negative than -0.41 V , the e-donor site catalyst must be more positive than 0.81 eV, and visible light ($\lambda > 400\text{ nm}$) should be applied.

In addition to the energy level requirements shown in [Figure 55.10](#), it is important to suppress back ET by kinetic design of the ET reactions and/or by adoption of a heterogeneous phase to achieve unidirectional ET.

In construction of artificial systems, we have to face with additional difficulty that arises from coupling of photoinduced CS with oxygen evolution or reduction of CO_2 because different numbers of electrons are involved in these chemical reactions. CS is a one-photon and one-electron process whereas water splitting is a four-electron process. In natural photosynthesis, the problem is solved by the magnificent Mn_4Ca cluster that (1) releases electrons in a stepwise manner at constant potential and (2) oxidizes water molecules in a concerted way avoiding the formation of high-energy intermediates. Such multiple ET process is coupled to proton transfer (proton-coupled electron transfer [PCET]) and becomes thermodynamically favorable [84]. Unfortunately, such efficient catalyst cannot be used directly in artificial systems, and the design of specific multielectron redox catalysts remains a fascinating and challenging but yet unsolved problem.

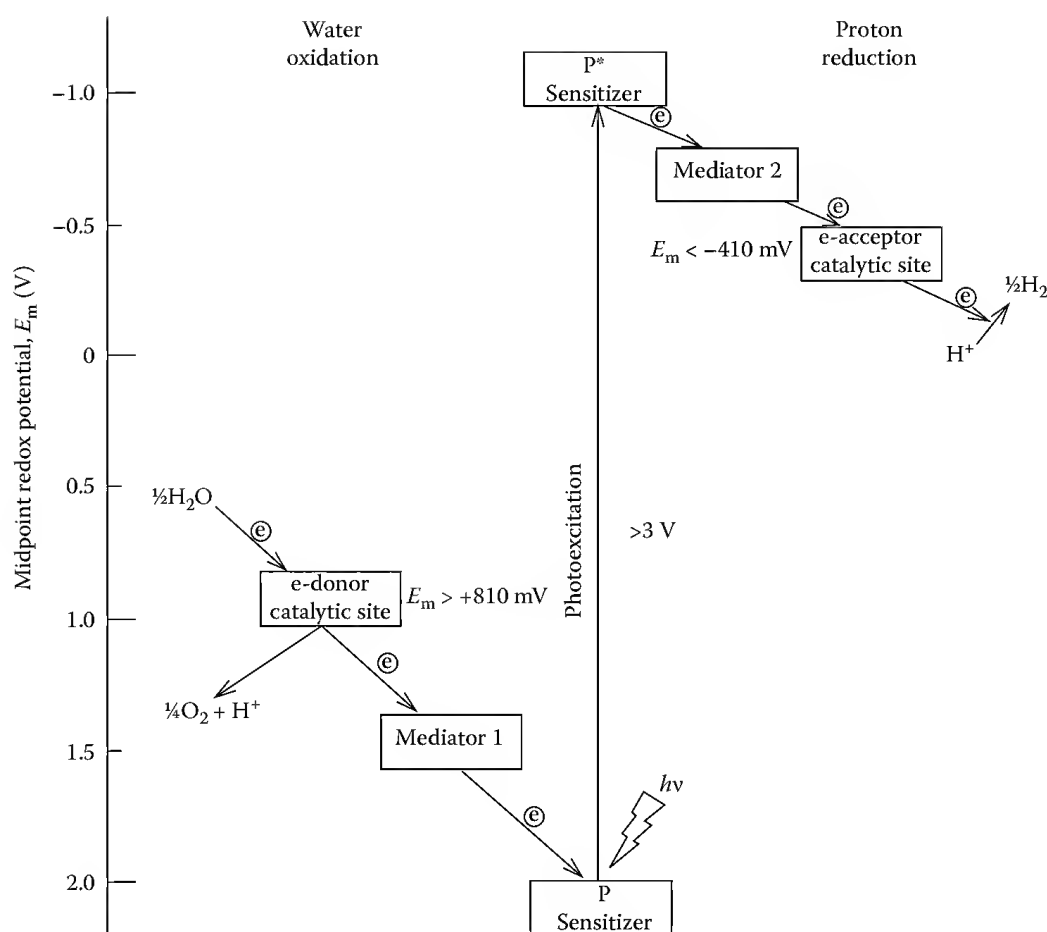

FIGURE 55.10 A schematic view of the electron flow and energy level requirements of sensitizer (P), catalytic sites, and mediators to oxidize water and to reduce proton (or CO_2). The minimum difference of the midpoint redox potentials between the two catalytic sites is $\Delta E_m = 1.23 \text{ V}$. P can be a dye sensitizer (often metal complex), small bandgap semiconductor or dye-sensitized large bandgap semiconductor. Selection of appropriate catalysts and mediators is a key problem of current research.

55.4.1.3 Molecular Catalysts for Water Oxidation

Photooxidation of water molecules into oxygen, electrons, and protons (hydrogen ions) is one of the two essential half reactions of artificial photosynthetic systems—it provides the electrons needed to reduce carbon dioxide to a fuel. Effective photooxidation requires a catalyst that is both efficient in its use of solar photons and fast enough to keep up with solar flux in order to avoid wasting those photons.

The last 10 years have witnessed important advances in this area but we are still far away from our great expectation [85]. We will list here a few of the more successful catalysts.

55.4.1.3.1 Manganese

Manganese-based organometallic complexes have been employed to model off photosystem II, showing some promises as photocatalysts for water oxidation. However, the manganese that acts as a catalyst in plants does not work as well in a man-made setup, mostly because of the poor water solubility, easy degradation, and less robustness. Additional disadvantage is that the molecular geometry in plants is extraordinarily complex and exact and man-made setups cannot replicate that level of intricacy. Presently, the manganese-based artificial systems are inefficient and impractical.

55.4.1.3.2 Manganese–Ruthenium Complexes

Among the several multifunctional supramolecular complexes that are currently designing and synthesized hoping to achieve the light-driven oxidation of water, oligopyridine Ru(II) complexes are frequently chosen [86,87] because of their suited photochemical, photophysical, and electrochemical properties [88]. A variety of mono- and multinuclear Mn(II) complexes have been covalently linked to such complexes. Furthermore, inspired by the presence of tyrosine as a mediator in the photooxidation of the Mn cluster in PSII, tyrosines or another type of phenol moieties were introduced in the model systems. One example of such systems is given in Figure 55.11, where a dinuclear Mn complex linked to a Ru(II) complex is shown. The photogenerated excited state of the Ru(II) complex is quenched by ET to an external electron acceptor. Subsequently, the Ru(III) complex is rereduced by rapid intramolecular ET either from the Mn cluster ($k > 1 \times 10^7 \text{ s}^{-1}$) or from the tyrosine unit. The dinuclear Mn complex is oxidized to the Mn(II)–Mn(III) state, or a tyrosine radical is generated. The Mn cluster has appropriate redox properties and is capable of multiple ET needed for splitting water molecules. The model system closely mimics the primary reaction steps on the donor side of PSII, but as yet catalytic water oxidation has not been achieved.

Beside the almost overwhelming demand of splitting water with the aid of sunlight (artificial photosynthesis), the serious drawback associated with the formation of very aggressive substances in the process of water oxidation needs to be addressed. Plants solve this problem by constantly repairing and/or replacing a part of their green catalysts, but such evolved mechanism is far from being achieved

FIGURE 55.11 Manganese center in natural and artificial catalytic sites. (A) 3D structure of the OEC of PSII from the cyanobacterium *T. elongatus* at 3.5 Å resolution [141]. The white spheres represent the four oxygen atoms, the gray spheres the four manganese (Mn_i) atoms, and the black sphere the bivalent calcium (Ca) ion (in the front bottom corner). (B) Light-induced intramolecular ET in binuclear Mn(II) and Ru(II) complex as model system of the donor and acceptor sides of the PSII RC. The Ru(II) complex is photoexcited (Ru(II) → Ru(II)*), quenched, and oxidized by ET to an external electron acceptor (Ru(II)* → Ru(III)) and rapidly rereduced from the Mn cluster or from the tyrosine unit (Ru(III) → Ru(II)).

in artificial systems. Notwithstanding this, stable catalysts are being designed. Recently, tetraruthenium complexes were synthesized as stable catalyst for water oxidation [89]. The metal oxide cluster with a core of four ruthenium ions catalyzes the fast and effective oxidation of water to oxygen while remaining stable itself. This water-soluble complex—effective in water solution already at room temperature—does not contain any organic components, which presumably would explain its high stability. Presently, such catalyst has only been used with chemical oxidants, but the following step is its integration into photo-active system which efficiently converts solar energy into chemical energy.

55.4.1.3.3 Cobalt Oxide

One of the more recently discovered catalysts, clusters of nanosized cobalt oxide molecules (CoO) have been found to be a very stable and robust system and can be efficiently employed in artificial photosynthetic systems [90]. Cobalt oxide is currently a popular industrial catalyst. Rod-shaped nanocrystals of cobalt oxide were found effective in water-splitting molecules, with a turnover rate slightly higher than 1000 oxygen molecules produced per second per cluster cobalt oxide (Co₃O₄) which is commensurate with solar flux at ground level ($\sim 1 \text{ kW} \cdot \text{m}^{-2}$). Interestingly, the oxygen evolution yield of cobalt oxide clusters of micrometric size is 1600 times smaller than in nanostructured systems. While the catalytic efficiency of the cobalt metal itself was important, the size of the bundled clusters was the major factor behind the enhanced efficiency and rate. The comparatively very large internal area of the bundles (where catalysis takes place) was the cause of the increased efficiency. The efficiency, turnover rate, and size of the cobalt oxide nanocrystal clusters are comparable to the similar characteristics of photosystem II. Due to the abundance of cobalt oxide, the stability of the nanoclusters, the modest overpotential, and the mild pH and temperature conditions, it is believed a promising catalytic component of an artificial photosystem. The next big step, however, will be to integrate the water oxidation half reaction with the carbon dioxide reduction step in an artificial leaf type system.

A cheap and promising new catalyst that produces oxygen from water without the need for excessive driving potentials is being developed [91]. An inert ITO electrode is immersed in water containing Co²⁺ and potassium phosphate buffer in 2:1 ratio. The electric potential on the electrode will produce cobalt-based catalyst *in situ* that oxidizes the water to oxygen gas and hydrogen ions. On the opposite electrode, coated with platinum, protons are reduced to H₂ gas. During operation, the cobalt-based catalyst falls apart, but cobalt and potassium phosphate in the solution soon reaggregate replenishing the catalyst.

The discovery of the new catalyst earned wide public interest but much research and engineering work need to be done before it can be incorporated into commercial devices: (1) It should be revealed how the catalyst is driving the water oxidation reaction. (2) The rate of oxygen production by the catalyst is small and should be increased. (3) In strict sense, the process has nothing to do with photosynthesis *per se*, but involves an improved electrode for “splitting water” by electrolysis to generate oxygen at a lower potential than normal. A light-harvesting material has to be developed that absorbs sunlight and generates the electrons needed to power the water-splitting catalyst. (4) Although the catalyst does split water, it does not produce hydrogen gas (H₂). A second electrode and a different catalyst will be needed to combine the electrons and the hydrogen ions from water to make hydrogen gas.

In some devices, the primary problem is not the design and construction of the catalyst but the electrolyte solution that absorbs the protons from the split water molecules. It can cause essential problems in the current state-of-the-art dye-sensitized cells, where the electrolyte is made of volatile solvents that can erode other components in the system. Advances in the last few years are starting to address these issues. Cobalt oxide is a stable, fast and abundant metal oxide. Researchers have come up with a non-solvent-based solution to replace the corrosive stuff in dye-sensitized cells.

55.4.1.3.4 Dye-Sensitized Titanium Dioxide

Titanium dioxide (TiO₂) is a stable oxide that can act as an efficient catalyst. It is used in a dye-sensitized solar cell, also known as a Grätzel cell [92]. The TiO₂ is suspended in a layer of dye particles that captures the sunlight and then exposes it to the TiO₂ to start the reaction. The Grätzel cell as all other molecular

PVs has to face with the fundamental roadblock at nanoscale. How to build nanostructures that reconcile the short diffusion lengths of charge carriers (due to the dimension of the structure) with the long optical light path for visible light (expected for efficient absorption of the light excitation)? The Grätzel cell tries to solve this dilemma with a serpentine (and random) matrix.

55.4.2 Carbon Fixation

The light-driven reduction of CO₂ to organic compounds as principal bioenergetic process should have appeared long before the emergence of photosynthesis and might have played key role in origin of life on the Earth [93,94]. The primordial atmosphere dominated by carbon dioxide (similarly as presently on Mars and Venus, where CO₂ still makes 95% of the atmosphere) and ultraviolet (UV) light-driven reactions were capable to reduce CO₂ to organic compounds in solution or at semiconducting minerals, such as TiO₂, MnS, or ZnS [95]. While Fe²⁺-catalyzed reduction of CO₂ in solution can occur with a quantum yield of 2%–3% only [96,97], the photoreduction of CO₂ to formate by colloidal ZnS particles shows much higher quantum yield of 80% [98]. The ability to store the solar energy and to drive CO₂ reduction is due to the depth of electron traps within the ZnS nanocrystals (nanoparticles) (see Figure 55.1).

55.4.2.1 Photosynthetic CO₂ Reduction, Native System

Natural photosynthesis by chlorophyll molecules involves the generation of carbohydrates and oxygen from the abundant raw materials CO₂ and H₂O at the expense of the driving force of the sun. On the other end, the photosynthesis is balanced by dark processes resulting in the oxidation of the reduced carbon compounds back to CO₂ and H₂O through combustion, decay, and cellular respiration. The two processes take place through a different sequence of chemical reactions and in different cellular compartments. Life on earth is sustained by maintaining the balance between the production and removal of atmospheric CO₂.

The dark reactions of photosynthesis in the chloroplast stroma are responsible for the biosynthesis of the carbohydrate that can occur even in the absence of photosynthetic electron transport. The biosynthetic reactions are catalyzed by a series of soluble enzymes, known collectively as the Calvin–Benson cycle. The enzyme RuBisCo (ribulose-1,5-bisphosphate carboxylase oxygenase) captures CO₂ from the atmosphere, and the cycle releases three-carbon sugars, which are later combined to form sucrose and starch. The overall equation is

that can be broken down into three major components:

1. Carbohydrate biosynthesis requires a source of electrons to ultimately reduce carbon dioxide to carbohydrate. The source is the oxidation of the NADPH produced during photosynthetic electron transport: $12\text{NADPH} + 12\text{H}^+ \rightarrow 12\text{NADP}^+ + 24\text{H}^+ + 24\text{e}^-$.
2. Utilization of atmospheric CO₂ for the synthesis of glucose using the electrons available from the oxidation of NADPH to NADP⁺: $6\text{CO}_2 + 24\text{e}^- + 24\text{H}^+ \rightarrow \text{C}_6\text{H}_{12}\text{O}_6 + 6\text{H}_2\text{O}$.
3. Utilization of ATP produced during photosynthetic electron transport. Carbohydrate biosynthesis from carbon dioxide is an endergonic process. It is coupled to the hydrolysis of ATP, a highly exergonic reaction: $18\text{ATP} + 18\text{H}_2\text{O} \rightarrow 18\text{ADP} + 18\text{P}_i$.

By catalyzing the first major step of carbon fixation, RuBisCo is the key enzyme of the Calvin–Benson cycle. It is not only the major protein component of the chloroplast stroma but also considered to be the single most abundant protein on Earth [99,100]. It accounts for 50% of soluble leaf proteins in C3 plants (20%–30% of total leaf nitrogen) and 30% of soluble leaf proteins in C4 plants (5%–9% of total leaf nitrogen).

Although RuBisCo is one of the most important proteins in the nature, it is also one of the most inefficient as it reacts not only with carbon dioxide but also quite often with oxygen. This did not cause any problems to the protein developed three billion years ago. Back then, there was no oxygen present in the atmosphere. However, as more and more oxygen accumulated, RuBisCo could not adjust to this change. Nowadays, O_2 and CO_2 compete with similar affinities to the same active site of RuBisCo which decreases the efficiency of CO_2 fixation significantly. The carbon fixation by RuBisCo can be enhanced by increasing the carbon dioxide level in the compartment containing RuBisCo (chloroplast stroma). The use of oxygen as a substrate is an apparently puzzling process, since it seems to throw away the captured energy. However, it may be a mechanism for preventing overload during periods of high light flux. This weakness in the enzyme is the cause of photorespiration, such that healthy leaves in bright light may have zero net carbon fixation when the ratio of O_2 to CO_2 reaches a threshold at which oxygen is fixed instead of carbon.

RuBisCo is not only inefficient but also a slow enzyme, being able to “fix” only three CO_2 molecules each second. Nevertheless, because of its extremely large concentration, under most conditions, and, when light is not otherwise limiting photosynthesis, the reaction of RuBisCo responds positively to increasing CO_2 concentration; therefore, the concentration of carbon dioxide is limiting. The ultimate rate-limiting factor of the Calvin cycle is RuBisCo, which cannot be ameliorated in short time by any other factors.

Since RuBisCo is often rate limiting for photosynthesis in plants, it may be possible to improve photosynthetic efficiency by modifying RuBisCo genes in plants to increase its catalytic activity and/or decrease the rate of the oxygenation activity [101]. This could improve biosequestration of CO_2 and be an important climate change strategy. Approaches that have begun to be investigated include expressing RuBisCo genes from one organism in another organism, increasing the level of expression of RuBisCo subunits, expressing RuBisCo small chains from the chloroplast DNA, and altering RuBisCo genes so as to try to increase specificity for carbon dioxide or otherwise increase the rate of carbon fixation [102].

The protein RuBisCo is a large molecular complex consisting of 16 subunits, which made it impossible its reconstruction or artificial synthesis. The obstacle, however, is partly defeated as artificial production and modification of RuBisCo with the help of cellular chaperones were reported recently [103,104]. The correct folding of the enzyme was controlled by chaperons. The combination of this technique with genetic modification can create RuBisCo, which binds CO_2 stronger and metabolizes oxygen less frequently than the native enzyme.

55.4.2.2 Photocatalytic Reduction of CO_2 , Artificial Systems

The CO_2 reduction process is thermodynamically uphill. The midpoint redox potentials, E_m° (vs. a normal hydrogen electrode (NHE) at pH = 7), are -1.9 eV for the reduction of CO_2 to CO_2^- (one-electron process), -0.61 eV to formic acid ($HCOOH$), -0.53 eV to carbon monoxide (CO) (two-electron/proton processes), and -0.38 eV to methanol (CH_3OH) (six-electron/proton process). Economical CO_2 fixation is possible if solar energy is used as the free energy source. The fact that the proton-assisted and multielectron routes to these products require much less energy than the one-electron process suggests that it might have considerable advantage to employ multielectron transfer routes using transition metal complexes. Reduced metal centers, in which the oxidation number of the central metal is +1 and the ligand has four-coordinating atoms, typically have one or more vacant coordinate sites which can be used to bind and activate CO_2 .

The artificial photocatalytic systems developed to reduce CO_2 have several common elements: they all contain photosensitizers (such as metalloporphyrins, ruthenium, or rhenium complexes with bipyridine), electron mediators or catalysts, and sacrificial electron donors (such as tertiary amines or ascorbic acid). Here, we will focus on artificial photosynthesis that is driven by photon absorption, CS through ET reactions, and energy storage in dark reaction, similar to the processes occurring in natural photosynthetic systems. From the development of artificial photochemical systems that carry out photocatalytic reduction of CO_2 , one can expect the partial solution of the twin problem: the utilization of atmospheric CO_2 and the limited access to fossil fuel sources.

55.4.2.2.1 Ru–Re Photocatalyst

Several catalysts were tested and characterized in artificial photosystems which were able to reduce CO_2 . Among these photocatalysts, the ruthenium–rhenium (Ru–Re) supramolecular complex has proved to be efficient to reduce CO_2 to CO by sunlight [105,106] (see Figure 55.12).

The Re complex has an excellent photocatalytic performance to reduce CO_2 . The rhenium–diimine tricarbonyl complex shows a quantum efficiency of 0.59 in an environment where a reductant such as amine coexists. However, it has absorption in the (ultra)violet region (shorter than 450 nm), not in the visible range. The Ru complex, which is an excellent photosensitizer, absorbs in the visible spectral range (longer than 500 nm) with a high quantum efficiency of 0.21. The combination of the Re complex, which has a high photocatalytic performance, with the Ru complex, which is an excellent sensitizer is a straightforward molecular design. There are many candidates for the compositions and structures to loosely combine the Re complex. The rhenium–trisdiimine complex with Ru complex demonstrated recently quantum efficiency as high as 0.34. The photocatalytic performance of the Re complex deteriorates when the two complexes are simply bonded. It turned out that the nonconjugated system is superior to the conjugated system. To develop a stable and practical supramolecular complex, the molecular design should be improved including the Re complex structure and the optimization of the length of the bridging ligand between the Re and Ru complexes in the nonconjugated system.

55.4.2.2.2 Carbon Nanotubes

As the synthesis of carbohydrates can only proceed when several energized electrons are available, you need to have multiple electrons in photosynthesis. A multiple electron system would comprise a donor molecule that can absorb visible light and release many electrons, and a receiver (acceptor) molecule capable of accepting and storing those electrons (Figure 55.13).

Single-walled carbon nanotubes (SWNTs) could act as the chemical heart of such a multiple electron system using isolated bacterial RC [107], Zn-porphyrin systems [67] (Figure 55.13), or phthalocyanine (PC) molecules [108]. A carbon nanotube can accept one electron for every 32 carbon atoms it contains,

FIGURE 55.12 Ruthenium–rhenium (Ru–Re) supramolecular complex as photocatalyst of reduction CO_2 to CO by light. Electrons move from the light-excited ruthenium complex toward the rhenium complex where the CO_2 is reduced to CO at the Re catalytic site, in the presence of two alternative ligands (NCS^- and Cl^-). (Redrawn from Takeda, H. et al., *J. Am. Chem. Soc.*, 130(6), 2023, 2008.)

FIGURE 55.13 Building block of molecularly controlled integration of SWNT with Zn-porphyrin systems into nanostructured device. (Adapted from Guldi, D.M. and Imahori, H., *J Porphyr Phthalocyanines*, 8(7), 976, 2004.) The organization in solution is achieved by electrostatic interactions between linkers ($L^{-/+}$) attached to SWNT and $ZnP^{8(+/-)}$. While the SWNTs are good electron acceptors and, at the same time, 1D nanowires, the Zn-porphyrin acts as an excited-state electron donor. Their combination is a fundamental design consideration and signifies an innovative concept to harvest solar energy and to convert it into useful electricity.

and so even a short nanotube accepts many electrons. That means a carbon nanotube could act as the acceptor molecule in artificial photosynthesis. On the donor side, the PC molecule does release a single electron when it absorbs light, but by covalently bonding a large number of PCs to a carbon nanotube, they could create a multiple electron system activated by visible light. One hundred and twenty PC molecules can be bound to a nanotube just 1 μm long; thus, multiple electrons are simultaneously or sequentially transferred to the nanotube upon light absorption and multiple-CS states are formed. About 25% of the electrons donated from those PCs end up being stored in the nanotube. The extra electrons stored in the nanotubes could be used to convert NADP into NADPH. In the Calvin cycle, NADPH helps to fix carbon dioxide to form glucose, the end product of photosynthesis.

55.4.3 Hydrogen Production

55.4.3.1 Photosynthetic Hydrogen Production

Hydrogen can be produced from water by use of biological catalysts that have been optimized by nature: the process of water-splitting photosynthesis on one hand and hydrogen production via the catalyst hydrogenase on the other (Figure 55.14).

Indeed, under certain conditions, instead of reducing CO_2 , a few groups of microalgae and cyanobacteria consume biochemical energy to produce molecular hydrogen [109]. The original discovery dates back to 1942, when Gaffron and Rubin reported that the green algae *Scenedesmus* produced molecular hydrogen upon illumination after being kept in darkness and under anaerobic conditions [110]. It was found recently that *Chlamydomonas reinhardtii* algae switched from the production of oxygen, as in normal photosynthesis, to the production of hydrogen if deprived of sulfur [111]. The key enzyme is the hydrogenase that catalyzes the most elementary reaction that can be imagined in biochemistry: it synthesizes one H_2 molecule from two protons (H^+ ions) and two electrons. The reducing power (electron donation) of hydrogenase does not always come from water, but may sometimes originate intracellularly from organic (carbon) compounds such as starch. The contribution of the fermentation pathway to

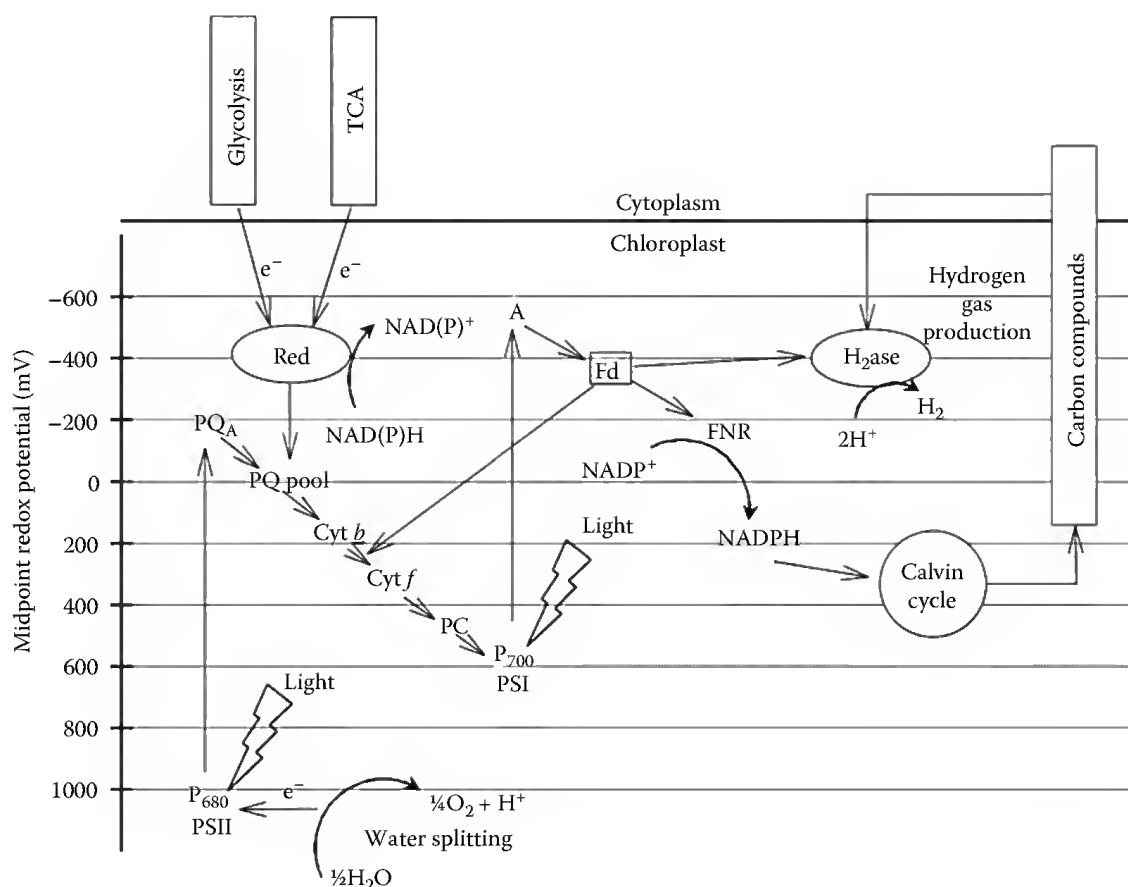

FIGURE 55.14 Coupling of photosynthetic electron transport and hydrogenase in green algae: H_2 gas production in expense of light and water splitting. Electrons (thin arrows) originate either at PSII upon photooxidation of water or at the PQ pool upon oxidation of cellular endogenous substrate (e.g., via glycolysis and the tricarboxylic acid cycle [TCA]) through NAD(P)H oxidoreductase [Red]). Electrons are transported via PSI to ferredoxin (Fd), which plays a pivotal role in distribution of electrons among Fe-hydrogenase (H_2 ase), cytochromes (Cyt *b* and Cyt *f*) of the Cyt *b*₆ complex (cyclic electron flow), and FNR. The other route of electrons to H_2 ase is the fermentative pathway of carbon compounds in the Calvin cycle. Additional abbreviations: P₆₈₀, RC of PSII; P₇₀₀, RC of PSI; P_{QA}, primary electron acceptor of PSII; A, primary electron acceptor of PSI; PQ, plastoquinone and PC, plastocyanin.

hydrogen production depends on the algal species and on culture conditions. The reason for hydrogenase inactivity in green algae under normal photosynthetic growth conditions is unclear. Hydrogenase is thought to become active in order to excrete excess reducing power under specific conditions, such as anaerobic conditions. The hydrogenase of green algae, however, is too oxygen-labile, and the light-dependent hydrogen production ceases within a few to several tens of minutes since photosynthetically produced oxygen inhibits or inactivates the enzyme.

Beside of hydrogenase, nitrogenase enzyme is also capable of hydrogen production. In 1974, Benemann and Weare demonstrated that a nitrogen-fixing cyanobacterium, *Anabaena cylindrica*, produced hydrogen and oxygen gases simultaneously in argon atmosphere for several hours [112]. Nitrogenase is responsible for nitrogen fixation by reduction of molecular nitrogen to ammonium with consumption of reducing power of ferredoxin and free energy of ATP. However, nitrogenase catalyzes proton reduction in the absence of nitrogen gas (i.e., in argon atmosphere). Hydrogen production catalyzed by nitrogenase occurs as a side reaction at a rate of one-third to one-fourth that of nitrogen fixation, even in 100% nitrogen gas atmosphere. Nitrogenase itself is extremely oxygen-labile. Unlike in the case of hydrogenase, however, cyanobacteria have developed mechanisms for protecting nitrogenase from oxygen gas and supplying it with energy (ATP) and reducing power.

In addition to cyanobacteria and green algae, some nonsulfur anoxygenic photosynthetic bacteria are also potent hydrogen producers, utilizing organic acids such as lactic, succinic, and butyric acids, or alcohols as electron donors. Since light energy is not required for water oxidation, the efficiency of light energy conversion to hydrogen gas by photosynthetic bacteria is in principle much higher than that by cyanobacteria. Hydrogen production by photosynthetic bacteria is mediated by nitrogenase activity, although hydrogenases may be active for both hydrogen production and hydrogen uptake under some conditions. Using *Rhodobacter* species, the maximum energy conversion efficiency (combustion energy of hydrogen gas produced/incident light energy) was 6%–8% in laboratory experiments [113].

55.4.3.2 Bioinspired Hydrogen Production

The potential combination of photosynthetic water oxidation and biophotolytic hydrogen production has been an enormous challenge to design photosynthesis-based artificial systems. Instead of complete treatment of the problem in one big step, several smaller steps have been made with partial solutions of related subproblems.

The self-organized platinization of the photosystem I nanoparticles from thermophilic cyanobacterium *Thermosynechococcus elongatus* allowed electron transport from sodium ascorbate to photosystem I via cytochrome c_6 and finally to the platinum catalyst, where hydrogen gas is formed upon illumination [114]. The maximum yield was $\sim 5.5 \mu\text{mol H}_2 \text{ h}^{-1} \text{ mg}^{-1}$ chlorophyll that hoped to be improved by replacing the platinum catalyst with a renewable and covalently linked hydrogenase to the acceptor end of the PSI complexes.

Following the determination of the 3D structure of the active site of NiFe hydrogenases, a variety of nickel-based complexes as potential electrocatalysts for hydrogen production were synthesized [115,116]. These catalysts may provide an adequate alternative to platinum. This biomimetic structural approach, however, could not fulfill the expectations yet, as no activity was reported for dinuclear biomimetic nickel–iron complexes. The perspective of Ni–Ru complexes as functional models of [Ni–Fe] hydrogenases seems to be more encouraging as they are relatively easy to synthesize, stable in solution, and show high yield and turnover numbers of proton reduction to hydrogen at the expense of relatively high overpotentials (0.5–0.8 V) [117].

A further step of biomimetic approach of light-induced hydrogen production is the coupling of di-iron-(μ -dichlorobenzene-dithiolate)hexacarbonyl ([Fe–Fe] hydrogenase) as catalyst and ruthenium(II)tris-bipyridine as photosensitizer into ruthenium–diiron dyad (Swedish Consortium for Artificial Photosynthesis [1994–2010]). The dyad has rigid geometry, the Ru photosensitizer exhibits prolonged excited state lifetimes, and the catalysis can be tuned to mild potentials by attachment of aromatic dithiolate ligands to the diiron complex. Using ascorbic acid as both proton and electron donors, the dyad started to produce hydrogen at a rate of $4 \mu\text{mol H}_2 \cdot \text{h}^{-1}$ but quitted to evolve H_2 after 100 turnovers (2.6 mL typical sample volume, H_2O :dimethylformamide 1:1 solvent, Ar atmosphere, pH 5.5, 0.1 M ascorbic acid, 140 μM sensitizer, 14 μM catalyst, 455 nm long-pass filter + infrared filter, and ~ 1 W light power). The chemical LEGO is supposed to be completed if the ascorbic acid is replaced by an Mn complex for water oxidation and linked to the Ru photosensitizer.

An alternative to the supramolecular (biomimetic) chemistry is the engineered natural systems including the (genetic) modification of the molecular machinery of living organisms (biophotolytic hydrogen production [37,118]). In special cells (heterocyst) of cyanobacterium *Nostoc*, hydrogen gas is formed from nitrogenase and electrons that enter the heterocyst from neighboring vegetative cells as a result of light-induced photosynthetic activity. The native nitrogenase is tried to be replaced by hydrogenase to get higher yield of hydrogen production [119].

The crucial step of water-splitting-based hydrogen production is the coupling of photosynthetic electron flow with hydrogenase. The key element is the ferredoxin that plays as the switching point for cyclic electron transport, CO_2 fixation (via ferredoxin, NADPH oxidoreductase [FNR], and NADPH) and hydrogen production (Figure 55.14). The main question of improvement of biosolar H_2 production is how to redirect the flux of electrons through PSI and ferredoxin into hydrogenase by downregulating the competing pathways.

Several pathways have been observed for light-induced H_2 production from water in natural photosynthetic microbes, and two pathways have proved to be encouraging candidates for realization in bioinspired systems (Figure 55.14). The first pathway, given by the overall stoichiometry of $H_2O \rightarrow H_2 + \frac{1}{2}O_2$, requires the two photosystems and complete electron transport chain to bring electrons from water to ferredoxin, the physiological electron donor to hydrogenase. This pathway requires four quanta per H_2 evolved and usually occurs concurrently with O_2 evolution in a single temporal stage with no gas separation. The pathway occurs in some cyanobacteria, but is inefficient and occurs appreciably in green algae only under conditions of sulfur deprivation, which significantly reduces PSII activity [120]. If this pathway was able to operate at full PSII capacity, it would require an O_2 -tolerant hydrogenase, a promoter that enables gene expression in the presence of elevated O_2 levels, and a hydrogenase assembly process that is O_2 insensitive. This pathway is efficient in the use of photons, but results in the coevolution of H_2 and O_2 gases which are technically challenging to separate, economically unfeasible, and a safety hazard as mixture.

The second pathway for H_2 formation, which is currently favored, involves electron and proton flow to the plastoquinone (PQ) pool, from fermentation and oxidative carbon metabolism of photosynthetically stored carbon, mediated by a dehydrogenase, through PSI into ferredoxin and then to hydrogenase. The stoichiometry of the indirect two stage pathway is given by

and requires six quanta/ H_2 (assuming all electrons are ultimately derived from water). This pathway is most efficient in two temporally resolved stages, a photosynthetic growth stage followed by an anaerobic stage in which hydrogenase expression is induced and PSI uses light to pump “fixed” electrons derived from stored reductants via the PQ pool to the potential needed to reduce ferredoxin, while the protons are pumped into the thylakoid lumen for use in ATP synthesis. The anaerobic stage requires O_2 to be substantially depleted (cyanobacteria) or virtually eliminated (green algae). The temporal separation of the H_2 - and O_2 -evolving steps is a major advantage for gas separation and safety. Suppression of O_2 -induced inactivation of hydrogenase by attenuation of PSII activity is being implemented by several research teams. They have used sulfur deprivation of green algae to suppress the biosynthetic repair of an essential PSII subunit that is damaged during photoinhibition and requires replacement for recovery of O_2 evolution. Current rates of continuous H_2 photoproduction using the sulfur depletion strategy yield around $2.2 \text{ mL } H_2 \text{ h}^{-1} \text{ L}^{-1}$ culture [121], while rates of $3.5 \text{ mL } H_2 \text{ h}^{-1} \text{ L}^{-1}$ culture have been achieved using the *C. reinhardtii* mutant *Stm6* [122]. Diuron (DCMU) inhibition of PSII suggests that approximately 80% of the H_2 is reportedly being produced from water.

55.5 Protonmotive Force in Artificial Systems

In the biomimetic systems listed earlier, the free energy of the light was converted into energy of chemical products via several steps. The conversion is more direct if the system is capable to generate protonmotive force, which is defined as the sum (linear combination) of electric membrane potential, $\Delta\Psi$ and proton gradient, ΔpH : $\text{pmf} = \Delta\Psi + 60 \text{ mV} \cdot \Delta\text{pH}$ (at room temperature) and then to synthesize ATP. In natural systems, the light excitation moves an electron abruptly across the biological membrane resulting in transmembrane electric potential. The reverse effect is also operating: the local electric field within phospholipid membranes modulates the charge transfer reactions in RCs [123]. By coupling of proton binding/unbinding redox reactions to a sequence of slower ET steps [124,125], proton translocation takes place resulting in pH difference between the two sides of

the membrane. The organism (bacterium) uses the stored chemical energy in form of *pmf* to generate ATP, which can meet all its energy needs.

Several model systems which use light energy to generate *pmf* were prepared and studied based on theory [126] and experiments [127]. As the RC operates as half of a light-driven proton pump in natural photosynthesis [128,129], artificial system can be achieved by insertion of either isolated bacterial RC [130,131] or artificial triad [127,132] into the liposome (Figure 55.15). The heart of the proton pumping system is a liposome vesicle comprising a synthetic phospholipid bilayer, which should be sealed enough to let build up the proton gradient through the membrane [107]. The bilayer is spanned by isolated or artificial RC that undergoes photoinduced ET to generate transmembrane charge-separated state. Shuttle quinones use the CS to transport protons across the membrane and establish proton gradient. The systems effectively mimic the entire process of bacterial photosynthesis. The proton transport can be detected using a pH-sensitive fluorescence indicator dye inside the liposome [130,132]. A *pmf*-powered enzyme, F_0F_1 -ATP synthase from spinach chloroplast (a nanomachine), has been also incorporated into the liposomal bilayer [127,133]. The illumination of the membrane with visible light leads to accumulation of sufficient *pmf* and to flow of protons through

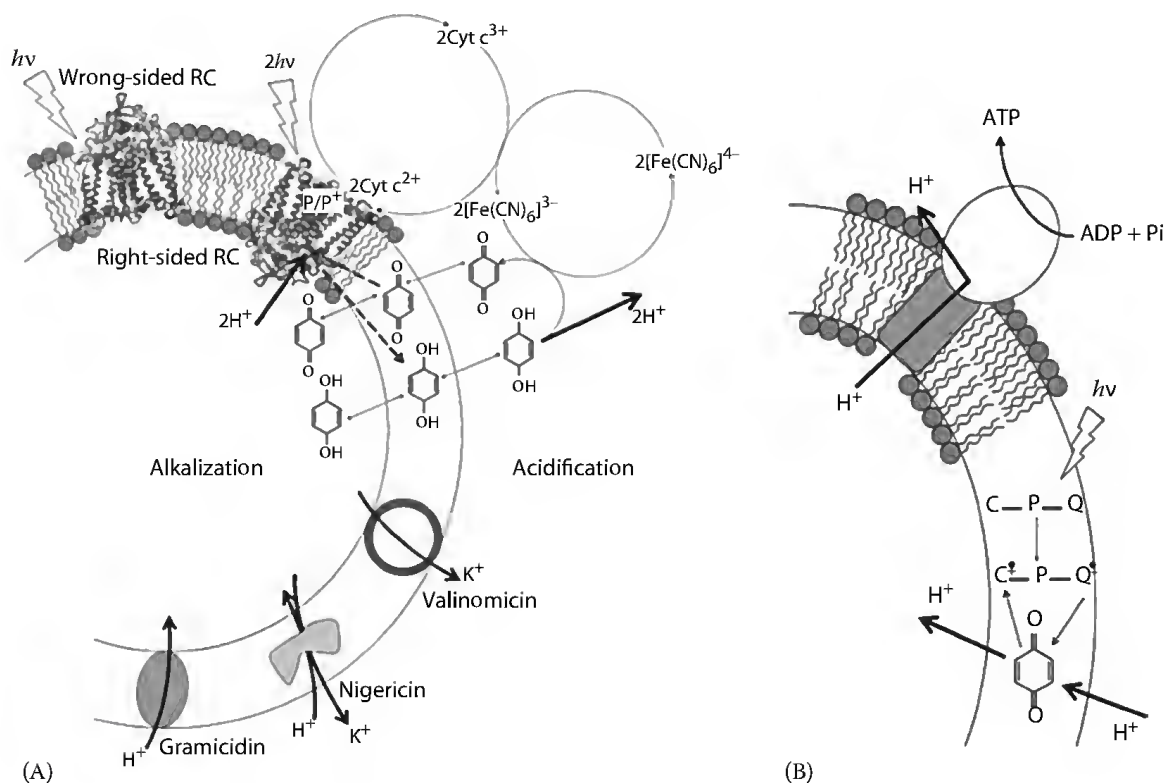

FIGURE 55.15 Generation of light-induced ΔpH by reconstituted bacterial RC [130] (A) and molecular triad [127] (B) in phospholipid vesicle. In (B), the ΔpH is used to drive ATP production. The liposome-based proton pumps are powered by photoinduced CS followed by proton-coupled ET reactions. Protons are taken up from one side (alkalization) and released to the other side (acidification) of the vesicle by a lipid soluble shuttle quinone which is part of the acceptor complex of the RC and undergoes to two-electron chemistry (A) or independent of the molecular triad (2,4-diphenyl benzoquinone) and undergoes to one-electron chemistry (B). Proton pumping results from the asymmetry of the system, ensured by cytochrome in RC vesicle (A). The proton gradient and protonmotive force depend on proton sealing of the vesicle that can be modified by protonophores (gramicidin and nigericin) and ionophore (valinomycin) (A) and by redox and diffusion properties of the shuttle quinone. Abbreviations: P, light-absorbing dimer (A) and tetraarylporphyrin (B); Q, quinone acceptor; C, carotenoid donor; $[Fe(CN)_6]^{3-}$ and $[Fe(CN)_6]^{4-}$, ferrocyanide and ferricyanide, respectively; Cyt, cytochrome.

the F_0F_1 -ATP synthase producing ATP from ADP and P_i . As one molecule of ATP is synthesized per 14 absorbed photons of 633 nm light, up to 4% of the energy incident on the sample is stored by the system. The photocyclic system operates efficiently over a timescale of hours with a turnover rate of seven ATP molecules per F_0F_1 per second. This number is similar to that observed in bacteriorhodopsin/ATP synthase system.

55.6 Efficiency of Solar Energy Conversion

The primary purpose of research of photosynthesis-based artificial photosystems is to capture the solar energy efficiently. The efficiency of conversion of light energy is defined as the usable electrical or harvestable chemical energy output divided by the total solar energy incident on the organism or device. Its limitations are reviewed recently by Gust et al. [134] and Dau and Zaharieva [135]. The question is generally crucial in energy producing artificial photosystems but not so in natural photosynthesis. In several cases, light is not the limiting factor of the growth of the organisms. For example, the key enzyme of the Calvin cycle is RuBisCo that shows low turnover rate and poor affinity to CO_2 resulting in slow (generally rate limiting) step in the overall photosynthesis. Under high light intensity (full sunlight), the plant needs photoprotection against harmful illumination rather than using the absorbed energy for CO_2 fixation. Under this condition, the plant has no need to maximize the efficiency of solar energy conversion, and it can sustain even with relatively low yield of conversion. This leads to formulate a general warning: "The whole complex process of photosynthesis, not to mention the plant's way of life, is certainly not a target for chemical mimicry ... mimick the photosynthesis, but just the best bits" [136].

The main efficiency-limiting factors are (1) the fraction of sunlight absorbed by the organism (or device), (2) the quantum yield of photoconversion, and (3) the photophysical-photochemical processes:

1. The photosynthetic organisms and simple PV devices such as silicon solar cells function as single-threshold systems with two obvious consequences. Photons below the threshold (i.e., having less energy than required for the lowest-energy absorption transition of the pigments [material]) will not be absorbed from the solar spectrum. Photons above the threshold will be absorbed but lose significant portion of their energy as heat during the electronic relaxation processes (internal conversion) that populate the lowest excited state of the chlorophyll (or the conduction band energy of a solar cell). The two opposite tendencies have an optimum value for the threshold (or bandgap) energy of about 1.3 eV (wavelength \approx 910 nm). The photosynthetic bacteria approach this value (see [Figure 55.6](#)). The bandgap in water-oxidizing photosynthesis is about 1.8 eV, well on the high-energy side of the optimum which leads to a loss of about one-fourth of the absorbed energy. Although 90% of incident solar irradiation is absorbed up to 700 nm, the light-harvesting efficiency (LHE) can be maximum 34% of the incident solar irradiation: $LHE < 0.34$. The increase in chemical potential of the charge-separated state with increasing bandgap comes at the expense of the fraction of photons absorbed.
2. The quantum yield of CS (Φ_{quant}) from trapped electronic excitation state of the RC pigment ($P^* \rightarrow P^+Q_A^-$) is very high and approaches the unity: $\Phi_{\text{quant}} > 0.95$ [56].
3. The photochemical free energy conversion processes sacrifice some of the potentially available energy in order to slow CR reactions and drive desired chemical or electrical processes forward. As a result of these factors, a significant fraction of free energy must be lost as heat or delayed fluorescence in any conversion devices. The cost of the charge stabilization is a concomitant loss of stored free energy. In purple photosynthetic bacteria, the initial free energy of 1.38 eV stored in the electron excitation energy of the dimer, P^* (or in the initial charge-separated state $P^+\Phi_A^-$) is gradually decreased upon forward ET (see [Figure 55.6](#)). The rates of forward reactions are 2–3 orders of magnitude larger than those of the back reactions. The largest drop in stored

free energy relative to P^* (860 meV) occurs when the electron is shifted to the primary quinone [52,55,137]. The fractional energy yield (FEY) values of the $P^+Q_A^-$ state is FEY = 38%. Depending on the S states, significantly larger FEY values (60%–75%) characterize the internal free energy conversion efficiencies in higher plants. In typical PV cells, the separated hole and electron are stabilized by an internal electric field at the junction of the *n*- and *p*-type semiconductor materials. The energy associated with separating the charges reduces the electrical energy available in the external circuit.

The total solar conversion energy efficiency (Φ_{total}) is the product of the three efficiencies: $\Phi_{\text{total}} = \text{LHE} \cdot \Phi_{\text{quant}} \cdot \text{FEY}$. The best single-threshold PV devices have efficiencies that approach the Shockley–Quiesser limit of $\Phi_{\text{total}} \approx 30\%$. The Si-based PV cells have $\Phi_{\text{total}} \approx 14.3\%$ efficiency. A new series of amphiphilic heteroleptic ruthenium(II) sensitizers self-assembled on TiO_2 surface from ethanol solution reveal $\Phi_{\text{total}} = 7.4\%$ power conversion efficiency [138]. In contrast, the efficiency of natural photosynthesis is relatively small (maximum about 6% but usually observed to be about 0.3%–0.8%), although the initial steps of plant and bacterial photosynthesis have very high quantum yields. The apparent paradox of a high quantum yield, Φ_{quant} and low total efficiency, Φ_{total} in natural photosynthetic systems can be explained by small FEY that includes losses due to internal conversion, regulatory dissipation, production of NADPH and ATP, CO_2 assimilation, and the energy needed for growth and maintenance of the plant, resulting in a typical efficiency for land plants of 0.3%–0.8%. Interestingly, some algae and cyanobacteria have remarkably higher efficiencies (4.6%) than terrestrial plants. This is because some of the efficiency-limiting factors are more important for large land plants than they are for microalgae in aqueous environments. For example, CO_2 fixation in leaves is often limited by CO_2 diffusion, whereas uptake of inorganic carbon is much less limiting in small organisms with much larger surface/volume ratios. Moreover, because the solubility of CO_2 in water is much higher than that of O_2 , the carbon fixation/carbon oxidation ratio of RuBisCo is much more favorable in aqueous environments. In addition, smaller organisms require less energy investment for chemical transport and for generation of a “skeleton,” and they tend, overall, to have better efficiencies than terrestrial plants.

Water oxidation in photosynthesis is essentially also a single-threshold process and is therefore subject to the Shockley–Quiesser limit of about 30% efficiency. This value is further reduced to maximum $\Phi_{\text{total}} = 10\%$ by taking the following values: two photosystems (two quanta per electron) are used, each with nonoptimal thresholds of 1.83 eV (PSII) and 1.77 eV (PSI), $\Delta E_m = 1.23$ V per e^-/H^+ at 1 bar, FEY = $1.23 \text{ V} / (1.83 \text{ V} + 1.77 \text{ V}) = 34\%$, LHE < 34% and $\Phi_{\text{quant}} \sim 90\%$. Similar value of about 10% describes the total solar energy conversion efficiency of H_2 production driven exclusively by PSII and PSI.

To explore the two-quanta-per-electron issue, artificial RCs are being used in conjunction with dye-sensitized semiconductor photoelectrodes (Grätzel-type photoanodes) to determine the overpotentials necessary to drive water oxidation and H_2 production at rates comparable to the solar photon flux, using biological and bioinspired catalysts. The interplay between natural and artificial constructs could lead to new materials or compounds. For example, the efficiency of the Grätzel PV cell would be substantially improved by a high-potential electron relay mimicking the tyrosine/histidine-based system used by nature in PSII.

55.7 Conclusions

Construction and study of biomimetic photosystems serve two reasons. They allow ready manipulation of individual components at molecular level and test of theoretical and practical suggestions, which are not readily feasible in the natural systems. The artificial systems are helpful in understanding the principles of natural photosynthesis. On the other end, artificial photosystems can be used as power supplies by conversion of sunlight into other useful forms of the free energy. In this field, efficiencies, powers, costs, and pollution are the determining factors whose control is occasionally beyond the capacity of the scientific community. Based on the present knowledge, and possible forecast for the next couple of years,

photosynthesis-mimicked artificial photosystems may have only limited (local) applications due to the not properly clarified principle of operation, the less robust constructions of the devices, and the relatively low total solar energy conversion efficiency. Photosynthesis-based oxygen evolution from water requires the absorption of four photons, at least. If the efficiency of water splitting could be increased to 50% by application of highly sophisticated catalysts (this would be a first ranked achievement in the science), then the quantum yield of O₂ evolution would be as low as 12% only. Semiconductor-based PV cells of higher efficiency, however, are already on the market and the stage is set for their widespread applications even on industrial level.

Although the free energy conversion efficiency of natural photosynthesis is low, it produces liquid fuel that is very convenient for human use. The solar cells have much higher efficiency, but they provide electricity “only.” The goals are clear for a “bioinspired” technology of the future: to get more stable and higher energy conversion efficiency for photosynthesis-based artificial systems and/or to design PV systems with high solar energy conversion efficiency, but resulting in fuels.

56.1 Introduction

The discovery of a fluorescent protein (FP) taking part in the bioluminescence system of jellyfish *Aequorea victoria* dates back to the early 1960s [1]. This protein was named green fluorescent protein (GFP), from its bright green fluorescence obtained by UV–blue light excitation; hereafter, it will be simply referred to as wild-type GFP or wtGFP to be consistent with the scientific nomenclature in use.

Thirty years later, with the cloning of the gene [2] and the demonstration that its expression in other organisms still produces fluorescence [3,4], the interest in wtGFP started to rise dramatically, eventually leading to a revolution in fluorescence microscopy bioimaging [5]. Soon after its cloning, many other fluorescent and nonfluorescent GFP homologues were discovered in a variety of organisms [6,7]. Additionally, protein engineering by sequence mutagenesis has produced a profusion of FPs with optical properties spanning most of the visible spectrum and beyond. Nowadays by the term FPs, it is customary to indicate all fluorescent variants of the original *A. victoria* wtGFP, notwithstanding their actual primary sequence homology. Many natural homologues of GFP are nonfluorescent, though they absorb visible light (chromoproteins or CPs). To provide the reader with some idea about the richness of FP world, Ref. [8] shows the phylogenetic tree of FPs, including some artificial mutants.

The mesmerizing success of FPs in bioimaging owes to the genetic encoding of fluorescence into their primary sequence without any additional help (enzymes, cofactors) from the host organism. This makes it possible to express fluorescent fusion chimeras of any FP with target proteins of relevant biochemical

interest in cells and follow their fate by real-time microscopy imaging. The fluorescent biomarker, coming from an unrelated organism, does not usually perturb the biological processes of the target protein. Hence, FPs represent a nearly perfect bionanodevice to unveil cell mechanisms.

Surprisingly, all known FPs show a remarkable structural similarity. A chromophore moiety, origin of fluorescence, is autocatalytically generated within the conserved β -barrel tertiary structure following a subsequential cyclization and oxidation of an internal tripeptide sequence; for many variants, further reactions can take place, increasing the variety of chromophore structures. A finer tuning originates from the noncovalent interactions of these chromophore structures with the surrounding molecular matrix. The structure-dependent variety of the optical response is surely one of the factors that have contributed to the success of FPs. Indeed, careful engineering of the protein sequence has enabled tailoring FPs to specific imaging techniques in cells. The tunability of FPs upon sequence engineering and careful sequence of the parent protein structure and chromophore represents a challenging, and very stimulating, field for all bioscientists interested in structure–property relationships in biomolecules.

It would be rather impossible to include in a single chapter the full list of developed FP variants together with the sheer number of their applications in molecular biology, biochemistry, and biophysics. For a more detailed overview on this general topic, the reader is referred to the complete reviews by Shaner, Chudakov, and Stepanenko on FPs as general molecular markers [9–11], Ibraheem on FP as general biosensors [12], Bizzarri on FPs as intracellular pH indicators [13], Takanishi and Masi on FPs to probe protein–protein interaction via FRET [14,15], and Lukyanov and Lippincott-Schwartz on photoactivatable FPs for high-resolution applications (including optical nanoscopy) [16,17].

Instead, adopting a physicochemical approach, this chapter focuses on how the protein structure influences the optical properties of FPs. Although it was the first FP to be cloned [2] and functionally expressed in other organisms [3], wtGFP has actually been replaced in most applications by its mutants and homologues. Nonetheless, being one of the best FPs characterized in terms of optical and photophysical properties, it is a suitable starting point to introduce the concepts recurring in this chapter. Hence, the reader is first presented with wtGFP, considered as the “photophysical” archetype of FPs. In Section 56.2.1, the structure and formation of wtGFP chromophore is presented, whereas Sections 56.2.2 and 56.2.3 dwell on the chromophore-related optical properties. Section 56.3 is devoted to the general description of FPs, addressing the chromophore structure and formation at Section 56.3.1, and the optical properties of FPs as derived by structure-induced spectral tuning. Note that FPs are grouped in five families on account of emission color. Finally, at Section 56.4, the role of chromophore protonation in determining the optical characteristics is discussed for FPs from *A. victoria* (avFPs), the protein class that include wtGFP.

56.2 Structure and Optical Properties of wtGFP

56.2.1 Structure and Chromophore Formation

wtGFP is constituted by a single peptide chain of 238 amino acids and 27 kDa molecular weight [5]. X-ray spectroscopy displayed that this sequence folds in a compact cylindrical 3D structure (referred to as β -barrel), whose lateral wall is an 11-stranded β -sheet, with a diameter of 24 Å and a height of 42 Å (Figure 56.1) [18]. Remarkably, all FPs share the β -barrel fold, regardless of the homology of their primary sequence [9]. Differences can be found in quaternary structure, as several natural FPs arrange as tightly bound tetramers or dimers, a feature that initially hampered their applications. Primary sequence mutagenesis, however, were able in most cases to reverse association and yield monomeric variants of the parent proteins.

The β -barrel of wtGFP (and, more generally, of FPs) is capped on both ends by short α -helical sections and run through by a α -helix, which contains the amino acids forming the chromophore. In wtGFP, the chromophore is a 4-(*p*-hydroxybenzylidene) imidazolinone, constituted by two conjugated aromatic rings, one being a six-member aromatic phenol and the other being a five-member imidazolidinone (Scheme 56.1) [5]. The chromophore originates from the posttranslational autocatalytic modification of three consecutive amino acids: Ser⁶⁵–Tyr⁶⁶–Gly⁶⁷ [19,20]. Actually, the formation of the GFP

FIGURE 56.1 3D structure of wtGFP from x-ray analysis [18]. The protein chromophore buried at the center of the tertiary structure is pictured in darker colors.

SCHEME 56.1 Formation of wtGFP chromophore from the cyclization–oxidation–dehydration posttranslational processing of the amino acid triplet Ser⁶⁵–Tyr⁶⁶–Gly⁶⁷ [21].

chromophore comprises three distinct chemical processes and is triggered by the protein folding into the β -barrel tertiary structure [21,22]: in step 1, the tripeptide Ser⁶⁵–Tyr⁶⁶–Gly⁶⁷ cyclizes (Scheme 56.1, Reaction 1); in step 2, the cyclic intermediate is oxidized by molecular oxygen to yield a conjugated structure (Scheme 56.1, Reaction 2); in step 3, a water molecule is released (Scheme 56.1, Reaction 3). The oxidation reaction represents the rate-limiting step of the overall process, and it requires at least 30 min to occur [23]. As demonstrated by the heterologous expression of *Aequorea* GFP gene in other organisms leading to fluorescence, the posttranslational synthesis of the chromophore does not require any jellyfish-specific enzyme [3,4]. Exogenous oxygen is, however, required because in anaerobic conditions wtGFP does not develop fluorescence [4,20].

The imidazolinone five-member heterocyclic ring is a common feature of all known FP chromophores. In wtGFP, the alternating single and double bonds in the bridge region extend the electron delocalization from the phenolate to the carbonyl of the imidazolinone. Efficient visible-light absorption is ultimately determined by this π -conjugated system. It is worth noting that the phenol ring of the chromophore derives entirely from the lateral group of Tyr⁶⁶. This leaves room for the replacement of Tyr⁶⁶ with other amino acids bearing aromatic side chains, such as phenylalanine, histidine, or tryptophan, in view of obtaining different optical properties; indeed, early mutagenesis studies showed that this is actually the case (see Section 56.3.1).

56.2.2 Optical Features of Chemical Model of wtGFP Chromophore

The *intrinsic* chromophore properties were thoroughly investigated by using several synthetic analogues. The established experimental model for the chromophore of wtGFP and many other FP variants derived therefrom is a *p*-hydroxybenzylidene-2,3-dimethylimidazolone or *p*-HBDI [24,25] (Scheme 56.2). Such a model encompasses the relevant π -conjugated system although it lacks the side chain of the first residue of the tripeptide, which is Ser in wtGFP.

p-HBDI bears two main protonation sites: the phenol group and the nonamide nitrogen in the imidazolinone ring (indicated in Scheme 56.2 and in general FP chromophore as N¹). Two protonation sites imply four protonation states, which we indicated as “protonated” **P** (protonated phenol and N¹, net charge: +1), “neutral” **N** (protonated phenol, deprotonated N⁶⁶, net charge: 0), “zwitterionic” **Z** (deprotonated phenol, protonated N¹, net charge: 0), and “anionic” **An** (deprotonated phenol and N¹, net charge: −1; Scheme 56.2). In *p*-HBDI, the **P** → **N** ionization has $pK_a = 1.8$ – 2.4 ,* whereas the **N** → **An** ionization has $pK_a = 8.1$ – 8.5 . The pK_a of **P** → **Z** was determined to be around 6.5 by using a zwitterionic-mimicking *p*-HBDI analogue [26]. These three pK_a values allow for the full thermodynamic description of the protonation reactions for *p*-HBDI (Scheme 56.2). Importantly, this calculation shows that **Z** always accounts for less than 0.01% of its isoelectric counterpart **N**. Hence, above pH = 3, the **N** → **An** ionization is overwhelming and residual presence of **Z** can be neglected.

In *p*-HBDI and similar structures, the four states have different optical properties (Figure 56.2a). The **P**, **N**, and **An** forms display absorption maxima at 387–393, 368–372, and 425–428 nm, respectively, in water [19,26,27]. The redshifted absorption of **P** and **An** states compared to **N** is attributed to extended electronic conjugation, which lowers the $S_0 \rightarrow S_1$ transition energy [28]. Owing to its negligible

SCHEME 56.2 Protonation reaction of the wtGFP chromophore model *p*-HBDI. The four accessible protonation states **P** (protonated), **N** (neutral), **Z** (zwitterionic), and **An** (anionic) and their associated protonation reactions are reported together with the related pK_a values [26,27]. The nonamidic nitrogen of the imidazolinone ring is indicated as N¹.

* Minor variability depends on the addition of a small amount of methanol/ethanol to improve *p*-HBDI solubility.

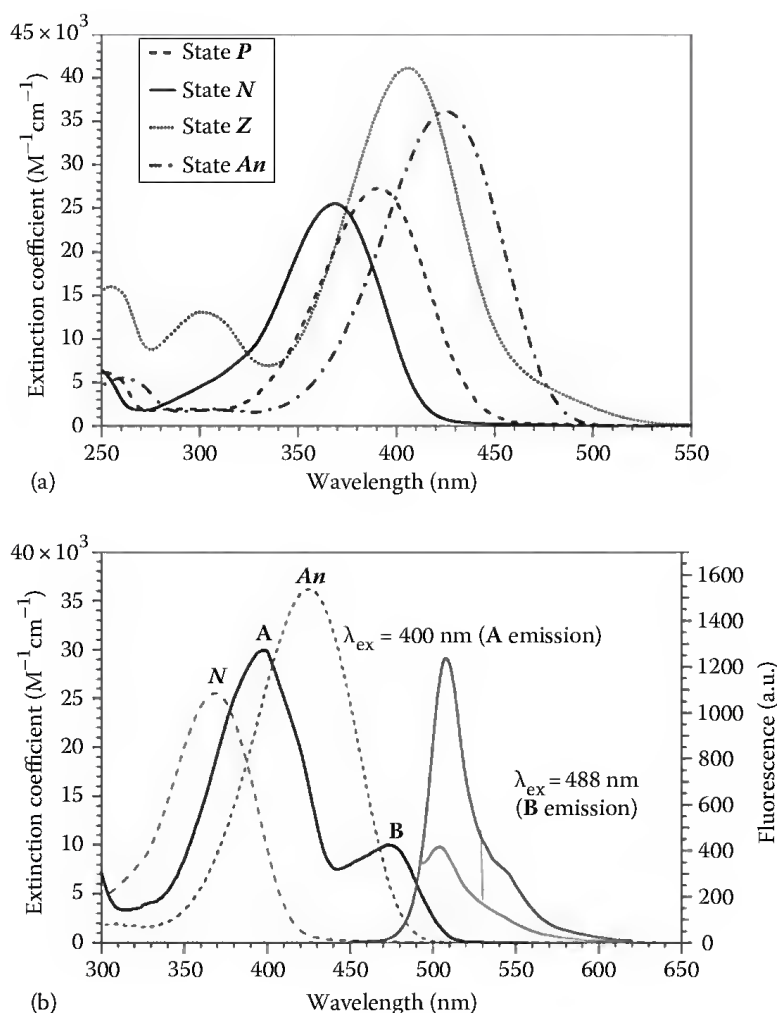

FIGURE 56.2 (a) Absorption spectra of the four protonation states of *p*-HBDI. (b) Absorption (left scale, green curve: states *A* and *B* are indicated) and emission (right scale, red and blue curves: emissions from each absorbing state are indicated) spectra of wtGFP at pH 7.4; the absorption spectra of *N* and *D* states in the denatured protein are added as reference. Note: For nomenclature and structural reference, see Schemes 56.2 and 56.3.

population at any pH, absorption of *Z* is not directly measurable. The aforementioned zwitterionic-mimicking derivative, however, was found to absorb at 406 nm in water (Figure 56.2a) [26].

The solvent sensitivity of *An* absorption (maximum shift from water taken as reference: +57 nm) has been highlighted by several authors [19,26,27]. By contrast, *N* and *P* chromophore states display a much narrower variation range (20 nm). Dong et al. were successful in interpreting these shifts by means of the Kamlet-Taft multivariant equation, indicating that acidic and basic properties of the solvent play a role comparable to that of solvent polarity [26]. The significant solvatochromic shift of the anionic state points to a marked sensitivity to the surrounding environment. As we shall see (Section 56.3), such sensitivity emerges also when the chromophore is embedded in the protein matrix: in different FPs, the absorption corresponding to the anionic chromophore of wtGFP shows a similar, if not larger, range of variation.

The four protonation states of *p*-HBDI display negligible fluorescence emission upon excitation at maximum wavelengths (quantum yields $< 10^{-3}$) [24]. Apparently, the poor emissivity is related to the presence of a fast and efficient deactivation channel that involves intramolecular *hula-twist* torsion of the chromophore in the excited state [29]. Consistently, indeed, *p*-HBDI fluorescence is restored when molecular mobility and the related torsional deactivation channel of the excited state is hampered, that is, at very low temperatures and in high-viscosity media [19,24,29–31].

The absorption and poor-emission properties of *p*-HBDI are mostly retained in the unfolded state of wtGFP, although the protein-corresponding *N* and *An* states are redshifted to 384 and 448 nm, respectively. Analogously to *p*-HBDI, the chromophore of the unfolded protein becomes emissive at 77 K [19]. Given this similarity, hereafter *P*, *N*, *Z*, and *An* will generally denote the states of wtGFP chromophore when it is outside the protein fold in water solution.

56.2.3 Optical States and Mechanism of Fluorescence Emission in wtGFP

wtGFP is folded between pH 4 and 11; in this range only the neutral (i.e., protonated phenol and deprotonated *N*¹) and anionic (i.e., deprotonated phenol and *N*¹) states of the chromophore contribute to the optical properties of the protein. By using Raman spectroscopy, Bell et al. showed that the zwitterionic state has a negligible population also in the protein, suggesting that this form is always very unstable from a thermodynamic point of view. Following a long-standing tradition in the field of FPs, the neutral and anionic states of the wtGFP chromophore in the folded protein will be hereafter identified as state **A** and **B**, respectively. The use of nonitalic symbols helps distinguishing the states of the chromophore in folded proteins from those in artificial models such as *p*-HBDI and unfolded protein.

The room-temperature absorption and emission spectra of wtGFP in the visible region are reported in Figure 56.2b; absorption spectra of *N* and *An* are included in the same figure as benchmarks. Notably, the β -barrel fold of wtGFP proteins deeply affects the optical properties of the chromophore. Absorption of state **A** and **B** are redshifted by 30 and 50 nm compared to *N* and *An*, respectively: **A** peaks at 398 nm, whereas **B** peaks at 475 nm (Figure 56.2b). As we shall try to highlight at Section 56.3, the observed optical changes likely stem from the complex network of interactions that take place into the protein fold between the chromophore and the nearby residues. X-ray data of wtGFP indicate that the chromophore is surrounded by four entrapped water molecules and several charged and polar residues such as Gln⁶⁹, Gln⁹⁴, Arg⁹⁶, His¹⁴⁸, Thr²⁰³, Ser²⁰⁵, and Glu²²² [18,32–34]. Additionally, in **A** and **B** states, the chromophore environment is significantly different [32]. A proton network that connects the chromophore phenol to Glu²²² is active in **A**, whereas it is hampered in **B** on account of the 120° rotation of Thr²⁰³ to establish a strong H-bond with the phenolate anion [32]. From the extinction coefficients of the two states, an **A/B** population ratio around 6/1 can be calculated. This ratio is nearly unaffected by changes of proton concentration in the 5–11 pH range [35]. This rather unexpected phenomenon, which suggests some additional contribution to simple phenol ionization, will be clarified at Section 56.4. It is worth mentioning that, beside the **A** and **B** bands, wtGFP display a strong peak at 278–280 nm attributable to the direct excitation of aromatic amino acids (10 Tyr and 1 Trp). This UV band is shared by all FPs.

The rigid folded structure of wtGFP is also responsible for the significant protein fluorescence emission compared to *p*-HBDI in water. The **A** state displays $\Phi_A = 0.78$ [36], whereas the **B** state has $\Phi_B = 0.79$ [37]. Fluorescence of both states is also unaffected by the presence of classical quenching agents [24,38]. **A** and **B** are characterized by minor differences of emission maxima and shapes, a rather unexpected property given their large difference in absorption maxima (Figure 56.2b). Pump–probe experiments targeting the excited-state depletion at short (ps) timescale highlighted that the emission similarity stems from a proton transfer mechanism occurring at the excited state [39,40]. Photon absorption by **B** leads to excited state **B*** that has a single emission channel at 503 nm. Conversely, upon excitation of **A**, two competing photo-processes leading to emission are triggered: (1) direct emission from **A*** (at 440–480 nm) and (2) excited state proton transfer (ESPT) from **A*** to Glu²²² through a proton wire of H-bonds involving one water molecule and Ser²⁰⁵ [39–41] eventually leading to 507 nm emission. ESPT takes place in a few picoseconds on account of the strongly increased acidity of the phenol group [28], and it represents a much more efficient depletion channel of **A*** than direct fluorescence emission [42]. In more details, upon ESPT **A*** evolves to **I***, an intermediate excited state where the chromophore is anionic like in **B*** but its surrounding residues are in the relaxed form typical of **A** owing to the very short timescale of **I** decay (a few ns) that does not allow for the rearrangement of the chromophore environment driven by phenol deprotonation (e.g., flipping of the lateral chain of Thr²⁰⁵) [39,43]. This explains why **I*** emits at wavelengths similar, but not equal, to **B*** (Figure 56.2b). Upon emission, **I*** decays to **I**, which quickly evolves to **A**, which is more stable by

7.6 kJ mol⁻¹ of free energy [44]. The I → A conversion seems to take place by reversing the internal proton wire associated with ESPT [32]. Some kinetic studies pointed out that I comprises two metastable intermediates I₁ and I₂, although I₁ is very short-lived (3 ps) compared to I₂ (0.4 ns) [45].

56.3 Structure and Optical Properties of Fluorescent Proteins

56.3.1 Chromophore Structure and Formation

Figure 56.3 summarizes both the chromophore structures and their proposed formation mechanism for most classes of known FPs.

The prechromophore tripeptide has a X₁-Tyr₂-Gly₃ sequence in all natural FPs discovered so far*; X₁ can be almost any amino acid, whereas no chromophore formation takes place upon mutation of the Gly₃ [21], suggesting that the peculiar conformational flexibility of glycine is necessary at that location. Conversely, the fluorescence is maintained by substitution of Tyr₂ with another aromatic amino acid (Phe, His, or Trp). The replacement of Tyr with Phe, His, or Trp leads to artificial mutants characterized by blueshifted excitation and fluorescence wavelengths with respect to the parent protein [20,46]. We shall refer to all chromophores originated by a tyrosine-based tripeptide as Y-chrom. Analogously, F-chrom, H-chrom, and W-chrom will denote tripeptides including Phe, His, or Trp, respectively.

The posttranslational processing around the X₁ α-carbon determines the ultimate chromophore structure (Figure 56.3). For several FPs, including wtGFP, no modifications of this site take place. By contrast, the oxidation of the C–N main chain bond of X₁, which leaves an acylimine substituent at the corresponding position of the imidazolinone ring, occurs in DsRed [47] and more generally for the class of red FPs (hereafter denoted as RFPs; Figure 56.3). It has been recently showed that the oxidation leading to the acylimine substituent actually precedes dehydrogenation of the bridging carbon [22]. From a photophysical point of view, formation of the acylimine moiety extends the π-conjugated system, and correspondently lowers the excitation energy, resulting in red–orange fluorescence.

In other FPs, additional reactions take place on the acylimine moiety, such as hydrolysis associated with backbone cleavage in asFP595 [48][†] or side-chain cyclization by nucleophilic addition of the threonine (orange), cysteine (mKO), or lysine (zFP538) side chain, the latter reaction being followed by backbone cleavage [49–51]. In Kaede and related proteins (KikGR, EosFP, Dendra), UV excitation cleaves the backbone between main chain N and Cα of the Histidine at X₁. The cleavage is followed by double bond formation between Cα and Cβ (Figure 56.3) [52,53]. All these variants retain redshifted excitation/emission bands and therefore belong to the RFP family.

As already shown for wtGFP (Section 56.2.3), in all Y-chrom proteins, the phenol group on the chromophore can exist either as neutral (protonated phenol) or anionic (deprotonated phenol). The absorption of the neutral form is always significantly blueshifted with respect to the anionic form. In some FPs, the change of the external pH enables the reversible population shift from the neutral to the anionic states of the chromophore; this phenomenon, which will be thoroughly described for FPs from *A. victoria* (avFPs) at Section 56.4, is associated with a pH-titration curve clearly observable both in absorption and in fluorescence. Nonetheless, in most FPs, and particularly in RFPs, the anionic chromophore is much more stable than its neutral counterparts in the 5–9 pH range. In RFPs, this effect stems from the increased phenol acidity brought about by the additional conjugated double bond(s).

According to some computational investigations, the zwitterionic form (with the imidazolinone nitrogen protonated) might be the emitting state in some FPs [54]. In addition, it is worth mentioning that the zwitterionic and other protonation state such as the cationic form (protonated phenol and imidazolinone) may be relevant to FP photophysics [55].

* Not all natural FPs are actually *fluorescent*. However, these nonfluorescent species (named chromoproteins) were eventually converted into fluorescent species by molecular engineering.

[†] As FP595 chromophore structure has been subject to debate, regarding the possible presence of an imino (NH) group in place of the ketone group at position 2 of the imidazolinone (see discussion in Ref. [48]).

56.3.2 Optical Properties of FPs: Mechanism of Spectral Tuning

Adopting a general perspective, rather than trying to exhaustively survey all FPs discovered and engineered so far, this section will focus on the structural mechanisms operating the observed spectral shifts in the main families of FPs: blue (BFPs), cyan (CFPs), green (GFPs), yellow (YFPs), and red (RFPs) emitting. Excitation and emission wavelengths in different representative FPs can be read in [Table 56.1](#).

Note that the optical properties of any FP are the result of (1) the chromophore structure, particularly the nature of the aromatic ring and the presence of an additional double bond conjugated to the imidazolinone and (2) the interaction between chromophore and its immediate environment. The environment can act on the chromophore by (a) deforming some of its bond lengths through H-bonds, (b) distorting the planarity of the chromophore, and (c) differentially stabilizing the ground and excited states by electrostatic interactions.

The subtle chromophore–matrix interactions deserve some further observation, on account also of recent experimental [84] and theoretical [85] studies. Early Raman spectroscopy studies on the wtGFP model chromophore in solution and some *av*Fps revealed a tight correlation between the shift in absorption peak and the frequency of a specific Raman-active band [27]. This correlation was rationalized by invoking the selective stabilization of one of the two resonance structures of the chromophore (Scheme 56.3a) [86]. Indeed, variations of the Raman spectrum reflect a changing stabilization between a benzenoid-like resonance structure (Scheme 56.3a, I) and a quinonoid-like resonance structure (Scheme 56.3a, II). This effect is also at basis of the significant solvatochromism of the anionic Y-chrom. The neutral Y-chrom, indeed, evidences less environmental sensitivity, as the protonated phenol enforces a benzenoid-like structure thus decreasing the potential influence of nearby residues. Actually, in Y-chrom FPs, the optical properties principally stem from the anionic form of the chromophore in the

SCHEME 56.3 Resonance forms of the Y-chrom anionic state. (a) Chromophore of wtGFP and related proteins. (b) Chromophore of DsRed and related proteins. I: benzenoid structure, II: quinonoid structure, and III: extended enol structure.

physiological pH range. When present, the neutral absorption peak displays little variation in the 385–400 nm interval* [33,88–90]; emission from the neutral chromophore is generally very similar to that of the anionic state on account of the ESPT mechanism.

The ubiquitous hydrogen bond between the imidazolinone carbonyl and conserved Arg⁹⁶ (in *av*GFP numeration) stabilizes the quinonoid form (Scheme 56.3a, II), thereby lowering the excitation energy. Vice versa, the establishment of H-bonds with chromophore phenolate (e.g., wtGFP) increases the contribution of the benzenoid form (Scheme 56.3a, I) in the anionic chromophore.

Other electrostatic interactions can be active and play a relevant role in determining the optical features of the protein. The interplay among all possible factors usually makes it difficult to predict the final outcome. Nonetheless, this general scheme is useful to decipher the mechanisms of spectral tuning. In the RFP chromophores, a third resonance structure is possible (Scheme 56.3, III). Hydrogen bonds to this additional site will tend to lower the excitation energy, stabilizing the excited-state charge displacement over the region [91].

Finally, the optical properties of the protein may be strongly related to protonation reactions and, in turn, by external pH. We shall describe this “chemical” effect (as complementary to the “electrostatic effects” described in this section) at Section 56.4.

56.3.2.1 Blue Fluorescent Protein (BFP) Family

Among the first *av*GFPs mutants to be produced, BFP were obtained by replacing Tyr⁶⁶ with a His or a Phe. Model H-chro and F-chro in water display 17 nm [92][†] and 21 nm [93] absorption blueshifts, respectively, compared to the neutral band of *p*-HBDI. Representative BFPs display absorption shifts from –37 to +5 nm, and emission shifts from the –68 to –43 nm, compared to the A state (neutral) of wtGFP (Table 56.1).

*av*BFP with F-chro was found to be extremely dim and it never found any biological application. Recently, however, Luin et al. suggested that the very low quantum yield of F-chro *av*BFP (named BFPF) stems from an efficient *cis*–*trans* photoisomerization of the chromophore [94]. The first “enhanced BFP” (EBFP) relied upon H-chro and included also other mutations to improve brightness and folding efficiency (F64L/S65T/Y145F) [92]. Even with those improvements, EBFP suffers from a low quantum yield (0.15) and is prone to fast photobleaching [95]. Recent mutagenesis efforts produced brighter and more photostable BFPs based on H-chro: Azurite [59], EBFP2 [58], and SBFP2 [96]. Two non-H-chro proteins also emit in the blue region, namely, mKalama1 [58], a *av*GFP mutant where the *neutral* chromophore is the stable state and is intrinsically fluorescent (i.e., ESPT is suppressed), and mBlueberry2 [58], a DsRed mutant with a F-chro with hyperconjugation.

56.3.2.2 Cyan–Teal Fluorescent Protein (CFP) Family

The most famous members of the cyan–teal family are artificial *av*GFPs where Tyr⁶⁶ has been replaced by Trp. Model W-chro in water display 20 nm absorption blueshift compared to the anionic band of *p*-HBDI [93]. Representative CFPs display absorption shifts from –34 to –15 nm, and emission shifts from –32 to –16 nm, compared to the B state (anionic) of wtGFP (Table 56.1).

Enhanced CFP (ECFP, F64L/S65T/Y66W/N146I/M153T/V163A GFP) has been the first W-chro *av*FP to find large use in molecular biology studies, owing to its optical properties (main excitation/emission: 434/476 nm [5]) that makes it a good donor for fluorescence resonance energy transfer (FRET) when YFPs are selected as acceptors. Nonetheless, the medium-low brightness of ECFP and its multiexponential emission decay (due to multiple conformations of the W-chro [97]) early prompted for the engineering of improved mutants for FRET studies. In 2004, Rizzo et al. described *Cerulean*

* Somewhat redshifted value (415 nm) is observed in the S65T/H148D *av*GFP variant, where the D148 carboxyl oxygen forms a very tight hydrogen bond (distance 2.4 Å) with the chromophore hydroxyl group [87].

[†] No data about the absorption of model H-chrom has been ever reported. The shift is calculated considering unfolded enhanced BFP (EBFP) and wtGFP.

(S72A/Y145A/H148D ECFP), a 2.5-fold brighter variant of ECFP with monoexponential emission [60]. The x-ray structure of *Cerulean* and additional molecular modeling studies have clarified the origin of the peculiar optical properties of this protein [98–100]. Since 2004, *Cerulean* has mostly replaced ECFP in FRET experiments. Yet, Kremers et al. have engineered SCFP1, SCFP2, SCFP3a, and SCFP3b, which are similar to *Cerulean* concerning brightness but are characterized by larger lifetime variability (SCFP1 and SCFP3a can be used for dual-lifetime imaging although they have the same optical properties) [101].

The cyan–teal family also comprises FPs isolated from reef corals, such as *Discosoma striata* (dsFP483), *Anemonia majano* (amFP485), and *Clavularia* (cFP484), as well as two cFP484 mutants, mTFP0.7 and mTFP1. These cyan-emitting proteins are naturally tightly bound tetramers, but recently mTFPs were engineered to avoid oligomerization and exist as monomers [90]. The chromophore of these proteins is a Y-chrom, so the blueshifted spectral properties of this group originate from peculiar chromophore–protein interactions. Singling out the specific blueshifting interactions has proven rather puzzling, also because the broad absorption/excitation band hints at structural heterogeneity of either the chromophore or its close surroundings [102]. cFP484, amFP486, and mTFPs (but not dsFP483) display a quadrupole network of salt bridges underlying the chromophore and entailing Arg⁶⁹, one His, and two Glu. The His is presumably cationic, being hydrogen bonded on both sides to the glutamates [103]. Replacement of this His by Thr in amFP486 restores the optical properties typical of green mutants such as wtGFP (absorption and emission are redshifted from 454 to 470 nm and from 486 to 515, respectively), and is accompanied by a decline in fluorescence quantum yield and heterogeneity of chromophore structure [103]. Nonetheless, the quadrupole configuration is missing in dsFP483 [102] and is instead present in green-emitting Dronpa [64] and cmFP512 [104].

The general requirement for cyan fluorescence appears to be the presence of a positively charged residue underlying the chromophore (His in cFP484, amFP486, and the mTFPs and Lys70 in dsFP483), together with the arrangement of the three H-bond donors facing the chromophore phenolate. Indeed, a water molecule and serine are present in all examined structures, and at H-bonding distance to the phenolate. A histidine, again at H-bonding distance, is present in dsFP483 and in cFP484 and related mTFP mutants. amFP486 features an Ala at the equivalent position. Though Ala cannot donate a H-bond, its small bulk allows a water molecule to fill the cavity. Neither Dronpa nor cmFP512, though featuring the quadrupole arrangement, and hence the charged His, has all three H-bond donors.

56.3.2.3 Green Fluorescent Protein (GFP) Family

The proteins belonging to this class have optical properties similar to those displayed by wtGFP (Table 56.1), although in most cases only the bright anionic form of the chromophore is optically active. Indeed, the most popular green variant, Enhanced GFP (EGFP) (F64L/S65T GFP) owes its high brightness to a predominantly anionic Y-chrom above pH 6 [88,105].

Recent experiments on *p*-HBDI suggest that the Y-chrom is characterized by similar optical properties in gas phase and when embedded in folded protein [106]. This result is apparently in contrast with the experimental evidence of relevant interactions between the chromophore and its surrounding residues and water molecules in green FPs. However, a meaningful rationalization takes into account the mutual cancelation of the various contributions. Computational studies [86] point at a counteraction between the redshifting hydrogen bond with conserved Arg⁹⁶ and the blueshifting of hydrogen bonds to the phenolate. This effect is supported by several experimental studies. Removal of Arg⁹⁶ blueshifts the optical properties, because the H-bond stabilization of the phenolate becomes predominant. This effect is clearly observable in the R96M mutant (absorption/emission 466/490 nm) where the H-bond of Arg with the imidazolinone carbonyl group is replaced with a, somewhat weaker, hydrogen bond with a water molecule (donor–acceptor distance is 2.9 Å in protein data bank (PDB) structure 2AWK [107]). By contrast, removal of Thr²⁰³ abolishes the H-bond to the phenolate and induces optical redshift.

Indeed, in T203V and T203I, the anionic state peaks at 502 nm [33]. Proteins from other sea organisms, such as Dronpa and cmFP512, also belong to this family.

56.3.2.4 Yellow Fluorescent Protein (YFP) Family

Proteins belonging to the yellow family (YFPs) share an aromatic moiety (from Tyr, Phe, or His) π -stacked to Y-chrom. The T203Y mutation was introduced in *avGFP* under the assumption that Tyr²⁰³ would be π -stacked to the chromophore phenolate, thereby lowering the excitation energy by increasing the polarizability of the environment around the chromophore [65]. The mutation indeed resulted in yellow-emitting variants (Table 56.1) and x-ray studies confirmed the π -stacking configuration [65]. Similar redshift was observed in T203F *avFP* mutant [33]. Notably, nature played the same stratagem in a natural FP named phiYFP [68].

Although redshifted fluorescence to the yellow region should be totally ascribed to the π -stacked Tyr or Phe, π -stacking is only one of the causes underlying the *absorption* redshift. Additionally, the x-ray structure of EYFP show a peculiar hydrogen bond between Glu²²² and the imidazolinone of the chromophore, which appears prodromic to redshift in other mutants [49].

Most notably, the π -stacking Tyr/Y-chrom of YFPs leads to the highest extinction coefficients ($>75,000 \text{ M}^{-1} \text{ cm}^{-1}$), emission quantum yields ($\Phi > 0.8$), and fluorescence lifetimes ($\tau > 3 \text{ ns}$) that can be found in FPs. Indeed, YFPs are among the best candidates for high-resolution and single-molecule imaging studies [108,109]. The yellow absorption of YFPs makes this class the perfect partner for FRET with CFP variants. *Venus* YFP was engineered to overcome the maturation and optical drawbacks of earlier YFPs [66] and soon it was demonstrated to be a good acceptor partner for *Cerulean* CFP (Section 56.3.2.2) for intracellular FRET studies [110]. Additionally, the peculiar proton and chloride sensitivity of many YFPs prompted their use as intracellular pH/Cl⁻ indicators [13,111–114].

56.3.2.5 Red Fluorescent Protein (RFP) Family

As already stated, the strong redshift of RFPs compared to wtGFP is mainly attributable to the enlargement of the π -conjugated system by the additional double bond, regardless if the latter has acylimine structure (as in DsRed and its progeny) or not. Model anionic RFP (DsRed) chromophores in water is redshifted by 57 nm [115] compared to the anionic band of *p*-HBDI. Representative RFPs display absorption shifts from +71 to +133 nm and emission shifts from +54 to +142 nm, compared to the **B** state (anionic) of wtGFP (Table 56.1).

In spite of the main role of extended conjugation in RFP chromophore, the protein matrix plays a relevant role in tuning the final optical properties of the folded protein, especially for variants where Y-chrom is predominantly anionic. We should note that in some RFPs, the chromophore undergoes covalent modifications that alter its structure; when the x-ray data are not available, the assignment of the chromophore structure may be doubtful. For example, the chromophore of mOrange and mBanana contains a structural modification at the acylimine tail and the blueshifted optical properties of these FPs cannot be wholly attributed to the chromophore–protein interactions.

The archetype DsRed protein is amongst the most blueshifted RFPs. Its optical features can be redshifted by dislocating Lys⁷⁰, which in wtDsRed is in close contact with the chromophore bridging carbon (at 3.6 Å distance) [49,116]. This mechanism is at play in K83M DsRed variant as well as in mCherry and mStrawberry, both featuring the K83L mutation. In the latter two mutants, additional redshift is provided by the hydrogen bond between protonated E215 and the closest N in the chromophore imidazolinone. If pH is raised to 10, the absorption peak of mCherry and mStrawberry shifts from 584 to 566 nm and from 574 to 548 nm, respectively, likely owing to the deprotonation of E215. A third source of redshifting is achieved in mCherry/mStrawberry by the additional K163Q/K163M mutations that eliminate one hydrogen bond to the chromophore phenolate.

Much alike in YFPs, π -orbital stacking of the RFP chromophore with a Tyr residue results in a noticeable optical redshift, like in the protein mGrape3 characterized by I197Y (608 ex and 646 em).

Unfortunately, mGrape3 is characterized by low quantum yield (0.03) and complex photophysics possibly connected with *cis-trans* isomerization of the chromophore [117].

Variations in the surrounding environment of the acylimine group can also contribute to the optical properties of RFPs. For example, mPlum, a significantly redshifted DsRed variant, features a hydrogen bond between (presumably neutral) Glu16 and the acylimine oxygen, in addition to “redshifting” K163M mutation and the E215-imidazolinone hydrogen bond. Removal of the H-bond by replacing Glu16 with Leu shifts the emission peak from 649 to 630 nm [49]. Actually, mutation of Glu16 appears to affect strongly just the emission peak, while leaving the excitation band almost unchanged.

Similarly in mNeptune [117], a far-red FP derived from eqFP578 of *Entacmaea quadricolor* [118], the acylimine oxygen is H-bonded to a water molecule. As is the case with many FPs, the redshift of mNeptune is, however, the result of multiple entangled contributions. As a consequence, it may be difficult to predict the outcome of a mutation. The slightly blueshifted optical properties of mKate (another eqFP578 mutant) compared to mNeptune can be traced back to the absence of the H-bond entailing the acylimine oxygen, on account of the Met41-promoted displacement of the hydrogen-bonded water molecule.

Deviation from coplanarity of the two aromatic rings in the protein chromophore (quantified by the twist around τ and ϕ , or also including the tilt angle defined as the deviation of the phenol oxygen from the perfectly planar chromophore [119]) is another determinant of optical properties. In general, distorted chromophore structures are associated with poor quantum yield of fluorescence. As an example, mCherry is characterized by a particularly distorted chromophore and a rather low fluorescence quantum yield (0.22) [11].

56.4 pH Dependence of Optical Response in *av*GFP Mutants

As anticipated at Section 56.2.3, wtGFP shows detectable deviations from the 3:1 optical ratio between the A and B bands only at pH below pH 4.5 and above pH 10 [35]. Thus, no *net proton transfer* between wtGFP chromophore and the external solution takes place in the physiological pH range, although the concomitant presence of A and B states points to an *internal* proton equilibrium between the chromophore and surrounding residues. By this means, natural selection has engineered wtGFP to be almost unresponsive to external pH changes to prevent fluctuations of the jellyfish bioluminescence that could hamper its biological role.

In many other FPs with Y-chrom, however, the optical response of the protein is very sensitive to the external proton concentration in the 5–10 pH range, on account of the ionization reaction of the chromophore phenol [105,120,121]. In such cases, the β -barrel tertiary structure that protects the chromophore from the outside world is bypassed by “proton-wires” constituted by several residues networked by H-bonds connected to “proton-collecting antenna” systems, that is, several carboxylates within H-bond networks on the surface of proteins, which convey protons to the orifice of an internal proton wire leading to the protein’s active site [122].

We shall restrict our discussion about the influence of pH on the optical protein response to *av*FPS with Y-chrom, owing to the much deeper comprehension of the protonation-related mechanism in this protein family. It seems likely, nonetheless, that similar mechanism hold also for other kinds of FPs as recently demonstrated for cmFP512 from *Cerianthus membranaceus* [104].

For many *av*FPS, the pH-dependent optical response follows that of *p*-HBDI or unfolded protein (Figure 56.4a and e), being characterized by the single-site protonation of Y-chrom phenol. Here, absorption spectra show the progressive interconversion of neutral state (absorbing at 390–420 nm) into anionic state (absorbing at 475–520 nm; Figure 56.4a). On account of a nearly pH-independent quantum yields of either chromophore forms, the fluorescence spectrum at each pH is determined by the relative populations of neutral and anionic Y-chrom; in the absence of ESPT, neutral Y-chrom is usually very dim, whereas anionic Y-chrom is always bright (Figure 56.4b). Notably, the pK_a of chromophore ionization usually ranges between 5 and 6 making anionic Y-chrom the most populated form at physiological pH.

FIGURE 56.4 (a–c) pH-dependent optical features of S65A/V68L/S72A/T203Y GFP (Mut2Y [88]): (a) absorption spectrum, (b) emission spectrum (ex: 473 nm), and (c) pH plot of the extinction coefficient of the anionic chromophore (abs: 510 nm) and, for comparison, of *p*-HBDI (abs: 425 nm): data are fitted to the sigmoidal curve of Equation 56.2 representing the pH titration of a single ionization site (see text).

(continued)

(d)

(e)

(f)

FIGURE 56.4 (continued) (d–f) pH-dependent optical features of F64L/T203Y (E'GFP, [88]): (d) absorption spectrum, (e) emission spectrum (ex: 395 nm), and (f) pH plot of the extinction coefficient of the anionic (abs: 510 nm, full circles), and neutral (abs: 420 nm) chromophore: data are fitted to the sigmoidal curve of Equation 56.2 representing the pH titration of a single ionization site (see text).

In other mutants, the absorption spectra display a peculiar pH trend: a single-site ionization is inferred from optical pH-titration data [47,88,123] but at $\text{pH} \gg \text{pK}_a$, the absorption band corresponding to neutral Y-chrom is still intense, although blueshifted (Figure 56.4d and f). Obviously, neither this phenomenon can be accounted for by the simple ionization scheme of the phenol group nor the experimental pK_a can be attributed solely to the chromophore. Additionally, these mutants display detectable emission also from neutral state(s) [41]. This effect appears to be pH dependent, leading to emission spectra that are redshifted by raising the solution pH (Figure 56.4e).

We recently proposed a comprehensive model (named 2S model) that rationalizes both the observed photophysical behaviors [88]. The preliminary assumption in our model is that the optical response of Y-chrom reflect the pH-dependent ground state populations of neutral and anionic forms and their (almost) pH-independent intrinsic optical properties. We have not included in our treatment structurally/environmentally “nonrelaxed” anionic species I (if present), as they negligibly contribute to the protein absorption spectra owing to their metastable character and short lifetime. The central assumption in our model invokes the influence on the protein optical properties of a second *ionizable site* XH (henceforth, denoted as X when deprotonated), which resides on the lateral chain of a nearby residue to the chromophore. XH (or X) and the phenol group of Y-chrom are supposed to mutually exchange protons at ground state (and perhaps also at excited state), possibly through a few proton relays belonging to an internal H-bonding network. Actually, x-ray structures of *avFPs* show that many protonatable groups may exchange protons with the chromophore (e.g., His¹⁴⁸, Glu²²², Arg⁹⁶). Both Y-chrom and XH are supposed to be in direct proton communication with the external solution through some proton wire/proton antenna pathways such as those described by Agmon et al [122].

The two protonation sites generate four possible ground states: **A'**, **A**, **B**, and **B'** (Scheme 56.4). This notation follows the reported protonation scheme of wtGFP [32,39,40], where the **A** state is characterized by neutral chromophore and anionic Glu²²² (the X residue in wtGFP and other *avFPs*, as we shall show in the following), while **B** has the opposite configuration. In the linear regime of the optical response, the absorption/fluorescence of the protein at a given pH is given by the sum of the fractional

SCHEME 56.4 2S model of pH-dependent optical response in *avFPs* [88]. XH is an ionizable residue nearby Y-chrom. The two ionizable groups, phenol and XH, yield four possible ground states **A'**, **A**, **B**, and **B'**.

population of each state multiplied by its molar absorbance or fluorescence, respectively. Following Ullmann [124], we can write

$$R = C_0 \frac{R_{A'} + R_A 10^{(pH - pK_{A'A})} + R_B 10^{(pH - pK_{A'B})} + R_{B'} 10^{(2pH - pK_{A'A} - pK_{A'B} + W)}}{1 + 10^{(pH - pK_{A'A})} + 10^{(pH - pK_{A'B})} + 10^{(2pH - pK_{A'A} - pK_{A'B} + W)}}, \quad (56.1)$$

where

R is the protein optical response (absorbance or fluorescence) of the protein at a given observation (excitation) wavelength

C_0 is the protein concentration

$R_{A'}$, R_A , R_B , and $R_{B'}$ are the molar absorbance/fluorescence of each state at the observation (excitation) wavelength

$pK_{A'A}$ and $pK_{A'B}$ are the pK_a values pertaining to the $A' \leftrightarrow A$ and $A' \leftrightarrow B$ proton dissociation equilibria, respectively (Scheme 56.3)

W is the *interaction free energy* between the ionization reactions of Y-chrom and XH, assumed positive in sign when the coupling is *cooperative* (i.e., deprotonation of one site stabilizes the deprotonation of the other), whereas it is negative when the coupling is *anticooperative* (i.e., deprotonation of one site hampers the deprotonation of the other).

A first remarkable case occurs for $W = 0$, which imply complete decoupling between Y-chrom and XH/X and *Chro* (i.e., the ionization of the first *does not influence* the ionization of the other). Here, we can safely assume that the optical properties of the chromophore states depend only upon their protonation state and are not affected by the protonation state of HX group (i.e., $R_{A'} = R_A$ and $R_B = R_{B'}$). In this condition, Equation 56.1 becomes

$$R = C_0 \frac{R_{A'} + R_B 10^{(pH - pK_{A'B})}}{1 + 10^{(pH - pK_{A'B})}}. \quad (56.2)$$

Equation 56.2 describes the sigmoidal response typical of the pH titration of a single ionizable group with $pK_a = pK_{A'B}$. Indeed, Equation 56.2 holds also for *p*-HBDI in water at $pH > 4$ (below the N^1 -protonation equilibrium must be included, Section 56.2.2). The simple, “chromophore-like,” optical response upon external pH change is shared by many *avFP* mutants (e.g., some YFPs [34,125], citrine [126], Mut2 class [121]); $pK_{A'B}$, however, is usually 1–3 pH units lower than the pK_a of the isolated chromophore.

The second remarkable case occurs when $W \ll 0$, that is, the ionization of XH strongly hampers the deprotonation of phenol in Y-chrom. Apparently, this condition ensues in all *avFPs*, where Glu²²² is not forced in a single protonation state by strong H-bonds with surrounding residues [88]. Here, the strong anticooperative coupling between $X = \text{Glu}^{222}$ and the chromophore ionization presumably stems from the strong negative energy implied in the creation of two close negative charges on both groups upon concomitant deprotonation. In these mutants, the fully deprotonated B' state cannot be reached within the stability range of the protein [note that B' becomes significantly populated at $pH \approx i(pK_{A'A} + pK_{A'B} - W)$]. Neglecting B' in Equation 56.1 with $W \ll 0$, we have

$$R = C_0 \frac{R_{A'} + R_M 10^{(pH - pK_{A'M})}}{1 + 10^{(pH - pK_{A'M})}}, \quad (56.3)$$

where we have recast the original thermodynamic and optical parameters into the new ionization constant $K_{A'M} = K_{AA} + K_{AB}$ and molar absorption/fluorescence R_M , respectively:

$$R_M = \frac{R_A + R_B \left(K_{A'B} / K_{A'A} \right)}{1 + \left(K_{A'B} / K_{A'A} \right)}. \quad (56.4)$$

Likewise Equations 56.2 and 56.4 describe the pH-dependent sigmoidal evolution of the optical response between the A' state (prevalent at $\text{pH} < \text{pK}_{A'M}$) and the new M state (prevalent at $\text{pH} > \text{pK}_{A'M}$). Differently to the case described by Equation 56.1, however, M state *does not coincide* with B , as M does not represent to the pure anionic phenolate of Y-chrom but a *mixed form* of A (neutral Y-chrom) and B (anionic Y-chrom) according to Equation 56.5 [88]. This explains the chemically puzzling observation, described at the beginning of this section, that some mutants display nonresidual presence of neutral chromophore in the absorption and/or fluorescence at pH well above the measured pK_a .

It is worth mentioning that also wtGFP belongs to the class of “coupled” *avFPs*, as previously suggested by Scharnagl [127]. Nonetheless wtGFP differs from other “coupled” mutants for a much lower $\text{pK}_{A'M}$, which is around 4.5–4.9 (other mutants display $\text{pK}_{A'M}$ from 5.5 up to 7.2) [88]. Hence, in wtGFP, the M state, that is, a constant mix of pure A and B spectra, is continuously observed from pH 5 to 11 (when B' and unfolding start to appear). Accordingly, the E222Q replacement has a dramatic effect in wtGFP: the optical response becomes strongly sensitive to external pH change in the physiological range [44,128].

Assuming $\text{pK}_{A'M} = 4.9$ and a population ratio $B/A = 6$, Equation 56.5 and the trivial identity $B/A = K_{A'B}/K_{A'A}$ make us calculate $\text{pK}_{A'B} = 5.75$ and $\text{pK}_{A'A} = 4.97$ for wtGFP. This result indicates that the M state of wtGFP finds its origin in the ionization of Glu²²² carboxylic group ($\text{pK}_{A'A} = 4.97$) at rather low pH values. We can therefore conclude that Glu²²² plays several pivotal roles in wtGFP: (1) it helps the maturation of chromophore [21]; (2) it “couples” anticooperatively with the phenol group of Y-chrom; (3) it deprotonates more easily than the chromophore lowering the optical pK_a ($=\text{pK}_{A'M}$) to a value outside the physiological range thereby stabilizing the protein emission; and (4) it is a good recipient for the *Chro*'s proton upon ESPT, conferring significant emission to the neutral A state. The third and fourth properties definitely concur to the biological function of wtGFP: the pH-independent mixed neutral/anionic M state allows for the excitation of protein fluorescence in a very large wavelength range (390–500 nm, Figure 56.1d), thereby making wtGFP a very efficient FRET acceptor for the bioluminescence of its partner *Aequorin* (which bioluminescences between 400 and 550 nm [36]) in the jellyfish cells.

56.5 Conclusions

Nowadays, FPs are the best available probes to monitor in vivo biochemistry. This predominant role owes to the genetic encoding of fluorescence in the protein primary sequence. Almost any kind of protein can be fused and expressed with one or more FPs at intracellular level, with usually negligible perturbation of the biochemical pathways it is meant to undergo.

The optical properties of FPs stem largely from the structure of the chromophore, a conjugated moiety buried inside the protein β -barrel that originates from the spontaneous posttranslational modification of three amino acids. Natural selection has evolved FP chromophores from the triplet $X_n\text{-Tyr}_{n+1}\text{-Gly}_{n+2}$, where X is very variable; artificial FPs, however, bear also another aromatic amino acid instead of Tyr_{n+1} . Owing to the phenol group of Tyr, Tyr-based chromophores (Y-chrom) have access to two protonation states: neutral phenol and phenolate. The latter one displays always redshifted optical properties compared to the former, on account of the enhanced electronic conjugation. Modification of the external pH can shift the protonation equilibrium of Y-chrom, although additional ionizable residue(s) may deeply

affect the pH-dependent optical behavior of the protein. When the electronic conjugation of the chromophore is further extended by posttranslational modification at the main chain of X_n, FPs emitting in the orange–red spectral window are obtained. In spite of the relevant role of chromophore structure, the optical and photophysical properties of each mutant are determined also by the effect of the protein matrix surrounding the chromophore. Indeed, the protein matrix can act on the chromophore providing different electrostatic environments, by establishing H-bonds, and by distorting the molecular planarity; all these interactions can be at play in a given FP and need to be considered to account for the observed optical properties.

In this chapter, we reviewed the subtle interactions that cooperate to finely tune the optical response of representative FP homologues. Notably, understanding the structure–property relationships is the starting point for rational engineering of FPs tailored to specific applications in vivo.

57.1 Introduction

Ultraviolet (UV) radiation contained in sunlight may be considered as one of the most frequently encountered deleterious agent for DNA by living organisms. UV radiation has a few positive consequences like the production of vitamin D. It is very likely to have been a major driving force in the evolution on early earth. However, UV exposure results mostly in numerous harmful effects, including induction of skin cancer and skin aging in humans, but also impaired growing in plants or deleterious consequences in the environment. Consequently, UV-induced DNA damage has been a very active field of investigation for several decades. First identification of the cyclobutane pyrimidine dimers (CPDs) was reported in the late 1950s, followed a few years later by that of (6-4) photoproducts. The cellular response to UV radiation was likewise extensively investigated. DNA repair of UV-induced photoproducts was in particular the topic of numerous works, which led among other outstanding discoveries to the elucidation of the mechanism of nucleotide excision repair (NER) through the study of the xeroderma pigmentosum syndrome. The purpose of this review is to provide basic information on the photochemistry of DNA with emphasis placed on the most recent aspects. Information is also provided on the basic molecular mechanisms of DNA repair. More biological aspects of repair and other important topics like mutagenesis or translesion synthesis are not addressed because of space limitations.

57.2 UVC and UVB Photochemistry of DNA

DNA is the main cellular chromophore in the UVC (230–280 nm) and UVB (280–320 nm) ranges, sometimes referred to as far-UV radiations. At these wavelengths, only pyrimidine and purine bases absorb the incident photons. The resulting excited states undergo a number of transformations into final stable products. Although UVB is the relevant biological radiation because it is less blocked than UVC

by the ozone layer, numerous studies aimed at identifying DNA photoproducts used the latter photons (254 nm), the wavelength of which is close to the absorption maximum of DNA.

57.2.1 Excited States of DNA Bases

DNA exhibits a maximum absorption in the UVC range at 260 nm as the result of a strong $^1\pi\pi^*$ transition. At these wavelengths, only bases efficiently absorb the incident photons. Like all chromophores, bases first reach singlet excited states. From there, deactivation through fluorescence or nonradiative processes allows the molecule to return to the ground state. Alternatively, chemical reactions may take place from the singlet excited state. Another pathway involves intersystem crossing into a triplet state that again may deactivate or give rise to photoproducts. The excited states of DNA bases are under investigations for many years as reported in excellent early reviews [1–4]. However, a large amount of information was gathered in the last decade on both isolated monomers and double-stranded helices [5]. This increase in knowledge was made possible by the progress in time-resolved absorption and fluorescence spectroscopies that could provide information on very short time scales as low as 100 fs. Advances in theoretical approaches also made possible a better characterization of the excited states and of their deactivation processes.

57.2.1.1 Monomers

Numerous data have been gathered in the last decade on singlet excited states of monomeric bases, nucleosides and nucleotides. For purine free bases, both 7H and 9H tautomers are possible. However, only the former is relevant to DNA because of the presence of the 2-deoxyribose ring. No data on the 7H isomers will thus be discussed in the following. First, calculations provided information on the lowest vertical excitation energies of the bases that were found to be in the following order: Thy < Cyt < Gua < Ade at different levels of theory [6–13]. Second, time-resolved techniques allowed the accurate determination of the lifetimes of excited states of DNA bases that are known to be very short. Femtosecond time-resolved fluorescence and transient absorption spectroscopies showed that the lifetimes of the excited state of DNA bases monomers are below 1 ps. The decreasing order of lifetime was found to be Ade < Gua < Thy < Cyt with lifetimes ranging between 300 and 750 fs for the nucleosides [14–19]. No difference is observed between the 2'-deoxy- and the ribonucleosides but addition of a phosphate group at the C5' position results in a slight increase in the lifetime [17,18]. These remarkable very short lifetimes of the singlet excited states could explain the poor photoreactivity of the DNA bases.

An additional interesting feature of DNA bases is their very low fluorescence quantum yield, indicative of a major contribution of nonradiative internal conversion in the relaxation processes. Evidence was obtained from transient absorption measurements in the UV region for the formation of hot ground states following relaxation of excited states [14,15]. Excess energy is then deposited in the solvent by vibrational cooling. Several hypotheses have been put forward to explain this photochemical behavior. First, proton transfer from the solvent and tautomerism has been proposed [12,13,20]. Thermodynamics considerations [21] and observation of limited solvent effects [19] seem to rule out this possibility. An alternative pathway that involves a coupling between the $^1\pi\pi^*$ and $^1n\pi^*$ states, which were reported by some authors to exhibit similar energy level, has been proposed [20,22–24]. This mechanism does not fully account for several experimental observations including solvent and methylation effects [5]. Therefore, a similar process involving conical intersections was proposed to take place for pyrimidine bases [5,25,26] and supported by the experimental observation of a long-lived excited states exhibiting lifetimes of tens of picosecond attributed to dark $^1n\pi^*$ states [27]. This excited state was proposed to lead to intersystem crossing into excited triplet states. In the case of adenine, spectroscopic data seem to favor a mechanism involving two $\pi\pi^*$ states [28].

57.2.1.2 Single- and Double-Stranded DNA

Like monomers, DNA is characterized by a rather poor photoreactivity in terms of quantum yield of products and a very low fluorescence that point to efficient relaxation pathways. However, the underlying processes differ from those in free bases and nucleoside as the result of stacking, base pairing, and

structural features of the DNA duplex. A first specificity of excited states in DNA is their delocalization along the strand that has been established by earlier works. The extent of this delocalization seems to be limited to a few base pairs [29]. Recent theoretical approaches based on spectroscopic observations have proposed that absorption of a UV photon by DNA populates numerous delocalized Frank–Condon states. Fast relaxation (<100 fs) then leads to the most stable ones [30–34]. Other authors have proposed a more localized initial excitation followed by energy transfer yielding excimers or exciplexes [35]. This hypothesis is supported by time- and wavelength-resolved studies in the case of an adenine polymer [28]. In order to get insights into this photochemistry in duplexes, time-resolved spectroscopy and theoretical studies have been conducted on model double-stranded systems that are mostly oligonucleotides bearing either A:T or G:C base pairs and of limited size (≤ 20 base pairs).

A rather larger amount of information has been gathered in the recent years on the deactivation pathways following UV excitation of adenine- and thymine-containing DNA models. As a general trend, excited states exhibiting longer lifetimes than the monomers were detected by time-resolved techniques in addition to monomeric-like transients. Lifetimes in the few picosecond range were observed by fluorescence up-conversion and found to be larger in homopolymers ($\text{dA}_n \cdot \text{dT}_n$) than in alternating sequences ($(\text{dAdT})_n \cdot (\text{dAdT})_n$) [36–38]. Additional decays larger than 100 ps were also observed [33]. Transient absorption measurement confirmed the existence of these excited states exhibiting a long lifetime, with a twofold lower value in alternating sequences with respect to homopolymers [38]. In spite of discrepancies on the interpretation of the experimental data obtained by these two techniques [39], it seems accepted that stacking of the bases along the DNA strands favors delocalization and stabilization of excited states, mostly through charge transfer states [33,35,40]. The link between the nature of these excited states and the formation of the final photoproducts remains poorly understood. The recent observation that formation of cyclobutane dimers in single-stranded dT_{18} is a very fast process suggests that only adjacent bases exhibiting the required orientation may yield stable photolesions [41].

The main features of the photochemical behavior of G:C-containing duplexes are different from those bearing only A:T base pairs. Indeed, deactivation of the excited state was found by fluorescence up-conversion to be faster in alternating $\text{poly}(\text{dG} \cdot \text{dC}) \cdot \text{poly}(\text{dG} \cdot \text{dC})$ than in an equimolar mixture of guanine and cytosine nucleotides [42]. A similar result was obtained by the same technique for isolated G:C base pairs in chloroform [43] and confirmed by resonance-enhanced multiphoton ionization in the gas phase [44]. These results are in line with a number of calculations that show the possible role of base pairing between G and C in relaxation of excited state [45–47]. Indeed, excitation can lead to a charge-transfer excited state with electron transfer from G to C. The resulting species undergo very fast proton transfer from G to C to yield a biradical state that fast relaxes to the ground state via a conical intersection. However, this pathway was recently challenged by transient absorption measurements that show a longer lifetime for the excited state of G:C polymers than for the corresponding monomers [48]. Involvement of nonemissive excited states in the deactivation pathway that cannot be detected by fluorescence-based techniques was put forward to explain these discrepancies. Understanding this process is of importance since substitution of a few A:T pairs by G:C pairs in double-stranded oligonucleotides leads to a sharp decrease in the fluorescence lifetimes [49].

57.2.1.3 Triplet States

The bulk of these recent data are related to the singlet excited state. Conversely, characterization of the triplet excited states of DNA has been less studied, although these transient species are well characterized in monomers [50,51]. Direct observation of the triplet state has been reported only in single-stranded thymine oligomers where its lifetime is 30 times shorter than in the monomer (150 vs. 4000 ps) while the intersystem crossing quantum is roughly similar (ca. 2×10^{-2}) [52]. To date, no evidence for the formation of triplet excited states in double-stranded DNA has been provided [53]. However, triplet energy transfer experiments from excited photosensitizers provide strong evidence for the high photoreactivity of this excited state. In these studies that involve various chromophores

such as aromatic ketones or quinolones, an efficient quenching of the triplet state of the photosensitizer by DNA is observed concomitant to the formation of CPDs [54,55]. This property was recently used to determine the energy level of the triplet state of thymine within double-stranded DNA that was found to be ca. 270 kJ/mol [56]. This value is 40 kJ mol⁻¹ lower than for the free base or nucleoside showing that triplet energy transfer photosensitization is favored in DNA duplex. Whether triplet excited states of DNA are at the origin of photoproducts in addition to singlet species upon direct excitation by UV photons is still a matter of debate. Evidence has been provided for the sole involvement of singlet states [57–59] but theoretical works led to the conclusion of a possible role played by triplet states, at least for CPDs [60].

57.2.2 Structure and Properties of the Photoproducts

Final products induced by UVB and UVC radiation within DNA mostly involve adjacent pyrimidine bases, although some monomeric damage is produced as well as some purine photoproducts.

57.2.2.1 Cyclobutane Pyrimidine Dimers

CPDs were the first isolated DNA photoproducts, in 1958, following irradiation of thymine [61,62]. They arise from a concerted [2 + 2] cycloaddition between the C5–C6 double bonds of adjacent pyrimidine bases. The reaction is a very fast one and was reported to occur in less than 1 ps in single-stranded DNA [41]. CPDs can be produced between either two thymines (T<>T), two cytosine (C<>C), or a thymine and a cytosine (T<>C and C<>T, depending whether thymine is at the 5'- or the 3-OH end of DNA). In monomers such as the base thymine or the nucleoside thymidine, a large number of isomers can be produced [63] (Figure 57.1). First, the two pyrimidine rings can be either on the same or an opposite sides of the cyclobutane ring; this is the *cis*, *trans* isomery. In addition, the bases can be parallel with the C5 atoms linked to one another (as well as the two C6 atoms) or the C5 of a base linked to the C6 of the other. Such isomers define *syn*, *anti* isomery. The *anti* isomers cannot be produced between adjacent bases within DNA because bases are all parallel on a same strand. In addition, all pyrimidines are in the same orientation along the *N*-glycosidic bond in B-form DNA. Consequently, the *cis*,*syn* cyclobutane dimers are the major isomers found in double-stranded duplexes [64–67]. They are also the major isomer obtained upon irradiation of dinucleosides monophosphate [68–72], although some *trans*, *syn* are obtained in lower amounts.

FIGURE 57.1 Diastereoisomers of the TT CPD. Only the *cis*,*syn* form is found in stable B-DNA.

57.2.2.2 Pyrimidine (6-4) Pyrimidone Photoproducts

The second main reaction taking place between adjacent pyrimidines is the formation of pyrimidine (6-4) pyrimidone photoproducts (64PPs) [73,74]. These lesions are proposed to arise from the decomposition of a heterocyclic intermediate, oxetane, or azetidine whether the 3'-end base is a thymine or a cytosine, respectively (Figure 57.2). This intermediate is expected to be the product of a Paterno–Büchi reaction [75], although an alternative pathway involving nucleophilic addition was also recently proposed [58]. The oxetane and azetidine intermediates have not been observed directly but a number of results strongly support the proposed mechanism. First, recent time-resolved studies showed that the (6-4) photoproducts appear only a few milliseconds after UV excitation, in agreement with the formation of a ground-state intermediate [53]. In addition, oxetanes are readily produced upon irradiation of thymine and specific ketones [76,77]. Finally, the corresponding thietane cyclic intermediate was isolated and characterized upon photolysis of a model system containing 4-thiothymidine [78]. The most characteristic features of 64PPs arise from the presence of the pyrimidone ring that exhibits strong absorption in the UVB range (315 nm for TC 64PP and CC 64PP; 325 nm for TT 64PP and CT 64PP) [70,79–81] and possesses fluorescence properties [82].

57.2.2.3 Secondary Photoreactions

Both types of photoproducts may undergo secondary photoreactions. CPDs have lost the aromaticity of the parent bases and thus the maximum absorption around 260–270 nm. Instead, a maximal absorption is observed around 220–230 depending whether thymine or cytosine is involved. Consequently, a residual absorption is still observed at 254 nm that should be taken into consideration in experiments with UVC. Indeed, upon excitation at this wavelength, CPDs undergo efficient photoreversion into the parent bases [71,83]. A consequence is that the formation of CPDs in DNA reaches a plateau at high doses while other photoproducts do not [66,67]. This may drastically modify the determination of the relative distribution of photoproducts like in a number of early studies that involved high doses because of the lack of sensitivity of the detection techniques. It is also worth mentioning that cytosine-containing CPDs undergo more efficient reversion than TT CPDs [67,71].

(6-4) Photoproducts also undergo secondary photoreactions in high quantum yield. Indeed, upon absorption in the 310–350 nm range, the pyrimidone ring undergoes intramolecular cycloaddition resulting in isomerization into a Dewar valence isomer [71,79,84,85] (Figure 57.3). These photoproducts do not exhibit absorption at wavelengths higher than 230 nm. Another UVC-induced secondary photoproduct of TT 64PP has been reported in the “locked nucleic acids” series but not in standard DNA [86]. Dewar isomers are detected upon UVB irradiation of DNA and cells [67,87] but high doses are required. The formation of these lesions is more efficient with simulated sunlight containing both UVB and UVA

FIGURE 57.2 Formation of TC 64PP. A cycloaddition between the imino form of the 3'-end cytosine and the 5'-end thymine yields the cyclic intermediate azetidine. When the 3'-end base is a thymine, the NH group of the intermediate is replaced by an oxygen atom and the compound is an oxetane.

FIGURE 57.3 Structure of TT 64PP and its conversion into a Dewar valence isomer. For the pure photoproduct, the reaction is more efficient at the maximum of absorption around 320 nm. However, UVA is more efficient in DNA because of shielding by excess of normal bases.

[87,88], or by successive exposure to UVB and UVA [89]. This observation points to an efficient photoisomerization by the latter radiation. This result can be explained by the competitive absorption of normal bases in the UVB range that limits the absorption by 64PPs. Consequently, Dewar valence isomers are likely to be biologically relevant upon exposure to real sunlight.

57.2.2.4 Deamination

Spontaneous hydrolytic cytosine deamination is one of the most frequent reactions taking place within DNA [90]. This reaction involves substitution of the C4 exocyclic amino group by a hydroxyl group, leading to the enol form of uracil that rapidly evolves into the canonical form. Recent theoretical investigations have provided details on the mechanism that involves two water molecules [91,92]. This reaction is quite slow with a half-reaction time of 30,000 years [93]. However, saturation of the C5–C6 double drastically accelerates the deamination rate since the half-life of 5,6-dihydrocytosine is 3 h [94]. Interestingly, CPDs, 64PPs, and Dewar isomers all bare C5–C6 saturated pyrimidine rings. As could be expected, cytosine-containing photoproducts readily deaminate into the corresponding uracil derivative, although the structure significantly affects the reaction rate. *Cis,syn* cyclobutane dimers deaminate roughly as fast as 5,6-dihydrocytosine. Interestingly, the *trans,syn* isomers deaminate much more slowly [68,69,72,95]. 64PPs have also been shown to undergo deamination (Figure 57.4) but only for derivatives with the cytosine located at the 5'-end [68]. Indeed, the 3'-end base remains unsaturated and loses the C4 substituent upon formation of the lesion. The (6-4) photoproduct and the Dewar valence isomer of the dinucleoside monophosphate dCpT deaminate more slowly than the *cis,syn* cyclobutane dimer. It may be added that

FIGURE 57.4 Deamination of the CT 64PP by nucleophilic addition of water on the C4 amino group. This reaction also takes place with cytosine-containing CPDs. However, it is not possible for TC 64PP because the C4 substituent is a carbonyl.

methylation of cytosine at the C5 position drastically reduces the deamination rate [96,97]. The rate of this reaction is increased by the presence of a guanine at the 5'-end in duplex DNA [98]. In addition, blockage of transcription machinery at the site of damage was found to accelerate the deamination rate.

Experiments involving synthetic oligonucleotides have shown that deamination of CPDs also takes place in double-stranded DNA, although with a decreased rate [99–102]. The results provided evidence for an important role played by deamination in the mutagenic properties of UV radiation. Indeed, the UV-induced mutation spectrum is characterized by C→T mutations at TC dinucleotides and CC→TT tandem mutations [103–105]. These features are likely to be explained by the coding properties of uracil moiety in deaminated cytosine-containing dimers that efficiently pair with adenine.

57.2.2.5 Minor Photoproducts

Dimeric photoproducts are not only produced between adjacent pyrimidine. Data were obtained, mostly in oligonucleotidic models, for the formation of lesions involving adenine linked either to another adenine or to a thymine. The first lesion involves a [2 + 2] cycloaddition between the C5–C6 double bond of a tautomeric form of adenine to the C8–N9 double bond of a second adenine. A ring-opening reaction then takes place [106]. The adenine–thymine dimeric photoproduct arises from a similar mechanism involving a [2 + 2] cycloaddition of the two C5–C6 double bonds, followed by a ring-opening reaction [107,108]. Only limited information is available on the yield of formation of these adenine-containing dimers. Work on homopolymers showed that the quantum yield for the AA dimer is ca. two orders of magnitude lower than that of TT CPD [109].

Reactions leading to monomeric lesions also take place within DNA upon far-UV irradiation. A first example is hydration of cytosine that results from the addition of a water molecule to the C5–C6 double bond and yields the enantiomers of 6-hydroxy-5,6-dihydrocytosine. At the nucleoside level, 2'-deoxycytidine photohydrates are not stable and undergo two competitive decomposition pathways, namely, deamination and dehydration with respective rate constants of 0.0008 and 0.0105 min⁻¹ [110,111]. Biochemical approaches based on the use of the repair enzyme endonuclease III showed that cytosine hydrates are 10 times more stable in double-stranded DNA and that deamination is favored over dehydration [112,113]. As a result, stable 2'-deoxyuridine hydrates accumulate within DNA. However, both enzymatic and chromatographic measurements showed that photohydrates are produced in a two orders of magnitude lower yield than CPDs [110,114]. A second class of monomeric far-UV-induced damage is oxidative lesions and particular guanine damage like 8-oxo-7,8-dihydroguanine (8-oxoGua). This lesion has been proposed to arise from reaction with singlet oxygen produced by DNA itself [115]. Another possibility is a one-electron oxidation process triggered by excitation of DNA. Although reported several times in isolated DNA, oxidation of guanine remains a minor lesion in UVB- and UVC-irradiated cells [116,117].

57.2.3 Formation of the Photoproducts within DNA

Study of the formation of pyrimidine dimers within double-stranded DNA strongly depends on the availability of appropriate techniques. Early works very mostly based on acidic hydrolysis of radiolabeled DNA and yielded only information on CPDs [118]. Sequencing methods such as ligation-mediated polymerase chain reaction (PCR) combined to T4 endonuclease V (T4endoV) provided information at the nucleotide resolution in targeted genes [119], although with limited sensitivity. Nevertheless, the major breakthrough in the field was the development of antibodies raised against the three classes of pyrimidine dimers [120–122]. More recently, chromatographic assays such as ³²P-post labeling [123] and high performance liquid chromatography (HPLC)–tandem mass spectrometry [66,67,124] yielded more detailed information on the individual yield of the four possible derivatives (TT, TC, CT, and CC) of each of the different classes of dimers.

57.2.3.1 Distribution of Dimeric Photoproducts in Isolated and Cellular DNA

In double-stranded DNA, CPDs are the main lesions. Only *cis,syn* isomers are detected in stable B-form duplexes [64,67,125,126]. Both UVB and UVC radiations lead to the same ratio between the yields of TT, TC, CT, and CC CPDs, namely, approximately 10:5:2:1 [67]. The quantum yield for TT CPDs has been

TABLE 57.1 Yield of Formation of Pyrimidine Dimers in Isolated Genomic DNA of Increasing GC Content upon Exposure to UVB Radiation

DNA Origin	<i>Clostridium perfringens</i>	Calf Thymus	<i>M. luteus</i>
%GC	25	41	72
TT CPD	49.8 ± 5.2 (59.2)	27.6 ± 1.8 (40.8)	2.8 ± 0.2 (8.7)
TT 64PP	2.7 ± 0.3 (3.3)	1.6 ± 0.1 (2.3)	0.2 ± 0.0 (0.5)
TC CPD	13.8 ± 1.3 (16.4)	15.0 ± 1.1 (22.2)	10.0 ± 0.8 (0.3)
TC 64PP	8.3 ± 0.8 (9.8)	11.3 ± 0.7 (16.7)	8.8 ± 0.7 (27.7)
CT CPD	7.4 ± 1.2 (8.7)	7.4 ± 0.5 (10.9)	3.7 ± 0.3 (11.5)
CC CPD	2.2 ± 0.3 (2.6)	4.7 ± 0.6 (7.0)	6.5 ± 0.4 (20.3)

Yields are expressed in photoproducts/10⁴ bases per J/cm². The value in brackets represents the proportion of each photoproduct (expressed in %).

shown to be in the range of 2%–3% per TT sites [125–127]. This low value is in line with the very efficient relaxation of the excited states of DNA bases discussed in the “excited states” section. In cells, the yield of CPDs is around 0.2–0.5/10⁶ bases per J/cm² upon exposure to UVB [87,89,116,128–130] while it ranges between 2 and 10 CPD per 10⁶ bases per J/m² with UVC [66,114,131,132]. The (6-4) photoproducts are also readily produced in three- to fivefold lower amounts than CPDs [67,87–89,128,133]. The relative distribution of photoproducts is similar in cells and isolated DNA. However, it must be emphasized that this distribution is obtained in DNA of mammalian that contains 40%–42% G:C base pairs. The G + C content of DNA, which significantly varies in bacteria, was found to drastically affect the relative yield of the different photoproducts [134]. At high G + C content, TT CPD is a minor lesion, produced in lower yield than CC CPD (Table 57.1). This study also revealed that the TC dinucleotide exhibits the highest photoreactivity. Another interesting observation on UV-induced DNA damage in cells is related to Dewar valence isomers. These photoproducts are not detected upon exposure to biologically relevant doses of pure UVB but can be found in the DNA of cells exposed to simulated sunlight [67,87,88]. This emphasizes the role of UVA in the photoisomerization process. Quantitative information on whole skin is less frequent but the available one points to a drastic decrease in the yield of photoproducts in the UVB range.

The formation of dimeric photoproducts is not homogenous within DNA in cells. Indeed, sequencing techniques showed that CPDs are produced in higher yield at specific “hotspots” that correspond to more frequently mutated sites [135,136]. Another important modulation is related to methylation of cytosine. 5-Methylcytosine is a minor base of DNA representing a few percent of all cytosines and is generated at CpG islands in order to regulate gene expression. Interestingly, methylation drastically modifies the basic photochemical properties of cytosine [137,138] and significantly increases its photoreactivity [96,97]. As a consequence, methylated sites are hotspots for the formation of photoproducts [139,140]. Telomeres were also identified as sensitive parts of the chromosome [141]. Inhomogeneous distribution of dimeric photoproducts is also observed within skin where the cells of the upper layer of the epidermis are more damaged than those closer to the basal layer [142,143]. This trend is more pronounced with high (254 nm) than low-energy (UVB) radiation, in agreement with the different absorption properties of the tissue at these different wavelengths.

57.2.3.2 Structural Effects

Although often presented in its standard B-form, DNA exhibits a dynamic structure. The observation that formation of photoproducts is a reaction faster than the structural fluctuations of the biopolymer [38,41] suggested that only bases exhibiting the required orientation undergo dimerization with a high

efficiency, in agreement with theoretical works [144,145]. It is thus obvious that any structural modification is likely to affect the yield and/or the nature of the photoproducts. Such effects can be observed on small dimeric model systems in which the 2-deoxyribose rings are locked in a 3'-endo conformation and that yield only CPD at the expense of 64PP upon UVC irradiation [146]. Other chemical modifications leading to a favored 3'-endo conformation were found to increase the photoreactivity of thymine-thymine sequence models [147,148]. Numerous studies have reported a strong impact of the experimental conditions on the photochemistry of isolated DNA. A first example concerns *trans,syn* cyclobutane dimers that are not produced in B-form DNA. However, destabilization of the double-stranded structure by increased temperature or decreased ionic strength leads to their formation in a significant yield [64,149,150]. The same approach showed that at low temperature, the photoreactivity of single- and double-stranded DNA is similar. However, reduced stacking in single-stranded DNA at higher temperature results in a much lower yield of lesions [118,149]. Modulation of the ratio between CPDs and (6-4) photoproducts was also observed upon increasing the temperature and lowering the ionic strength [149,150].

More biologically relevant situations also illustrate the major impact of structure on the yield of photoproducts. A first example is the effect on the binding of transcription factors. These observations cannot be accounted for by shielding since, in a same DNA/protein complex, photoreactivity is enhanced at some sites and reduced at others [151]. Interestingly, strong sequence effects in promoters of human genes were observed *in vivo* in agreement with binding of transcription factors [152,153]. Another important aspect in cells is related to chromatin structure. Evidence has been obtained for a strong modulation of the formation of CPDs that is more efficient in the nucleosome core [154,155]. In contrast, 64PPs are preferentially produced in the linker DNA [156]. Conversely, the presence of dimeric photoproducts strongly impacts the stability of the nucleosomes [157,158]. It may finally be added that the difference in photoreactivity along sequences can also be explained by the rigidity of specific "steps," as illustrated by the different photochemistry at ATT and TTA sequences [159,160].

57.2.3.3 Interstrand Photoproducts

All dimeric photoproducts discussed earlier involve adjacent pyrimidine bases on a same DNA strand. Interestingly, studies in isolated DNA and oligonucleotidic probes have shown the possibility of formation of interstrand photoproducts under specific conditions. Formation of interstrand cross-links upon UV irradiation has been reported in single-stranded DNA [161,162], DNA loops [163], and in fragments of viral and plasmid DNA [164]. Unambiguous evidence for the actual involvement of a bipyrimidine dimer in such cross-links was recently obtained in an oligonucleotide at acidic pH [165]. The biological relevance of these results is strengthened by the observation of interstrand CPDs in models of the telomeres [166]. The characterization of these CPDs as *anti* derivatives definitively establishes that they are interstrand lesions because their formation requires an antiparallel orientation. Significant amounts of nonadjacent photoproducts were also obtained within isolated genomic DNA exposed to UVC either in the dry state or in aqueous solution containing 80% ethanol [167]. *Anti* isomers were also the major ones, together with *cis,syn* derivatives that were either produced between nonadjacent bases on a same strand or between bases belonging to two different helix turns. Interestingly, very low amounts of interstrand 64PPs were detected.

57.2.3.4 Photochemistry in Spores

Spores are dormant forms of a series of bacterial species (*Bacillus*, *Clostridium*) produced under unfavorable conditions such as drought, lack of nutriment, or external stresses. Bacterial spores exhibit a much higher resistance to a series of damaging agents including UV radiation [168]. This topic has been extensively studied with respect to UV-mediated sterilization procedures and in exobiology. Spores, which are produced by asymmetric division, are first characterized by the presence of several walls and membranes that surrender a highly dehydrated core. DNA is located in this part of the spore and bound to large amount of very specific small acid-soluble proteins (SASP) that modify its structure into an A-like form [169]. A last specific feature is the presence of large amounts of the calcium dipicolinate (DPA) [168]. These three parameters, namely, dehydration, SASP, and DPA, strongly modify the photochemistry of

FIGURE 57.5 Relative distribution of SP, CPDs, and 64PPs in wild-type and mutant spore of *B. subtilis*.

DNA. A sole and specific lesion identified in 1965 [170] is produced upon exposure to far-UV radiation that arises from the formation of a link between the methyl group of a thymine with the C5 position of an adjacent one. This dimer 5-(α -thyminyI)-thymine is referred to as the “spore photoproduct” (SP).

Formation of SP has been shown by labeling experiment to involve a concerted mechanism [1] rather than a biradical recombination reaction as first proposed. Two sources of isomery have to be considered for SP. First, the methylene bridge may arise from the thymine located either at the 5'-OH or the 3'-OH end. In addition, the C5 atom of the saturated ring exhibits either a *S* or a *R* configuration. Structural configuration though suggested that the methylene arose from the 3'-end thymine and that the *R* isomer was the most likely configuration [171]. This hypothesis was only recently confirmed by a combine nuclear magnetic resonance (NMR)/density functional theory (DFT) study of SP under the form of the dinucleotide monophosphate released from DNA by enzymatic hydrolysis [172]. The main role of dehydration in the formation of SP is shown by its efficient formation in dry films of DNA [173,174]. In addition, the importance of the A-form was confirmed by the formation of SP in aqueous solutions of DNA containing large amounts of ethanol [64,167]. The role of SASP was shown by experiments carried out either on isolated DNA or in mutant spores. Lack of the SASP led to increased formation of the “classical” pyrimidine dimeric photoproducts at the expense of SP [175–177]. In a similar way, DPA was shown both *in vitro* and in whole spores to behave as a photosensitizer favoring formation of SP [178,179]. The major role of SASP and DPA in the very high specific formation of SP in spores is shown by the high similarity between the distribution of photoproducts in dry films of DNA and that in spores lacking SASP and DPA [174,179] (Figure 57.5). Interestingly, the overall yield of damage is the same in wild-type spores, and in this double mutant, the only difference being the nature of the photoproduct.

57.3 Photosensitization of DNA

In addition to photoproducts arising from direct excitation in the UVC and UVB ranges, photosensitized reactions also play a major role in cells and skin exposed to UVA and, to a lesser extent, visible light. The most widely studied photosensitization reactions in DNA involve oxidation processes. However, photosensitized triplet energy transfer may also take place and lead to the formation of cyclobutane dimers. It should be mentioned that the nature of the photosensitizers involved in these deleterious processes is not known, although compounds such as flavins, heme, and other biologically important chromophores are likely candidates [180].

57.3.1 Photooxidation

Several oxidative pathways are involved in UVA- and visible light-induced DNA damage. They are triggered by singlet oxygen (type II photosensitization), electron abstraction (type I photosensitization), or hydroxyl radicals. The two first arise from interaction of a photosensitizer in a

triplet excited state with molecular oxygen and DNA itself, respectively, while $^{\circ}\text{OH}$ radicals are by-products of metal-catalyzed reactions.

57.3.1.1 Singlet Oxygen

In its ground state, molecular oxygen is in a triplet state. Upon energy transfer from an excited photosensitizer in its triplet state, molecular oxygen is converted into a reactive excited singlet state. The $^1\Delta_g$ O_2 form of singlet oxygen ($^1\text{O}_2$) exhibits lifetimes in the microsecond range in pure solvents (2–3 μs in water and 20–50 μs in deuterium oxide), making it long-lived enough to react with biomolecules. $^1\text{O}_2$ reacts primarily with double bonds to yield oxetane, conjugate double bonds to produce endoperoxide and H atoms in α -position of a double bond through the ene reaction. In DNA, $^1\text{O}_2$ reacts only with guanine rings [181] and gives rise to a 4,8-endoperoxide as revealed by NRM studies carried out at low temperature [182]. This intermediate undergoes subsequent rearrangement into a C8 hydroperoxide that is reduced into 8-hydroxyguanine [183], a tautomeric form of 8-oxoGua (Figure 57.6). Interestingly, 8-oxoGua is the sole oxidation product in double-stranded DNA [184,185] but a minor one at the nucleoside level. Indeed, reaction of $^1\text{O}_2$ with 2'-deoxyguanosine rather yields the two diastereoisomers of a spiroiminodihydantoin (Sp) type lesion [186,187]. Sp is produced by successive dehydration and hydration of the hydroperoxide leading to the formation of 5-hydroxy-8-oxo-7,8-dihydro-2'-deoxyguanosine that then undergoes acyl shift. It may be added that singlet oxygen has sometimes been reported to induce strand breaks in DNA, in contrast with the total lack of reactivity of $^1\text{O}_2$ with the phosphodiester backbone [188]. These observations are most likely explained by the occurrence of secondary oxidation of 8-oxoGua that is much more prone to react with $^1\text{O}_2$ than the parent molecule [189]. The resulting lesions are quite unstable, in particular under mildly alkaline conditions. In agreement with this scheme, the formation of strand breaks in DNA is a second-order reaction that requires two $^1\text{O}_2$ molecules per cleavage site [190].

57.3.1.2 Electron Abstraction

Photosensitized oxidation of DNA may also involve direct electron abstraction from nucleic bases by an excited photosensitizer in its triplet state. As a result, a DNA radical cation is produced together with the radical anion of the sensitizer. This latter species reacts with molecular oxygen to yield superoxide anion ($\text{O}_2^{\cdot-}$) and ground-state sensitizer. Radical cations of DNA bases have been extensively studied at the nucleoside level. Two main reactions can take place, namely, hydration and deprotonation. In thymidine and 2'-deoxycytidine [191–193], hydration occurs at the C6 position, yielding a 6-hydroxy-5,6-dihydro-5-yl radical. This intermediate may then react with molecular oxygen and gives rise to a 6-hydroxy-5,6-dihydro-5-peroxyl radical that is then converted into 5-hydroperoxy-6-hydroxy-5,6-dihydropyrimidine [194]. This compound may be further reduced into thymidine or dCyd glycols (mixture of *cis* and *trans* diastereoisomers) or undergo ring-opening and cyclization to give rise to lesions such as the formamido residue and hydantoins. In thymidine, deprotonation takes place mostly at the methyl group and gives rise to a methyl-centered radical. This intermediate then reacts with oxygen and yield 5-(hydroxymethyl)-2'-deoxyuridine and 5-formyl-2'-deoxyuridine as final products. Deprotonation of cytosine involves mostly the C1' position on the deoxyribose moiety and leads to the formation of the oxidized abasic site 2-deoxyribonolactone (Figure 57.7).

FIGURE 57.6 Formation of 8-oxodGuo by reaction of dGuo with singlet oxygen.

FIGURE 57.7 Final products upon one-electron oxidation of thymidine.

Guanine is more susceptible than pyrimidines to one-electron oxidation because it exhibits the lowest ionization potential among DNA bases [195–197]. Hydration of the guanine radical cation leads to the formation of a reducing 8-hydroxyl-guanyl-7-yl radical [198]. This radical (Figure 57.8) may be oxidized into 8-oxoGua or reduced into the ring-opened 2,6-diamino-4-hydroxy-5-formamidopyrimidine (FapyGua) [199–202]. Like for singlet oxygen, 8-oxoGua does not accumulate in solutions of the free nucleoside dGuo upon photosensitized one-electron oxidation [203]. Indeed, 8-oxoGua has a lower oxidation potential than guanine [204] and is readily further oxidized into Sp as well as guanidinohydantoin under acidic conditions [205–207]. Because of the availability of oligonucleotides containing these secondary oxidation products, large amounts of information on their repair and their mutagenic properties are available [208]. However, their biological relevance is likely to be limited because guanine is present in an at least six orders of magnitude excess over 8-oxoGua in cellular DNA [209]. Secondary oxidation of the latter modified base is thus very unlikely, in agreement with *in vitro* experiment showing that 8-oxoGua can accumulate to very larger extent in isolated DNA [210] and with the lack of detection of these secondary oxidation products in cells exposed to intense oxidative stress [211]. Another interesting feature of the reactivity of the guanine radical cation is its ability to react with nucleophiles other than water. In particular, a series of amino acid can undergo such reactions that could be at the origin of the formation of DNA–protein cross-links [212–214]. A last set of oxidation products of guanine involves deprotonation into an oxidizing radical and leads to the formation of a transient imidazolone derivative further hydrolyzed into oxazolone [215,216]. It was recently proposed that superoxide anion rather than molecular oxygen is involved in the formation of imidazolone [217].

FIGURE 57.8 Final products arising from the reducing radical of guanine produced by electron abstraction.

TABLE 57.2 Distribution of Oxidized Bases within Isolates DNA Oxidized by Type I Photosensitizers and by G-Rays

Lesion	Benzophenone	Menadione	Riboflavin	γ -Rays
8-oxodGuo	80.3	77.5	86.9	37.4

All experiments were done under air bubbling. Results are expressed in %.

Like guanine, the radical cation of adenine undergoes hydration at the C8 position leading to the formation of 8-oxo-7,8-dihydroadenine and 2,4,6-triamino-5-formamidopyrimine (FapyAde) through the transient formation of a 8-hydroxy-7-yl radical. Deprotonation leads to an oxidizing radical that deaminates and yields inosine.

Although one-electron oxidation can take place with the four bases at the nucleoside level, guanine is by far the main target (Table 57.2) in double-stranded DNA. This is explained by its low oxidation potential that promotes efficient charge transfer through the double helix. The exact mechanism has been a matter of debate for almost a decade [218–222]. It appears that direct tunneling is involved on short distances while hopping is at the origin of long-range transfer. Evidence for predominant guanine oxidation upon one-electron oxidation has been mostly gathered from experiments involving photosensitizer tethered to double-stranded oligonucleotides [223–225]. The induction of guanine damage is monitored following conversion of the lesions into strand breaks by alkaline treatment. Such a strategy is only semi-quantitative because 8-oxoGua is not sensitive to such conditions [226]. It should also be emphasized that no direct strand breaks is observed before alkaline treatment, further supporting that the phosphodiester backbone is not a target of one-electron oxidation. Predominant oxidation of guanine has also been observed upon DNA ionization by high-intensity 193 nm laser pulses combined with biochemical analysis of the damage [227,228]. More specific chromatographic measurements confirmed the bulk of these results in isolated genomic DNA exposed to UVA light in the presence of type I photosensitizers [210] or upon biphotonic ionization triggered by a 266 nm laser beam [229].

57.3.1.3 Hydroxyl Radical Chemistry

Hydroxyl radical is a very reactive oxidizing species that reacts with 2-deoxyribose and with the four bases in double-stranded DNA [230–233]. In that respect, OH^\bullet -mediated DNA damage is very different from that triggered by singlet oxygen and type I photosensitization. Production of OH^\bullet is not a direct photochemical process but rather involves Haber–Weiss and Fenton chemistry. Indeed, UVA irradiation is at the origin of the release of significant amounts of superoxide anion in cells [234], either as a response of mitochondria or upon reaction of the radical anion of type I photosensitizers with molecular oxygen. Superoxide anion has the ability to dismutate into hydrogen peroxide, the precursor of hydroxyl radicals. These two last reactions are catalyzed by transition metals such as cuprous or ferrous ions. Interestingly, UVA has also been shown to induce the release of large amounts of iron from ferritin inside the cells [235]. Thus, irradiation leads to the simultaneous presence of excess $\text{O}_2^{\bullet-}$ and Fe^{2+} , making formation of OH^\bullet a likely reaction.

Observation that UVA leads to the formation of DNA strand breaks is a clear evidence of the production of OH^\bullet . Indeed, the other photooxidation pathways only damage the bases. Breaks in the phosphodiester backbone are accounted for by the abstraction hydrogen atom from the 2-deoxyribose ring by OH^\bullet ,

mostly at 4' and 5' positions [236]. Addition of molecular oxygen to the resulting carbon-centered radicals followed by decomposition of the resulting peroxides leads to cleavage of the phosphodiester bonds associated with the formation of 2-deoxyribose oxidation products. Bases are also major targets of $\cdot\text{OH}$ within double-stranded DNA. Identification of the products was mostly performed with monomeric model systems. $\cdot\text{OH}$ radical was mostly found to add to double bonds. For instance, $\cdot\text{OH}$ adds to the C8 position of purine rings, yielding the 8-hydroxy-purin-7-yl radical precursor of 8-oxopurines and Fapys [198,199,202]. $\cdot\text{OH}$ also adds to the C6 and C5 positions of the double bonds of pyrimidines [237], leading to hydroxylated carbon-centered radical that reacts with oxygen like following one-electron oxidation. $\cdot\text{OH}$ may also abstract hydrogen atom from the methyl group of thymine, leading to 5-HMdUrd and 5-FordUrd. In summary, the bulk of the final lesions are similar to those produced by type I photosensitization, although in different proportions. For instance, methyl oxidation products of thymidine represent 30% of one-electron oxidation lesions while they account for only 5% with $\cdot\text{OH}$. In isolated DNA exposed to $\cdot\text{OH}$ produced by γ -radiation in aerated aqueous solution, a wide variety of base oxidation products can be detected (Table 57.2). Interestingly, the ratio between 8-oxo and Fapy derivatives of purine decreases in the absence of oxygen, in agreement with the proposed redox chemistry of their common radical precursor [237].

57.3.1.4 Photooxidation in Cells

Direct chromatographic measurements by several groups have unambiguously shown the formation of 8-oxoGua in significant amounts in cells exposed to UVA [117,238,239]. In addition, traces amounts of Fapys were detected but in a ratio much lower than that obtained upon exposure to γ -radiation [240]. This observation rules out a major contribution of type I photosensitization processes triggered by endogenous chromophores. Information on other types of DNA damage can be inferred from assays involving purified repair enzymes used to cleave DNA at specific lesions. Formamidopyrimidine *N*-glycosylase (Fpg) recognizes oxidized purines while endonuclease III (endo III) reveals the presence of oxidized pyrimidines. The additional breaks produced by the enzymatic treatment are quantified by gel electrophoresis, comet assay, or alkaline elution. The same conclusion was obtained on the basis of these three different techniques, namely, that the most common UVA-induced oxidative lesions were oxidized purines, while breaks and oxidized pyrimidine were produced with a roughly threefold lower frequency [88,240,241]. This distribution is very different from that obtained for $\cdot\text{OH}$ (ionizing radiation) where breaks are produced in a twofold higher yield than oxidized bases. In sharp contrast, only oxidized purines corresponding to 8-oxodGuo were observed in cells exposed to UVA in the presence of exogenous type II sensitizers [240]. Altogether, these results suggest that singlet oxygen is the main mediator of oxidative damage to DNA in UVA-irradiated cells, with a small contribution of hydroxyl radical.

57.3.2 Formation of CPDs

Although considered as typical UVB-induced DNA photoproducts, CPDs are also involved in the genotoxicity of UVA. Indeed, they can be produced upon photosensitization by specific chromophores, but were also more recently shown to be induced in significant yield in mammalian cells and in skin in the absence of exogenous compounds.

57.3.2.1 Photosensitized Triplet Energy Transfer

The possibility of directly populating the triplet excited state of pyrimidine bases by energy transfer from a triplet excited sensitizer was established in the late 1960s [242,243]. Aromatic ketones were first used because they absorb in the UVA range, far from the maximum absorption of DNA, and exhibit a very high intersystem crossing yield. In addition, a requisite for the efficiency of the triplet energy transfer is an energy level higher for the sensitizer than the nucleic base. A number of other compounds were found to mediate this photosensitization process both in bases, nucleoside, and double-stranded DNA. The most studied include nonsteroidal anti-inflammatory drugs [55,244] that bear an aromatic ketone

motif and, more recently, fluoroquinolones [245–248]. Emphasis was placed on these molecules because they exhibit a high phototoxicity and photomutagenicity. Photosensitization of CPDs by exogenous molecule was found to take place in isolated DNA as well as in cultured cells. No (6-4) photoproduct is formed under these conditions, and TT CPDs represent ca. 90% of the CPDs [88], in higher predominance than upon UVC or UVB irradiation. This observation is in agreement with the lower energy of the triplet excited state of thymine with respect to that of the other bases, at the nucleoside level as well as in DNA. A number of basic studies have correlated the photophysical properties of the sensitizers with their ability at undergoing triplet energy transfer. It was observed for some of them that the results could not explain the induction of CPDs in DNA. It was actually found that photodecomposition products of the sensitizer could be the actual triplet energy transfer photosensitizers [249]. It was also shown that phosphate ions may exhibit drastic effect on the excited states of the sensitizers, maybe mimicking properties of DNA backbone [250].

57.3.2.2 UVA-Induced Formation of CPDs

UVA radiation alone also promotes the formation of CPDs in cells and skin in the absence of exogenous photosensitizer. This is a rather poorly efficient process with a yield roughly three orders of magnitude lower than UVB. However, its biological relevance cannot be neglected because the intensity of UVA is much higher than that of UVB in sunlight. The first observation of UVA-induced CPDs was reported after exposure of bacteria to narrowband 365 nm radiation [251]. It was then observed in mammalian cell lines [87,241,252,253] and in human skin [143,254]. Interestingly, recent quantitative chromatographic unambiguously showed that CPDs are produced in higher yield than oxidative damage (Table 57.3), in particular the most frequent one 8-oxoGua, in both cultured cells and whole human skin [88,116,255]. These results are in line with some mutagenic studies showing a large number of mutations at bipyrimidine sites in UVA-irradiated cells [256–258]. The distribution of CPDs is very similar to that observed after triplet energy transfer with a predominance of TT CPDs over the CT and TC derivatives, lack of formation CC CPD, 64PPs, and Dewar isomer. It was thus first proposed that a photosensitization process might be involved [88]. However, some reports have been made of the induction of CPDs upon UVA irradiation of isolated DNA, namely, in the absence of cellular sensitizers [239,259–262]. Unfortunately, these studies were based on biochemical approaches that do not provide an extensive distribution of the dimeric photoproducts. One interesting exception is a gel sequencing analysis that showed the predominance of TT CPDs, like in the DNA of UVA-irradiated cells [262]. More extensive chromatographic measurements showed the absence of 64PPs in UVA-irradiated isolated DNA and the same ratio between the yields of the different CPDs [263]. In addition, formation of CPDs was found to take place with a similar efficiency in isolated and cellular DNA [87,262,263]. Another similarity is the roughly constant yield of CPDs over the UVA range [241,263]. These results, combined with the observation of a weak but significant absorption of DNA in the UVA range [263,264], make a direct photochemical process like a plausible explanation of the UVA-induced formation of CPDs. However, the basic underlying photochemistry, such as the nature of the involved excited states, remains to be elucidated.

TABLE 57.3 Yield of 8-OxodGua and TT CPD in CHO Cells, Primary Culture of Human Fibroblasts and Keratinocytes, and in Human Skin upon Exposure to UVA

	CHO	Keratinocytes	Fibroblasts	Skin
8-oxodGua	0.064 ± 0.020	0.015 ± 0.005	0.026 ± 0.019	0.007 ± 0.003
TT CPD	0.191 ± 0.010	0.089 ± 0.004	0.164 ± 0.008	0.066 ± 0.035
Ratio TT CPD/8-oxodGua	3.0	5.9	6.4	9.3

57.4 DNA Repair

A series of DNA repair systems are based on the excision of the portion of the damaged strand around the lesion, followed by resynthesis using the undamaged strand as template and final ligation. Differences are mostly related to the size of the portion of DNA removed that can be a single nucleotide [base excision repair (BER) for small oxidized bases] or a short oligonucleotide (NER for bulky photoproducts). These two systems are conserved in all cell types, although the proteins can be structurally very different in eukaryotic and prokaryotic cells. In addition to these excision/synthesis mechanisms, some species possess repair enzymes that use radical reactions to restore unmodified bases from UV-induced photoproducts.

57.4.1 Nucleotide Excision Repair

NER is a versatile system that can remove from DNA a wide range of lesions inducing large structural modifications. NER is the major repair pathway for UV-induced dimeric pyrimidine photoproducts. In mammalian cells, more than 30 proteins are involved that act in a concerted way from the initial damage recognition to the restoration of the intact duplex. A large number of them were discovered in relationship with photosensitivity syndromes such as xeroderma pigmentosum, Cockayne syndrome, or trichothiodystrophy. Two subpathways have to be considered for NER. The first one is associated with blocking of the transcription [transcription-coupled repair (TCR)] and mostly removes damage from the transcribed strand of active genes [265–267]. The second NER subpathway removes bulky lesions from the rest of the genome and is referred to as global genome repair (GGR) [268]. The main difference in the two processes is related to the initial sensing of the damage.

57.4.1.1 GGR in Mammalian Cells

In GGR, lesions are recognized on the basis of local modification of the DNA structure. Consequently, lesions inducing larger distortion are more rapidly removed. For instance, CPDs only induce limited modifications with 10° unwinding and bending ranging between 9° [269] and 30° [270] and hardly perturb the hydrogen bonding. This is mostly explained by the parallel orientations of the bases. In contrast, the two pyrimidine rings adopt a perpendicular orientation in 64PPs resulting in a much more drastic distortion of the DNA helix and loss of base pairing [269]. The bending and unwinding angles of a duplex containing a TT 64PP opposite two adenines are 44° and 30°, respectively [271]. These strong differences in DNA-distorting properties of the two main classes of pyrimidine dimers are reflected in the repair kinetics. Indeed, it is now well established that GGR removes 64PPs much more rapidly than CPDs, with a half-lifetimes of 3–4 and 24 h, respectively [87,272–275]. Dewar isomers are repaired as efficiently as their (6-4) precursors [89]. It may be added that the nature of the two modified pyrimidines was recently shown to drastically impact the rate of removal of CPDs in the following order: CT > CC > TC > TT [276]. This observation points to a major impact of subtle structural differences on the recognition by the DNA damage-sensing proteins.

In GGR [268], this step is performed by the XPC–HR23B complex (Figure 57.9). In the case of CPDs, the DDB (DNA damage binding) complex acts as an key upstream sensor [277,278], possibly through the recognition of modifications of the chromatin structure [279]. The resulting increased DNA conformational modification is then recognized by XPC–HR23B. The next step in GGR involves recruitment of the TFIIH factor that contains among other proteins the two helicases XPB and XPD. These enzymes unwind DNA and verify the actual presence of a lesion in the repair complex. A preincision complex is then formed by assembly of RPA and XPA proteins, followed by XPG. The latter protein is believed to induce the release of XPC–HR23B. In a following step, ERCC1–XPF joins the complex. XPG and XPF perform incision of the single-stranded DNA at the 3'- and 5'-end, respectively. The produced 24–32 nucleotides long ssDNA piece containing the lesion is released. The proteins then leave the ssDNA with the exception of RPA that assists the DNA synthesis performed by Pol δ , RFC, and PCNA. The final nick is sealed by ligase I.

FIGURE 57.9 (See color insert.) Main steps in global genome repair (GGR) in eukaryotic cells.

57.4.1.2 TCR in Mammalian Cells

TCR differs from GGR in the damage recognition step that involves stalled RNA polymerase II (RNAPII) at the site of a lesion [265–267] (Figure 57.10). Because the signal for repair is not the lesion itself, CPDs and 64Ps are removed with equal rates by TCR. Although not completely established, it seems likely that RNAPII stays at the lesion site, possibly after backtracking in order to facilitate access of the repair proteins. Conformational changes induced by the Cockayne syndrome B protein (CSB) could also be involved in the latter process. CSB exhibits other key properties in TCR and appears as a central protein. Even in the absence of damage, CSB is in dynamic interaction with the transcription machinery. However, binding of CSB strongly increases upon UV irradiation as the result of the induction of DNA photoproducts. In a subsequent step, TFHII localizes at the arrested complex. Another Cockayne syndrome A protein (CSA) is then loaded onto the complex, as well as XPG and chromatin remodeling factors such as HAT, p300, and HMGN1. The TCR complex then recruits the incision proteins involved in GGR, namely, RPA, XPA, and XPF–ERCC1. Excision of the oligonucleotide bearing the photoproduct is then carried out. DNA synthesis and ligation subsequently take place by likely using the same enzymes as during GGR. Disassembling of

FIGURE 57.10 (See color insert.) Schematic representation of transcription-coupled repair (TCR) in eukaryotic cells.

the repair complex is initiated by CSA that ubiquitylates CSB that is further degraded. Restart of transcription involves the THIIIS factor, recruited earlier in the process by CSB, which cleaves the 3'-end of the nascent RNA strand and restores its correct positioning in the active site of the RNA polymerase.

57.4.1.3 NER in Bacteria

NER is well-preserved process in evolution and is present in all cell types. In bacteria, GGR is performed by the UvrABC system [280,281]. The main steps are similar to those encountered in eukaryotic cells, namely, damage recognition, DNA unwinding, formation of the preincision complex, incision, release of the damaged ssDNA, DNA synthesis, and ligation. The main difference is that only six proteins are involved (UvrA, UvrB, UvrC, UvrD, Pol I, and ligase). Expression of *uvrA* and *uvrB* genes is controlled by the SOS response, a process triggered in bacteria by various stresses that block replication. The UvrA homodimer is the initial sensor for potentially damaged sites. The affinity of UvrA for damage DNA is 1000 times higher than for normal undamaged substrate. It then forms a complex with UvrB that first checks for the actual presence of a lesion. UvrB also exhibits helicase properties that permit DNA unwinding. UvrC is then recruited and cleaves the damage strand at the 8th nucleotide on the 5'-end and the 5th nucleotide on the 3'-end with respect to the photoproduct. The UvrD helicase facilitates oligonucleotide elimination. In a final step, UvrB is displaced from DNA by polymerase I that performs DNA synthesis prior to ligation. Bacteria also possess a system equivalent to TCR that involves the Mfd (TRCF) protein [282]. Mfd first removes RNA polymerases from the damaged site and then recruits UvrA in order to initiate repair. In that respect, TCR is different in eukaryotic cells where the polymerase remains close to the damaged site during repair.

57.4.2 Other Excision Enzymes for Dimeric Photoproducts

NER is a general repair process for CPDs and 64PPs present in all cells. In addition to NER, some unicellular systems possess additional repair enzymes for these photoproducts that also involve cleavage of DNA followed by resynthesis (Figure 57.11).

FIGURE 57.11 Excision repair of pyrimidine dimers by T4endoV and UVDE.

57.4.2.1 Thymine Dimer Glycosylases

A well-known protein is endonuclease V of bacteriophage T4 [283]. This enzyme specifically recognizes CPDs, but not 64PPs, and is widely used as a biochemical tool in order to convert CPDs into strand breaks detectable by electrophoresis techniques. T4endoV is actually a glycosylase rather than an endonuclease that catalyzes the cleavage of the *N*-glycosidic bond of the 5'-end pyrimidine nucleotide of the dimer (Figure 57.11) [284,285]. The nucleophilic group that attacks the C1' atom is the α -NH₂ of the N-terminal end. It also exhibits an AP lyase activity that cleaves the 3'-phosphodiester bond of the abasic site, leaving a 5'-phosphorylated extremity and a 3'-end carrying an oxidized ring-opened 2-deoxyribose derivative. T4endoV exhibits an interesting repair mechanism. Upon binding to a damaged site, the enzyme induces a 60° kink to the DNA helix. In addition, the adenine opposite the 5'-pyrimidine of the dimer is flipped out from the duplex in order to let the catalytic amino acids localize close to the photoproduct. Followed cleavage of the DNA strand, the damaged nucleotide is then hydrolyzed together with three nucleotides by the exonuclease activity of the polymerase I of the infected bacteria. DNA synthesis and ligation then take place. Interestingly, enzymes exhibiting an activity identical to that of T4endoV were identified in several bacterial species including *Micrococcus luteus* [280,284]. With the exception of a single report in *Saccharomyces cerevisiae* [286], no cyclobutane dimer glycosylase activity was observed in eukaryotes.

57.4.2.2 UV Damage Endonuclease

Another series of enzymes involved in repair of UV-induced dimeric photoproducts are endonucleases. The first protein of this class, referred to as UV endonuclease (UVDE), was isolated from the yeast *Schizosaccharomyces pombe* [287–289], and later from bacteria such as *Deinococcus radiodurans*, *Bacillus subtilis*, and *Thermus thermophilus* [280]. A consequence of this alternative repair pathway for UV-induced pyrimidine dimers is the lower sensitivity of *S. pombe* with respect to *S. cerevisiae* to UV radiation. These proteins cleave the phosphodiester bond on the 5'-end of pyrimidine dimers, both the CPDs and the 64PPs, thereby introducing a nick in the strand (Figure 57.11). Polymerization of DNA induces the displacement of the damaged strand, leaving a single-stranded 5'-flap. This structure is resolved by rad2, the yeast homolog of FEN-1 that cleaves DNA at the single/double-strand junction. The resulting nick is then ligated. The role of *rad2* in UV excision repair is shown by the higher sensitivity of the corresponding mutant while the double *uvde rad2* mutant is less sensitive. This is explained by the accumulation of nicks produced by UVDE in the *rad2* mutant. However, a fraction of these endonucleotidic sites are repaired, in agreement with observation that DNA recombination proteins may be also involved in this alternative repair pathway.

57.4.3 Base Excision Repair

Modified bases that induce only limited structural deformation of the DNA duplex are mostly repaired by BER [290,291]. Most oxidized bases, as well as strand breaks and abasic sites, are repaired by BER, that, in contrast to NER, involves a series of repair enzymes exhibiting a define substrate specificity.

57.4.3.1 Specific Features of BER

N-glycosylases, which are responsible for the initial cleavage of the sugar-base bond in BER, can excise either oxidized pyrimidine [292–296] or oxidized purine [297–301], with some partial substrate overlapping [302,303]. Other largely expressed *N*-glycosylases recognize deaminated cytosine. Interestingly, all glycosidic activities are conserved in the different cell types, although the involved proteins are structurally very different (Table 57.4). It may be also emphasized that inhibition a single specific glycosylase does not seem to drastically affect cellular viability and genome integrity in knockout animal models [304–306]. This is mostly explained by the broad substrate specificity of these classes of enzymes that can back up the missing activities. A possible role of NER in these alternative pathways has been also

TABLE 57.4 The Main *N*-Glycosylases Involved in the Repair of Oxidized Bases

<i>E. coli</i>		Human	
Enzyme	Substrate	Enzyme	Substrate
UNG family, monofunctional			
Ung	Uracil	UNG SMUG1	Uracil Uracil (+5-hydroxycytosine, 5-hydroxymethyluracil)
Nth family, bifunctional (β -elimination)			
Nth (EndoIII)	Thymine and uracil glycols, cytosine hydrates, 5-OHCyt	NHT1	Thymine and uracil glycols, 5-formyluracil
MutY	Adenine in 8-oxoGua:Ade	MUTYH OGG1	Adenine in 8-oxoGua:Ade 8-OxoGua, FapyGua
Fpg family, bifunctional ($\beta\delta$ -elimination)			
Fpg	8-OxoGua, FapyGua, FapyAde (+5-OHCyt)		
Nei (EndoVIII)	Thymine and uracil glycols, 5-OHUr	NEIL1 (in ssDNA) NEIL 2 (in ssDNA)	FapyAde, FapyGua, thymine glycols, 5-OHUr Hydantoin, 5-OHUr

proposed. One has also to emphasize the sophisticated systems aimed at preventing expression of the mutagenesis of 8-oxoGua. All cell types possess *N*-glycosylases that cleave 8-oxoGua paired with cytosine. In addition, proteins (MutY in bacteria and HMUY in human) are present that specifically remove adenine paired with 8-oxoGua to prevent mutation fixation [307]. Last, an enzyme (*Escherichia coli* MutT) is devoted to the hydrolysis of 8-oxodGuo triphosphate in the nucleotide pool that could be incorporated during DNA synthesis [308].

57.4.3.2 *N*-Glycosylases

BER events involve first a cleavage of the base-sugar link by an *N*-glycosylase (Table 57.4) followed by cleavage of the resulting abasic site (Figure 57.12). The last steps correspond to the synthesis and ligation of an undamaged DNA strand. Three main types of *N*-glycosylases have been identified [308]. The first one corresponds to monofunctional enzymes, and the nucleophile undergoing the *N*-glycosidic bond cleavage is an activated water molecule. The resulting abasic site is then cleaved in a second step by a pure AP lyase like APE1 present in large amounts in mammalian cells. The cleavage product is a gap that exhibits a 3'-OH and a 5'-deoxyribose-phosphate end. Typical proteins of this class are uracil *N*-glycosylases (UNG). Other *N*-glycosylases are bifunctional and perform both the excision of the base and the cleavage of the damage strand. A first type of bifunctional *N*-glycosylases is related to the bacterial endonuclease III (*Nth*) enzyme [309]. The nucleophile is an internal lysine residue. It triggers a β -elimination reaction leading to the release of the base, and the formation of a one-nucleotide gap with an oxidized deoxyribose unit linked to the 3'-end while the 5'-end carries a phosphate group. Last, other bifunctional *N*-glycosylases belong to the Fpg family [310]. Their enzymatic reaction involves an *N*-terminal proline and catalyzes a β,δ -elimination. Their final product is a gap with both ends phosphorylated. It should be emphasized that for all *N*-glycosylases, the modified base is flipped out of the DNA duplex into the active of the enzyme after damage recognition [311].

57.4.3.3 End Cleaning and DNA Synthesis

The nature of the single-nucleotide gap produced by the two first steps of the BER process has a major impact on the subsequent DNA synthesis phase. Indeed, natural substrates for polymerases are gaps with 5'-phosphate and 3'-OH residues. End cleaning is thus required after the action of *N*-glycosylases

FIGURE 57.12 Chemical structure of the gap left in DNA after action of mono- or bifunctional *N*-glycosylases.

FIGURE 57.13 Schematic representation of the short-patch and long-patch synthesis pathways in BER. The selection of the process depends whether or not the 5'-end blocking group (X) can be efficiently processed.

and AP endonucleases before completion of repair. This is also true for the repair of single-strand breaks produced by oxidative stress, which exhibit a wide variety of structures frequently involving blocking ends. In mammalian cells, the 5'-deoxyribo-phosphate group produced by the action of APE1 on abasic sites is cleaved by Pol β that further adds the missing nucleotide [312]. The nick is then ligated. This pathway is referred to as short-patch repair (Figure 57.13). It is also involved after cleavage by polynucleotide kinase of the 3'-phosphate group [313] resulting from the action glycosylases with β,δ-elimination mechanism, and following cleavage of the unsaturated aldehyde produced by β-elimination. However, another synthesis pathway can take place, the long-patch repair. It involves strand invasion over 2–8 nucleotides by the polymerase followed by cleavage of the 5'-flap segment by FEN1 [314,315]. Long-patch repair occurs for instance when the 5'-end blocking group of an oxidative strand breaks [316,317] or a cleaved oxidized abasic site [318,319] cannot be processed. It is also triggered when polymerization is performed by Pol δ or Pol ε loaded onto PCNA instead of Pol β after cleavage of AP sites by APE1. It may be added that *N*-glycosylases, AP endonucleases, and polymerases are not the only proteins involved in BER. XRCC1 is a scaffold molecule [320,321] that interacts with PNK, Pol β, and XRCC1, and is thus a major player in short-patch repair. Poly(ADP-ribose) polymerase (PARP1 and 2) performs ADP-polyribosylation of numerous proteins at the site of strand breaks and thus induces early signaling and BER enzyme recruitment [322].

57.4.4 Radical Repair

Data presented in the photooxidation part unambiguously show that radical chemistry may be extremely harmful for DNA. Yet, some species possess enzymes that use specifically generated radicals in order to split UV-induced photoproducts back to the initial pyrimidines. The two main classes are the photolyases and the spore photoproduct lyase (SPL).

57.4.4.1 Photolyase

Photolyases are enzymes that use visible or near-UV radiation in a photoreactivation process [323,324]. By this strategy, cells are protected by using the genotoxic agent itself, sunlight, to repair the DNA damage it induces. Photolyases repair either CPDs or 64PPs. CPD photolyases are found in half of the

eubacteria [280], while both 64PPs and CPDs photolyases represent a major repair pathway in plant, especially in leaves where most cells are not dividing [325]. Photolyases have been also identified in some fishes, in drosophila, in some archaeobacteria, and non-placental mammals (opossum) [326]. Humans do not possess photolyase but analog proteins, cryptochromes, are present and play a role in circadian rhythm. The photoenzymatic process of photolyases is now quite well understood, in particular for the CPDs photolyases. Recent advances mostly arose from state-of-the-art time-resolved measurements and crystallographic studies [326,327].

All CPD photolyases bare a fully reduced flavin adenine dinucleotide (FADH^-) cofactor (Figure 57.14). The reduction of the FAD cofactor into FADH^- is catalyzed by light in a reaction that takes place independently of DNA repair, likely in order to keep the enzyme always functional. Three tryptophan residues are involved with the first one located at the surface of the protein and harvesting light energy [328,329]. The subsequent step is a series of electron transfer through the three tryptophans leading to the generation of FADH^- . During repair, the latter species is excited and cleaves the cyclobutane ring by initial injection of an electron into the photoproduct and formation of semi-reduced FADH^\bullet . The resulting CPD radical anion undergoes intramolecular C5–C5 bond cleavage. The C6–C6 bond is broken in a subsequent step with formation of an intact pyrimidine at an end and of the radical anion of the pyrimidine at the other end. Oxidation of the latter species by FADH^\bullet regenerates FADH^- and yields a second repaired pyrimidine. These reactions are quite fast, with decays around a few hundred picosecond for FADH^- in the presence of CPDs while the C5–C5 and C6–C6 bonds were found to be broken in 60 ps and 1.5 ns, respectively [330]. The actual repair pathway is more complex because the photons are not directly absorbed by FADH^- . Indeed, photolyases possess another cofactor that behaves like an antenna and then transfers the absorbed energy to FADH^- . These compounds are either 5,10-methenyltetrahydrofolylpolyglutamate or 8-hydroxy-5-deazaflavin that exhibits respective absorption maximum in the 377–410 nm or the 430–460 nm range. The Förster-type energy transfer between light-harvesting cofactor and FADH^- takes place within ca. 100 ps with high-quantum yield (0.6–1) [331,332]. It is facilitated by the proximity (15 Å) of the interacting compounds.

In addition to CPD photolyase, a number of species also possess a similar enzyme specific for 64PPs [333–335]. Interestingly, such activity is not present in eubacteria. Because the enzyme exhibits a high degree of homology with CPD photolyase, a similar enzymatic reaction was postulated in both proteins. Yet, 64PPs do not exhibit a ring to be split upon repair. It is rather believed that electron is injected into their oxetane (or azetidene) derivatives, the species which are the intermediate in the formation of 64PPs.

FIGURE 57.14 Scheme of the repair of CPDs by photolyases.

The likelihood of this mechanism was confirmed by model studies [336–338]. When free in aqueous solution, the oxetane (azetidine) derivative exhibits a very short lifetime. A key step in the enzymatic process is the induction of a drastic change in the balance between the pyrimidine (6-4) pyrimidone and the oxetane (azetidine) structure. Crystallographic studies strongly suggest that such a shift in the equilibrium results from the interaction of specific amino acids like glutamate 304 and aspartate 397 and 399 in the 64PPs photolyase of *Drosophila melanogaster* [339]. In contrast, histidine residues are more likely involved in the *Xenopus laevis* enzyme [340]. 64PPs photolyases seem to be less efficient than their CPD homolog as shown by their lower quantum yield (ca. 0.1). Surprisingly, 64PPs photolyases bind to Dewar isomer-containing DNA but do not cleave the photoproduct.

57.4.4.2 Spore Photoproduct Lyase

The peculiarity of the photobiology of spores has already been mentioned. This dormant form of some bacteria is highly resistant to UV radiation. In addition, SP is formed as the only photoproduct at the expense of CPDs and 64PPs. Understanding the repair of SP explains why such an evolutionary strategy has been selected. SP is reverted to the initial thymines by the SPL [341–343]. Because spores are dormant forms, UV-induced damage accumulates in their genome and has to be quickly repaired upon germination. This requirement is achieved through the fast repair of spore photoproducts by SPL that is more efficient than the repair of 64PPs and CPDs by NER. In order to make repair even faster upon germination, spores are loaded with SPL during sporulation. Another interest in SPL is that it does not need ATP, a source of energy almost absent from spores. Altogether, the UV resistance of spores can be explained by the voluntary accumulation of a very specific photoproduct easy to repair upon germination.

Like photolyase, SPL is a radical enzyme but it does not require light activation. SPL belongs to the radical S-Adenosyl-Methionine (SAM) superfamily where the initial radical is provided by the cleavage of S-adenosyl methionine into an adenosyl radical (Ado^\bullet) [344,345]. This last step is preformed in a [4Fe–4S] cluster located in the CXXXXCXXC sequence specific for this class of proteins. Ado^\bullet then abstracts a hydrogen atom to the C6 position of the saturated thymine (Figure 57.15) [346]. A rearrangement leads to the cleavage of the methylene bridge with restoration of the 3'-thymine and formation of a methyl-centered radical on the 5'-thymine. Two pathways have been proposed for the completion of the process. First, the thymine radical may abstract H from AdoH and complete the cycle. Recent works with mutants also raised the possibility that a cysteine located out of the cluster (Cys 141 in SPL from *B. subtilis*) could be the final H donor [347], leading to the reversion of the second intact thymine. The observation that mutation of Cys 141 is as lethal as that of cysteines in the cluster supports the latter mechanism [348]. Another interesting issue is the stereoselectivity of SPL. The initial observation that the *S* enantiomer [349] was the favored substrate was surprising because the *R* isomer is expected to be the biologically relevant form. More recently, evidence were obtained that the *R* isomer of SP-TpT was a good substrate [350]. Moreover, the initial report of a favored repair of the *S* isomer of SP as a thymidine derivative was challenged [351].

FIGURE 57.15 Principle of the repair of the SP by the SPL.

57.5 Conclusion

UVC and UVB photochemistry of DNA has been the topic of intense research for more than half a century, and large amounts of information have been gathered. The structure of the photoproducts and the relative contribution of the different lesions to UV genotoxicity are well established. Yet, questions remain open on the initial excited states involved in these photoreactions and how they can explain structural or sequence effects. In the UVA range, the photosensitized oxidation reactions are well described in model systems. However, the actual oxidative pathways in cells remain to be identified, although singlet oxygen seems to play a major role. DNA repair has also been extensively investigated, and the major repair enzymes or enzymatic complexes have been identified, as well as their substrate specificity. A large field of investigation remains open on molecular interaction between these proteins and damaged DNA. Other key questions are related to the interaction between the different repair pathways as well as between DNA repair protein and other major cellular functions. Altogether, the field of formation and repair of UV-induced DNA damage remains a very active one.

58.1 Introduction

Even though there is a continuum of energies in the electromagnetic spectrum of radiations, the ultraviolet (UV) has been divided into UVC (below 290 nm, nonsolar), UVB (290–315 nm), and UVA (315–400 nm) for categorizing the main effects of solar exposure on human skin. Wavelengths below 290 nm are blocked by the stratospheric ozone. These wavelengths are of the highest energies (>4.4 eV) and coincide with maximal absorption by DNA and other biomolecules, and would be extremely damaging to genetic material and biological tissues in general if they reached the surface of the earth. The stratospheric ozone layer therefore protects life from UVC radiation, also called abiotic radiation.

Longer wavelength UVB (λ > than approximately 290 nm) penetrates the ozone layer and constitutes about 5%–10% of the terrestrial solar UV radiation. It is absorbed by nucleic acids and has the ability to directly cause genotoxic damage to DNA and ultimately skin cancer. For many years, biologically nonrelevant UVC and, later, UVB focused most of the efforts of photobiologists to understand the phenomena underlying skin carcinogenesis. Although UVA radiation had been recognized as a powerful oxidant (Tyrrell 1991), wavelengths in this range had received relatively little attention until the 1990s, although they are by far the most abundant solar UV radiation that reaches the surface of the earth and they penetrate human skin more effectively than UVB.

Once thought to be relatively innocuous, UVA is now known as a damaging agent for DNA, proteins, and lipids, with harmful consequences that include skin aging and particularly carcinogenesis. In addition to these damaging effects, UVA is known to dramatically influence signal transduction and

thereby modify a myriad of cellular functions including cell death pathways through alterations in gene expression. While these may contribute to the deleterious effects of UVA such as preventing apoptosis of cancer cells or enhancing metastasis by increased metalloproteinase activity, they are not necessarily harmful and it is clear that UVA also has a potential protective role (reviewed recently by Tyrrell and Reeve 2006). UVA is also the basis for several types of therapy of diseases including atopic dermatitis and lupus erythematosus (see Krutmann 1998) where selective destruction of T helper cells has been postulated as an underlying mechanism. The purpose of this review is to provide a picture of the multiple and often opposing effects of UVA with particular focus on the explosion of studies in the last decade. We provide a synthetic view on DNA damage, inspect the numerous contradictory studies on UVA mutation spectra, and discuss recent advances in our understanding of the relevance of UVA effects on solar mutagenesis and skin cancer. Emphasis will also be placed on the potential role of protein damage on UVA effects. However, we will also consider how UVA can disrupt iron and heme homeostasis, alter cell cycle, and generate powerful signaling intermediates with dramatic effects on the balance of gene expression and biological outcomes. Not all aspects of UVA photobiology will be covered by the review. Mechanistic aspects of DNA damage (including that induced by UVA) will be considered by Douki (Chapter 57) elsewhere in this volume as will the crucial area of photoimmunology covered by Reeve (Chapter 63). The cellular and molecular responses to UVA in relation to skin carcinogenesis have recently been reviewed by Ridley et al. (2009). Given the oxidative nature of UVA damage, a very large literature has now emerged on agents that protect against UVA effects such as flavonoids and carotenoids, and a description of these many protective studies is beyond the scope of the current review.

Finally, we sound an obvious but sometimes overlooked note of warning when considering the UVA literature. Wavelengths shorter than 320 nm (i.e., not UVA) can have effects several orders of magnitude greater than those observed following irradiation at UVA wavelengths. For example, pyrimidine dimers are induced a 1000 times more efficiently at narrowband 313 nm radiation than at narrowband 365 nm radiation. Most studies employ broadband UVA sources for convenience and low cost. Short wavelengths that contaminate such sources have the potential to totally distort observations. We have tried to exclude work where we are aware that this is the case.

58.2 Chromophores

The biologically relevant cellular chromophore(s) that absorb UVA to generate reactive oxygen species (ROS) remain(s) a matter of debate. The photodynamic properties of porphyrins make them key candidates for generation of singlet oxygen. Of these, protoporphyrin IX, the immediate precursor to heme and a very strong photodynamic agent, merits particular consideration (Watkin and Tyrrell 2000). Other possible chromophores for UVA-generated ROS have been described by Wondrak et al. (2004, 2006) and include evidence for a role of 3-hydroxypyridine derivatives arising from a range of molecules occurring in skin (e.g., enzymatic collagen cross-links).

Baier et al. (2006) have studied singlet oxygen generation by time-resolved luminescence measurements at 1270 nm in various candidates and shown that UVA generates higher yields of singlet oxygen from riboflavin and flavin mononucleotide than from exogenous photosensitizers such as Photophrin. Beta-nicotinamide adenine dinucleotide and its phosphate (NADP) as well as cholesterol showed very low to undetectable levels of UVA-induced singlet oxygen.

58.3 UVA as an Oxidative Stress

Observations nearly 100 years ago demonstrated that UVA radiation inactivated enzymes such as amylase, catalase, trypsin, and tyrosinase and that the damage occurred in an oxygen-dependent fashion. Pioneering studies by Webb and co-workers (e.g., Webb and Lorenz 1970) demonstrated that the bacterium, *Escherichia coli*, showed a clear oxygen dependence for UVA inactivation and studies followed in several

microorganisms (reviewed in Tyrrell 1991) and in human cells (Danpure and Tyrrell 1976) where the oxygen dependence of inactivation of colony-forming ability was even more marked.

Work from several laboratories using components of cells *in vitro* demonstrated that UVA radiation at relevant fluences had the potential to generate various ROS in cells, and this, together with evidence for the oxygen dependence of most UVA-mediated biological events, provided the basis for concluding that UVA would generate a strong oxidative stress in cells and tissue (reviewed by Tyrrell 1991). Experiments with human fibroblasts demonstrated that reduction in the major source of cellular reducing equivalents (reduced glutathione) dramatically enhanced UVA-mediated events such as cell death (Tyrrell and Pidoux 1986) and gene activation (Lautier et al. 1992). Similarly, very strong evidence accumulated that singlet oxygen was the major ROS that mediated both UVA-induced cell death (Tyrrell and Pidoux 1989) and gene activation (Basu-Modak and Tyrrell 1993). Although this was first demonstrated with the heme oxygenase 1 (HO-1) gene, studies with other UVA-inducible genes reported a similar dependence (for reviews see Tyrrell 1996a; Grether-Beck et al. 1997). Many subsequent studies demonstrated the role of this species in UVA-mediated signaling (Ryter and Tyrrell 1998) so that UVA-generated singlet oxygen is now generally accepted as a primary signaling messenger.

More recently, Valencia and Kochevar (2008) have shown that nicotinamide adenine dinucleotide phosphate (NADPH) oxidase, an enzyme activated by UVA radiation, is a major source of ROS in human keratinocytes and that the generation of such ROS initiates rapid prostaglandin E2 (PGE2) synthesis. Importantly, these authors showed that knockout of the oxidase (*Nox1*) gene function completely prevents generation of these intermediates. In related studies comparing normal primary keratinocytes with cells knocked out for phagocyte oxidase (PHOX), He et al. (2005) concluded that the PHOX played only a limited role in both the induction of ROS and the increased apoptosis that follows UVA irradiation.

ROS have been measured in the skin of hairless rats (Yasui and Sakurai 2003) and in the stratum corneum of human skin after UVA (Herrling et al. 2003; Ou-Yang et al. 2004) (electron spin resonance [ESR] of nitroxides) with some evidence of ROS generation in deeper layers. Jain et al. (2010) have complemented these studies of the UVA radiation-induced chemiluminescence of human skin *in vivo* by following the decay characteristics of UVA-induced photon emission caused by different radiation doses.

In addition to the production of ROS, UVA radiation can influence the levels of pro-oxidant catalysts, particularly iron and heme (for reviews see Ryter and Tyrrell 2000; Tyrrell 2005). Iron plays a catalytic role via Fenton chemistry as a result of which peroxide is generated in cells, and although iron is not involved in the initial step of lipid peroxidation, it can play a catalytic role in the lipid peroxidation chain reaction. Reflecting these observations, there have been numerous examples where modulating free cellular iron levels by iron chelation has led to modulation of UVA-mediated effects (Tyrrell 2005). Importantly, a study by Pourzand et al. (1999) has shown that low-dose irradiation of human skin fibroblasts with UVA can increase the levels of labile iron in these cells by severalfold. This appears to result from UVA damage to the lysosomal membranes. Subsequent studies have confirmed these findings and shown that free iron is also increased in other skin cell types following UVA (Basu-Modak et al. 2006) and further implicated iron in necrotic cell death (Zhong et al. 2004).

Bystander effects whereby treatment of cells with a particular agent can lead to effects in untreated cells are well known in radiation biology. UVA radiation generally leads to an increase in excreted soluble cytokines, which may have effects including autocrine effects on other cells in the vicinity such as terms of gene activation, etc. For example, a recent study (An et al. 2010) showed that tumor necrosis factor (TNF)-alpha, interleukin (IL)-1 beta, and IL-10 were all upregulated in a c-Jun N-terminal kinase (JNK)-dependent pathway by UVA in cultured human keratinocyte (HaCaT) cells. On the other hand, Smit et al. (2009) observed that UVA inhibited calcineurin (Cn) in skin and skin cells as well as Jurkat cells and peripheral blood mononuclear cell (PBMC). In the latter two cell types, UVA also reduced the production of cytokines such as IL-2, gamma-interferon, IL-4, and IL-10 that are controlled by the Ca(2+)-Cn pathway. Although UVA irradiation has been reported to lead to release of histamine from human basophils (Monfrecola et al. 2003), other studies (Krönauer et al. 2001, 2003) indicated that UVA inhibits histamine release elicited by a variety of stimulants. UVA radiation has also been shown to decrease both basal and

cytokine-stimulated chemokine production in the specific case of the thymus and activation-regulated cytokine (TARC) in HaCaT cells (Zheng et al. 2003). All these factors may lead to effects on surrounding cells. However, long-lived ROS have received particular attention as agents of bystander effects. For example, UVA induces elevated mutation rates for several generations following UVA radiation by a proposed bystander effect, which can be abrogated by glutathione (Dahle et al. 2005a). In a classical bystander experiment by Whiteside and McMillan (2009), populations of keratinocytes (HaCaT) and fibroblasts (MRC5) were separated by a medium-permeable insert, and it was demonstrated that UVA (but not UVB) irradiation of one population leads to lethal damage in the untreated population.

Free heme can also play a catalytic role in the appropriate cellular environment and is a major UVA-absorbing chromophore. It has been known for some time that UVA can damage heme-containing proteins (e.g., catalase), and Kvam et al. (2000) have shown that following UVA damage to cells, free heme is released. The release of both labile iron and free heme by UVA radiation will further amplify the oxidative stress engendered by direct production of ROS.

58.4 UVA as a Damaging Agent

58.4.1 DNA Damage

Unlike UVB, the UVA component of solar radiation is very weakly absorbed by DNA (Sutherland and Griffin 1981) and acts by exciting other endogenous chromophores to generate ROS. Consequently, for many years, UVA was believed to generate mostly oxidative DNA damage. Indeed, Peak and Peak (1990) reported an induction of single-strand breaks (SSBs) by UVA, mediated by H_2O_2 . In the 1990s, new and sensitive methods became available for the detection and measurement of various types of DNA lesions, for example, comet assays, commercially available specific antibodies and DNA repair enzymes, high performance liquid chromatography (HPLC) coupled with electrochemical detection to reveal 8-oxoguanine (8-oxoG), and more recently HPLC coupled with tandem mass spectrometry. This has led to new measurements of UVA-induced DNA damage.

58.4.1.1 UVA Induces Oxidative DNA Damage in Mammalian Cells

It is well established that UVA promotes photosensitization of DNA, triggered by singlet oxygen (type II photosensitization), electron abstraction (type I photosensitization), or hydroxyl radicals. The use of specific DNA repair proteins helped considerably in investigations of the different types of DNA lesions thus generated. The *E. coli* Fpg and Nth proteins served to reveal oxidation products of purine (mainly 8-oxoG) and pyrimidine, respectively, and Nfo protein abasic sites. The additional breaks generated by the enzymes at the damaged sites were quantified by comet assay, alkaline elution, or alkaline gel electrophoresis. The 8-oxoG was more specifically measured by HPLC coupled with electrochemical detection. It has been shown that UVA radiation induces SSBs, oxidized pyrimidine, and oxidized purines in various mammalian cells (Zhang et al. 1997; Kvam and Tyrrell 1997; Douki et al. 1999; Besaratinia et al. 2005, 2008; Javeri et al. 2008), and that the most abundant oxidative DNA damage produced is 8-oxoG (Kielbassa et al. 1997; Pouget et al. 2000; Douki et al. 2003). The ratio SSB:oxidized pyrimidine:oxidized purine/8-oxoG is about 1:1:3. The low amounts of SSB and oxidized pyrimidines likely produced by hydroxyl radicals originated from the Fenton reaction and the predominance of 8-oxoG indicate a major contribution of singlet oxygen in the formation of oxidative DNA damage in cells by UVA (Cadet et al. 2009). Importantly, the human DNA N-glycosylase OGG1, which clears 8-oxoG, appears to be expressed more abundantly in the superficial than the basal layer of human skin (Javeri et al. 2008). This may lead to a lack of repair in the basal cells of the epidermis and therefore to accumulation of mutations due to 8-oxoG.

58.4.1.2 UVA Induces the Formation of Bipyrimidine Photoproducts in Mammalian Cells

Cyclobutane pyrimidine dimers (CPDs), pyrimidine (6-4) pyrimidone photoproducts (6-4PPs), and their Dewar valence isomers are produced by direct absorption of UVC or UVB radiation by DNA.

The inability of DNA to readily absorb in the UVA range means that these photoproducts are not expected to be formed by UVA. In fact, the first observation on CPDs induction by very pure narrowband 365 nm UVA was made by Tyrrell (1973) in bacteria. The quantum yield was 7×10^5 less at 365 nm than at 254 nm and the longer wavelength radiation induced predominantly thymine dimers, whereas at the shorter wavelength CPDs were induced in the ratio 5:4:1 (TT:CT:CC). CPDs were also observed in mammalian cells and human skin but it was a matter of debate because, unlike the original studies in bacteria, the protocols did not involve rigorous exclusion of short wavelengths (Enninga et al. 1986; Freeman et al. 1989; Hacham et al. 1990). In the late 1990s, the formation of CPDs by UVA has been reassessed in various laboratories with the help of more sensitive methods. Using denV protein from T4 phage to reveal CPDs or specific antibodies, CPDs were detected in mammalian cells, including in human skin (Chadwick et al. 1995; Kielbassa et al. 1997; Zhang et al. 1997; Young et al. 1998; Douki et al. 1999; Ley and Fourtanier 2000; Perdiz et al. 2000; Douki et al. 2003; Rochette et al. 2003; Courdavault et al. 2004; Besaratinia et al. 2005; Mouret et al. 2006). The yield of CPD formation by UVA is low in comparison to that produced by UVC or UVB. This may explain why cells from *xeroderma pigmentosum* patients who cannot repair bipyrimidine photoproducts and are thus extremely sensitive to sunlight and skin cancer, are not highly sensitive to UVA. Perdiz et al. (2000) found that CPDs were produced 10^3 - and 10^5 -fold less efficiently by UVA than by UVB and UVC, respectively. In addition, (6-4) photoproducts were barely detected after UVA (trace amount; Perdiz et al. 2000). Such yields of CPDs formation are in good agreement with the DNA absorption spectrum by Sutherland and Griffin (1981). Therefore, Perdiz et al. (2000) concluded that CPD formation by UVA could be compatible with direct absorption by DNA.

The formation of CPDs and 6-4PP can be analyzed with nucleotide resolution, either on the bulk DNA by HPLC–tandem mass spectroscopy (MS/MS) or at the gene level by ligation-mediated polymerase chain reaction (LM-PCR). In agreement with the original studies in bacteria (Tyrrell 1973) comparing induction at 365 and 254 nm, the distribution of CPDs induced by UVA drastically differs from that produced by UVC, UVB, or simulated sunlight. UVA-induced CPDs were predominantly formed at TT sites, while those produced at CC sites were poorly represented (Rochette et al. 2003). HPLC–MS/MS also revealed a predominance for TT CPDs over CT and TC CPDs, whereas CC CPDs and 6-4PPs were not detected (Douki et al. 2003; Mouret et al. 2006). The principal induction of CPDs at T-containing bipyrimidine sites, and mostly at TT sites, is similar to that observed when DNA was damaged by a photosensitization reaction with aromatic ketones (Lamola 1968; Charlier and Helene 1972). These data are consistent with an alternative hypothesis that most CPDs are formed through triplet energy transfer from photosensitizer to excited thymine which, in fact, has the lowest triplet state energy with regard to other bases. The hypothetical UVA-absorbing chromophore tightly bound to DNA to allow energy transfer remains to be identified.

58.4.1.3 CPDs May Be the Major DNA Lesions Induced by UVA in Mammalian Cells and Human Skin

Using the same method to measure 8-oxoG and CPDs in the same samples, either HPLC:MS/MS or DNA repair enzymes and alkaline agarose gel, it was shown that CPDs were roughly three times more efficiently produced than 8-oxoG. In skin biopsies, this ratio may vary depending on the donor (Douki et al. 1999, 2003; Courdavault et al. 2004; Mouret et al. 2006). The sensitivity of most DNA lesion detection methods requires high UVA dose exposure (above 750 kJm^{-2}). Nevertheless, CPDs have also been measured at environmentally relevant UVA doses (as low as 40 kJm^{-2}), and their formation increases linearly with dose (Sage and Douki unpublished). A conflicting publication (Besaratinia et al. 2008) claims a predominance of 8-oxoG lesion induction by UVA. This discrepancy can be partly explained by the use of less sensitive methods by the latter workers and the use of different irradiation conditions. Interestingly, in the yeast *Saccharomyces cerevisiae*, 8-oxoG is by far the major lesion produced by UVA, as revealed by mutation analysis of DNA repair mutants and alkaline agarose gel analysis (Kozmin et al. 2005).

58.4.1.4 Distribution of Damage Induced by UVA Is Similar in Plasmid/Isolated DNA and in Cells

A similar distribution of damaged induced by UVA in isolated DNA and cells was shown using various DNA repair enzymes (Kielbassa et al. 1997; Kuluncsics et al. 1999; Pouget et al. 2000; Douki et al. 2003; Jiang et al. 2009; Schuch et al. 2009) and more recently HPLC:MS/MS (Mouret et al. 2010). However, UVA irradiation of plasmid DNA should not lead to photosensitization reactions. This raises the question of the mechanism of DNA damage by UVA, and in particular that of CPDs formation. In addition, Schuch et al. clearly demonstrated that UVA radiation is able to induce 6-4PPs in plasmid DNA. However, 6-4PPs cannot be formed by photosensitization and are only produced by direct absorption. Thus, it could well be that in cells, the low energy of UVA photons is sufficient to directly excite DNA with subsequent formation of bipyrimidine photoproducts, both CPDs and 6-4PPs, yet at low level, whereas 8-oxoG is essentially formed by a photosensitization reaction mediated by singlet oxygen.

58.4.1.5 Does UVA Induce Other Types of DNA Lesions?

UVA is able to photoisomerize 6-4PPs produced by UVB in simulated sunlight into Dewar photoproducts (Perdiz et al. 2000; Douki et al. 2003). This is consistent with the observation that Dewar photoproducts are more frequently produced by natural and simulated sunlight, than by UVB, and conversely, the ratio 6-4PP to Dewar photoproduct is higher for UVB (Clingen et al. 1995; Perdiz et al. 2000). DNA-protein cross-links are expected to be produced by ROS and, indeed, have been reported to be formed upon UVA irradiation, even more efficiently than by ionizing radiation (Peak and Peak 1991; Arai et al. 2000). SSBs are induced in bacterial DNA by narrowband 365 nm radiation at yields approximately half that of CPDs, and the induction is totally dependent on the presence of oxygen (Tyrrell et al. 1974). Since DNA double-strand breaks (DSBs) are considered among the most deleterious DNA lesions, the question arose whether UVA induces DSBs, either directly or through processing of other types of DNA damage, such as at replication forks stalled at DNA photoproducts. DNA DSBs, revealed by neutral comet assay or γ -H2AX foci (phosphorylated H2AX variant histone), are not readily produced in human transformed fibroblasts or keratinocytes by direct UVA irradiation, but arise at low levels during the processing of DNA lesions (Girard et al. 2008; Wischermann et al. 2008). Long-lasting DSB may be responsible for the appearance of micronuclei and chromosomal aberrations in human HaCaT transformed keratinocytes (Wischermann et al. 2008). Interestingly, low doses of UVA induce ROS-mediated slowdown of DNA replication independently of cell cycle checkpoint activation and from the main DNA lesions such as CPDs, 8-oxoG, or delayed DSB (Girard et al. 2008). There may be biologically relevant DNA damage produced by UVA yet to discover.

58.4.2 Mutagenesis and Cancer

58.4.2.1 UVA Induces Mutations in Cultured Mammalian Cells

After long debate on whether or not UVA promotes the formation of bipyrimidine photoproducts, it is now recognized that the two major known photolesions induced by UVA radiation are 8-oxoG and CPDs, the ratio of which presumably depends on irradiation conditions, cell and skin types, and individuals. The UVB mutational signature, found in a large majority of nonmelanoma skin tumors, has been well established as C to T transitions at bipyrimidine sites and tandem CC to TT mutations (Brash et al. 1991), mostly mediated by CPDs in repair-proficient cells/individuals (Pfeifer et al. 2005). However, the relative contribution of bipyrimidine photoproducts or 8-oxoG to the mutagenic and cytotoxic effects of UVA exposure remains a topic of active debate. Moreover, the relative contribution of UVA radiation to solar mutagenesis and carcinogenesis is still an open question. The following reviews the types of mutations that have been reported to be induced by UVA over the last 15 years, with respect to the different DNA lesions induced and their repair rate (see the review by R  nger and Kappes (2008) for detailed discussion).

A first general observation from most of the studies is that UVA radiation is weakly mutagenic at environmentally relevant doses, while it is cytotoxic, in mammalian cells as well as in yeast and *Drosophila* larvae (Drobetsky et al. 1995; Negishi et al. 2001; Kozmin et al. 2005; Kim et al. 2007; Besaratinia et al. 2008). It has clearly been demonstrated in yeast that the cytotoxicity of UVA does not depend on DNA damage (Kozmin et al. 2005), but rather on damage to other constituents, particularly membrane lipids.

The first comprehensive work on mutagenesis induced by solar UV radiation of different wavelengths including the UVA range was by Drobetsky et al. (1995) in Chinese hamster ovary cells. It revealed that the UVA-induced mutation spectrum is dominated by AT to CG transversions, which, in fact, correlate with sites of UVA-induced TT CPDs (Rochette et al. 2003). However, such mutations could also be caused by incorporation of 8-oxodGTP (from dNTP pool oxidized by UVA) opposite adenine by replicative DNA polymerase, or by another unknown process. The relative induction of C to T transitions is lower for UVA, in comparison with UVB or simulated sunlight, but their distribution is identical for the three radiation types and correlates well with sites of induced C-containing CPDs (Rochette et al. 2003). In the absence of repair of bipyrimidine photoproducts (in nucleotide excision repair-deficient cells), the mutation frequency is greatly increased (sevenfold) and the spectrum is largely dominated by C to T transitions after UVA (Sage et al. 1996). On the other hand, the G to T transversions, the so-called hallmark of 8-oxoG, represent no more than 4% of the total UVA-induced mutations. Among point mutations generated by UVA in an episomal plasmid transfected in transformed human embryonic kidney cells, C to T transitions are the predominant events, and mutations at AT base pairs are increased in comparison with UVB, whereas G to T mutations are barely recovered (Robert et al. 1996). The OGG1^{-/-} mouse embryonic fibroblasts, that are unable to repair 8-oxoG, did not exhibit an increase in mutation induction in comparison with the OGG1^{+/+} counterpart, after exposure to UVA or UVB (Kappes and R nger 2005). Kappes et al. (2006) observed that in cultured primary human fibroblasts, UVA, like UVB, primarily induces C to T transitions at bipyrimidine sites. Interestingly, they also noticed that at similar cellular growth inhibition doses, UVA is more mutagenic than UVB in these skin cells. Since UVA also induced a much weaker and short-lived activation of p53 protein than UVB, the authors proposed that DNA damage induced in low amount by UVA relative to UVB does not elicit an effective protective response in human skin cells. Altogether, this series of data is not consistent with a prominent role for 8-oxoG in UVA-induced mutagenesis, but rather indicates CPDs as the culprit.

Pfeifer and collaborators (Besaratinia et al. 2005, 2008; Kim et al. 2007) using Big Blue mouse embryonic fibroblasts claim that promutagenic oxidative DNA damage, namely 8-oxoG, is the major cause for UVA mutagenesis. Indeed, in their hands, G to T transversions represented 26%–28% of the total mutations. Small deletions (about 10% of the mutations) also characterized the UVA-induced mutation spectra in the system used. All the small deletions comprised adjacent pyrimidines interrupted by a guanine, where CPDs (mainly TT CPDs) can potentially be formed. In addition, the most frequent events (30%–40% of total) were C to T transitions occurring at bipyrimidines. This class of mutation was excluded from the analysis by statistics, since they were also observed in unirradiated cells, albeit at a 2–3 times lower frequency. It is well known that spontaneous mutations occur primarily by deamination of methylcytosine in mCpG sequences, leading to C to T transitions. Due to the low relative induction of these mutational events by UVA, in comparison with UVB, it was legitimate to ask whether or not they originated from UVA-induced DNA lesions and were possibly caused by CPDs. Conversely, the distribution and sites of mutations are as important as the frequency. In addition, to assign a specific DNA lesion as the origin of a mutation at a given site is sometimes elusive. Nevertheless, reexamining the sites of mutations, it appeared that most of the C to T transitions induced by UVA, except for one hotspot (occurrence of four mutations that could be of spontaneous origin), occurred at sites different from that of the spontaneous C to T transitions. Moreover, part of them were recovered at sites which were also UVB mutational hotspots. Consequently, the latter data cannot be interpreted only as oxidative damage to guanine and points to a role for CPDs as premutagenic lesions. However, in contrast to all the other studies, cell irradiation was performed in the presence of culture medium that contained a well-known

photosensitizer, riboflavin, at high concentration so that the elevated frequency of G to T transversions may be explained by a prominent production of 8-oxoG by photosensitization via riboflavin (Besaratnia et al. 2007).

Altogether, the data may not be as conflicting as first thought and generally point to a role for CPDs. However, the relative contribution of 8-oxoG in UVA mutagenesis is not yet totally clear. The 8-oxoG is efficiently and quickly eliminated within 3–6 h by base excision repair in mammalian cells and is not expected to lead to extensive mutations in repair-proficient cells. The 6-4PPs are efficiently repaired by nucleotide excision repair and totally eliminated within 6 h, in contrast to CPDs, which are still partly present 24 h after exposure. In addition, UVA may compromise the repair of bipyrimidine photoproducts (Mouret et al. 2006). A still puzzling question concerns the role of TT CPDs, which largely predominate over C-containing CPDs, in UVA-induced mutagenesis. In mammalian cells and yeast, TT CPDs are supposed to be bypassed essentially in an error-free manner by the translesional DNA polymerase pol η (Johnson et al. 1999; Masutani et al. 1999), whereas they are more mutagenic in bacteria (Gibbs et al. 1993). It has also been proposed that beside CPDs, more complex DNA lesions play a role in UVA-induced mutagenesis, at least in hamster cells (Biverstål et al. 2008).

58.4.2.2 UVA Induces Mutation in Skin

Work on UVA-induced tumors in hairless mice showed a low incidence of p53 mutations in tumors (van Kranen et al. 1997). All of the p53 mutations were C to T transitions, mostly occurring at sites of UVB mutational hotspots. This indicates a role for CPDs in the formation of p53 mutation by UVA in mouse skin. The most extensive analysis of mutations induced in skin has been performed by Ikehata et al. (2008) in mice, using 364 nm UVA1 laser light, in comparison with UVB and sunlight. It was found that 65% of the total mutants recovered in the UVA-irradiated epidermis carried C to T transitions, 90% of which occurred at bipyrimidine sites. In contrast, G to T transversions, possibly generated by 8-oxoG, represented only 6% of total mutations, and no T to G transversions were found (Ikehata et al. 2008). The UVA-induced mutation spectrum differed somewhat from that induced by UVB. It is characterized by a high frequency of C to T mutations at 5'-TCG-3' sequences where CpG is methylated at the cytosine residue, a feature which is less pronounced after UVB or sunlight exposure. As for UVA, 6% of the total mutations recovered in sunlight-irradiated epidermis were G to T transversions. As expected, UVB contributed much more than UVA to the sunlight-induced mutation spectrum (Ikehata et al. 2004). Remarkably, the authors calculated that the UVA component of sunlight would provoke a threefold induction of mutations after a whole day of sun exposure, while UVB or sunlight would cause 15-fold and 35-fold mutation induction after an hour exposure at noon. The genotoxicity of UVA is indeed much smaller than that of UVB. However, these results cannot be directly applied to the human situation to predict UVA genotoxicity and risk to health, since human skin is much thicker than mouse skin and, in reality, the human population is exposed to multiple doses rather than single doses of UVB or UVA.

Very limited data are available on the mutations induced by UVA in human skin. Persson et al. (2002) analyzed p53 mutation in individual human skin keratinocytes repeatedly exposed to UVA and found three p53-mutated cells, all with a G to T transversion. Engineered human skin was exposed four times to UVA, UVB, or a mixture, which resembled sunlight, and p53 mutations were recovered in all cases (Huang et al. 2009). UVA led to a predominance of mutations in the basal epidermis, which contains dividing keratinocytes and is thought to give rise to skin cancer. The low number of mutations observed and the presence of a strong mutational hotspot in UVA-irradiated samples do not allow further conclusions at the molecular level. However, the data did confirm an earlier report that UVA and UVB contribute to sunlight-induced p53 mutations in human skin tumors (Agar et al. 2004).

58.4.2.3 UVA Induces Delayed Mutations and Persistent Genomic Instability

There is increasing evidence for long-term consequences of UVA exposure. UVA-induced DNA damage may persist or continue to be generated not only during the postirradiation period in the irradiated cell, and its progeny, but also in surrounding cells. These long-term changes may lead to cells that can

eventually acquire a hypermutator phenotype and later carcinogenic potential. In particular, it has been shown in Chinese hamster fibroblasts that UVA produces fewer immediate mutations but more delayed mutations than UVB or x-rays (Dahle and Kvam 2003). ROS generated by UVA has been associated with such persistent genomic instability. Using a specific screen to reveal large gene alterations, Dahle et al. (2005b) observed that UVA is able to induce large deletion as both immediate and delayed mutations. Similarly, UVA exposure of human HaCaT transformed keratinocytes lead to a continuous reduction of cell survival, an increase in mutations and an increase in micronuclei formation up to 21 days postirradiation (Phillipson et al. 2002). It has also been proposed that long-lasting DSB may be responsible for the appearance of micronuclei and chromosomal aberrations in HaCaT keratinocytes and may confer tumorigenic phenotype (Wischermann et al. 2008). Notably, a dose-dependent telomere shortening has been reported in UVA-irradiated cells, which has been correlated with a targeting of 8-oxoG in the GC-rich telomeric sequences (Oikawa et al. 2001). This event could be one of the possible causes of skin aging.

58.4.2.4 Role for UVA in Human Skin Cancer?

UVA may play a role in solar mutagenesis and skin carcinogenesis that is manifested as mutations in tumor suppressor genes in melanoma and nonmelanoma skin cancers. A role of UVA in the promotion steps of carcinogenesis is beyond the scope of this chapter.

There are several lines of evidence but not absolute proof for a role of UVA in cancer: (1) UVA damages DNA, inducing CPDs, 8-oxoG, and other secondary lesions; (2) UVA is mutagenic at environmentally relevant doses, including to skin; (3) a UVA mutational signature has been observed in sunlight-induced mutation spectra in various biological systems, even though the UVB component largely predominates (Drobetsky et al. 1995; Kozmin et al. 2003, 2005; Ikehata et al. 2004, 2008; Besaratinia et al. 2008); and (4) the basal layer of the epidermis, where tumors originate, receives far more UVA than UVB radiation. UVA is likely involved in some of the skin cancers in the human population, at least in case of heavy exposure to UVA, that is, repeated and excessive use of sunbeds and sunlamps or misuse of sunscreens.

Based on the analysis of p53 mutations and on the presence of CPDs and 8-oxoG in biopsies from squamous cell carcinomas (SCCs) and excised premalignant solar keratosis (SK), Agar et al. (2004) reported that the basal layer in tumors harbors more UVA than UVB fingerprint mutations. The UVB fingerprints, C to T transitions at bipyrimidine sites, were located in keratinocytes in the stratum granulosum in SCC and SK, whereas the events chosen as UVA fingerprints, the T to G and G to T mutations, showed a bias toward basal layers. In addition, CPD detection occurred throughout the epidermis but was maximal in the upper layers, while 8-oxoG detection exhibited a bias toward basal layers in all SKs and SCCs. This is consistent with the ability of UVA to penetrate down to the basal epithelial layers and dermis, whereas the penetration of short-wavelength UVB is confined predominantly to the superficial epidermis. Even though the mutational specificity of UVA is not yet clearly established, in particular in skin cells and tissue, these data strongly suggest a role for UVA in human skin carcinogenesis (Halliday et al. 2005).

UVA and melanoma have been the subject of intense research activity and debate, since Setlow et al. (1993) discovered that UVA is susceptible to cause melanoma in pigmented backcross hybrids of the platyfish *Xiphophorus*. Among comprehensive reviews are those by Wang et al. (2001), Jhappan et al. (2003), and Bennett (2008). Briefly, suggestions for a role of UVA in the pathogenesis of cutaneous malignant melanoma can be summarized as follows: (1) Epidemiological studies tentatively suggest positive relationship between melanoma incidence and use of sunlamps; (2) the use of sunscreens which provide a better protection against UVB than against UVA may also be a melanoma risk factor; (3) UVA (and UVB) induces melanoma in the melanoma-prone pigmented fish *Xiphophorus*, through the generation of ROS from melanin (Wood et al. 2006); (4) prolonged UVA exposure, but not UVB, can induce melanocytic hyperplasia (melanoma precursor) in pigmented Opossum *Monodelphis domestica* (Ley 1997). In contrast, UVB, but not UVA, could induce malignant melanoma in engineered transgenic mice. In fact, virtually none of the animal models developed exhibits susceptibility to melanoma incidence by UVA.

Moreover, Mitchell et al. (2010) reexamined the induction of melanoma by UVA in a *Xiphophorus* hybrid model similar to that in Setlow's studies and could not confirm the original data. This recent and important report refutes the only direct evidence that UVA causes melanoma.

An important question yet to be resolved is to what extent melanin protects from skin cancer and in particular from melanoma. The fair-skinned population is far more prone to develop melanoma than darker-pigmented individuals. In addition to genetic predisposition of fair-skinned individuals, the pheomelanin present in fair skin may act as a photosensitizer and produce ROS, in contrast to eumelanin, which is more abundant in dark skin and exhibits a protective effect against solar radiation. Kvam and Tyrrell (1999) observed that human melanoma cells with high melanin content accumulated two times more 8-oxoG after UVA irradiation than cells with low melanin content. In addition, melanocytes have recently been shown to be deficient in repair of oxidative DNA damage and UVB photoproducts (Wang et al. 2010). Thus, UVA-induced melanoma could originate from melanocyte stem cells present in the basal layer of the epidermis. In contrast to what has been observed in the mutated genes p53 and patched homolog (*Drosophila*) (PTCH) in nonmelanoma skin tumors (Giglia-Mari and Sarasin 2003), no clear UV signature has been found in the genetic alterations found in melanoma. Meanwhile, the BRAF (gene encoding the serine/threonine-protein kinase B-Raf) missense mutation (V600E) present in 66% of melanoma has been tentatively attributed to CPDs, produced by UVB by an error-prone translesion synthesis (Thomas et al. 2006). Since the surrounding sequence is a T-rich region, it could also be produced by UVA. Even though some evidence from basic research argues for an involvement of UVA in skin cancer, we are far from being able to estimate the extent of it.

58.4.2.5 Mitochondrial Mutagenesis and Photoaging

The mutation frequency of mitochondrial DNA (mtDNA) is generally much higher than that observed in the nuclear genome. This is partly due to the lack of protective histones and the absence of nucleotide excision repair, but mainly to the deleterious effect of ROS issued from electron leak from the respiratory chain and reaction with oxygen. Large mtDNA deletions (3–10 kbp) have been detected in many human tissues, at high levels in nonreplicating tissues like muscle and brain, and at a lower extent in mixed replicating tissues. As a replicating tissue, normal human skin carries low content of mtDNA deletions that have been associated with cancer in many tissues. The accumulation of mtDNA deletions has been proposed as an underlying cause of the aging process. The use of mtDNA damage as a biomarker for cumulative sun exposure in human skin and skin photoaging is relatively recent (reviewed by Berneburg and Krutmann 2000; Birch-Machin and Swalwell 2010).

The most frequent deletion, a 4977bp deletion known as the common deletion, has been observed at a higher frequency in chronically sun-exposed skin than in sun-protected skin or blood cells (Berneburg et al. 1997, 2004; Berneburg and Krutmann 1998). This common deletion and some others have been found with a higher frequency in the margin of nonmelanoma skin tumor of old patients, and age-related, but were typically absent from the tumors (Eshaghian et al. 2006). Furthermore, there was a greater frequency of mtDNA mutations (common deletion and tandem duplications) in “usually” sun-exposed compared to “occasionally” sun-exposed skin and none in sun-protected (i.e., rarely exposed) (Krishnan and Birch-Machin 2006). In addition, a rare 3895bp mtDNA deletion observed in sun-exposed body sites and reproduced *in vitro* by in cultured HaCaT cells, repetitively, exposed to sublethal doses of UVA + UVB light has been proposed as a marker for cumulative sunlight exposure in human skin (Krishnan et al. 2004). UVA, in contrast to UVB, has long been known as an oxidative stress. Interestingly, earlier studies assessed the role of UVA and ROS in the process of mtDNA deletion, using normal human fibroblasts. They revealed that singlet oxygen mediates the UVA-induced generation of the photoaging-associated common deletion (Berneburg et al. 1999) and that such deletions can be prevented by supplementation with beta-carotene, a known ROS and singlet oxygen quencher, or with creatine, the adenosine triphosphate (ATP)-producing precursor (Berneburg et al. 2005). Recently, Schroeder et al. (2008) elegantly linked mtDNA deletions with photoaging by showing that gradual depletion of mtDNA from human skin fibroblasts causes a gene expression profile, which is reminiscent of

that observed in photoaged skin. In terms of DNA repair, mitochondria possess functional base excision repair, DSB repair, and mismatch repair, pathways that are essential to protect mtDNA from extensive damaging effect of ROS (Berneburg et al. 2006, see also Kamenisch et al. 2010).

The role of mitochondria and mtDNA mutagenesis in photoaging and photocarcinogenesis is related to mitochondrial functions in the bioenergetic system and in apoptosis. The ROS-mediated mtDNA damage causes mitochondrial misfunction which in turn favors ROS generation. Cancer cells may exhibit enhanced intrinsic ROS stress, partly because of increased metabolic activity and mitochondrial dysfunction. Indeed, ROS-mediated mtDNA damage may be a mechanism to amplify ROS stress in cancer cells (Birch-Machin and Swalwell 2010). Due to the current lifestyle favoring increased exposure to UVA and in order to limit the adverse effects of natural or artificial UV exposure, such as photoaging and photocarcinogenesis, protective effect of natural antioxidants such as beta-carotene (Eicker et al. 2003) or lycopene (Rizwan et al. 2008) is being proposed as potential protective agents.

58.4.3 Membrane Damage Effects on Fluidity and Lipid Oxidation Products

Pioneering studies by Hollaender (1943) demonstrated that the rate of UVA inactivation of bacterial populations was greatly enhanced as the salt content of the postirradiation incubation medium was raised, strongly indicating that UVA produced potentially lethal membrane damage. Many subsequent studies have demonstrated that UVA can peroxidize membrane lipids (for reviews see Tyrrell 1991; Girotti 2001; McMillan et al. 2008) and that the membrane damage arising can lead to many consequences including cell death, lysosomal rupture, and aberrant protein trafficking. UVA-mediated lipid oxidation involves iron, singlet oxygen, and hydroxyl radical (Vile and Tyrrell 1995; Dissemond et al. 2003) and, importantly, the lipid oxidation products are also key signaling intermediates (see the following).

Several studies have detected changes in cell membrane fluidity following UVA treatment, generally by using fluorescent probes. Gaboriau et al. (1993) showed that a UVA-induced change in fluidity was associated with increased lactate dehydrogenase (LDH) leakage, and since both were protected by the lipid antioxidant vitamin E, lipid peroxidation is likely to be the cause of the changes. Growing cells are more susceptible to such UVA-induced change than quiescent cells. A study of the effect of UVA on the membrane fluidity of human fibroblasts using electron paramagnetic resonance (after incorporation of spin-labeled stearic acids) indicated increased rigidity of the fibroblast membrane structure (Budai et al. 2004). Susceptibility of keratinocyte membranes to UVA-induced lipid oxidation can be influenced by substituting cholesterol by phytosterols (Mora-Ranjeva et al. 2006). Sitosterol is protective whereas stigmasterol dramatically increases lipid peroxidation (+70%) and increases prostaglandin release.

Fractionating UVA radiation with short intervals between doses can enhance cytotoxicity and oxidative damage (Merwald et al. 2005). However, allowing an interval of several hours between UVA irradiations can lead to a significant adaptive protection of human skin fibroblasts against oxidative membrane damage (Vile et al. 1994) and apoptosis (Yang et al. 2003). Although Vile et al. used antisense experiments to link this protection to the activation of heme oxygenase, repetitive low-dose UVA irradiation also leads to a substantial upregulation of manganese superoxide dismutase (MnSOD) activity (Poswig et al. 1999) and selenium-dependent upregulation of glutathione peroxidase (GPx) activity, and it has been suggested that this enzyme as well as inducible MnSOD is involved in protection against UVA (Meewes et al. 2001). Schneider et al. (2006) have also shown adaptive protection of human dermal fibroblasts against UVA radiation and demonstrated that the response is very variable from donor to donor and depends on glutathione content. Although these authors linked the protection to UVA activation of GPx, it should be noted that UVA upregulation of heme oxygenase is exquisitely sensitive to intracellular glutathione levels (Lautier et al. 1992), and it seems likely that the induced protection against membrane damage in cells and skin will be due to the combined activity of the inducible antioxidant enzymes.

Using guinea-pig ventricular monocytes, La et al. (2006) showed in whole-cell voltage clamp experiments that UVA caused a progressive increase in late (slowly inactivating) Na(+) current that

had been elicited by 200 ms depolarizations. This not only provides a cellular cardiac model but also injects a cautionary note for imaging studies since UVA wavelengths are commonly used for Ca(2+) imaging.

58.4.4 Heme and Iron Homeostasis

Both heme and iron are essential for synthesis of a variety of proteins but low levels must be maintained by tight homeostatic mechanisms to avoid cell and tissue damage resulting from an excess of these pro-oxidant catalysts (Tyrrell 2005). UVA radiation severely disturbs both heme and iron homeostasis. UVA irradiation of mammalian cells leads to a sharp increase in the levels of labile iron, and this occurs in all skin cell types tested (Pourzand et al. 1999; Zhong et al. 2004; Basu-Modak et al. 2006) and has been linked to UVA-mediated cell death (Zhong et al. 2004). The release appears to be primarily due to UVA disruption of lysosomal membranes, which leads to protease leakage and degradation of proteins that include the crucial iron storage protein ferritin. Iron homeostasis is largely controlled in mammalian cells by the state of the iron-responsive protein, which changes its capacity to bind to specific mRNAs as a function of labile iron levels (for recent review see Recalcati et al. 2010). Activation of this protein by binding to free iron results in downregulation of the transferrin receptor and upregulation of ferritin. The increase in ferritin levels observed 1 or 2 days following UVA radiation is likely to be due to both this immediate release of free iron and the activation of HO-1 (see the following), which breaks down heme to release iron (Vile and Tyrrell 1993).

As well as iron, free heme appears to be released in cultured fibroblasts following UVA irradiation and in a cyclooxygenase-dependent fashion (Kvam et al. 1999), and this disruption in heme homeostasis is likely to be the trigger for the dramatic increase in HO-1 transcription following relatively low fluences of UVA radiation (see the following).

58.4.5 Photooxidation of Proteins and Enzyme Damage

Proteins are highly susceptible to oxidation so it is not surprising that they will be damaged by the ROS and the pro-oxidant catalysts generated by UVA radiation. This is due in part to their abundance in cells but also to the fact that they include chromophores such as amino acids with aromatic rings (e.g., tryptophan) that give rise to the UV absorption of the proteins in the region 250–320 nm. As a result, direct photooxidation may occur and arises from absorption of radiation by the protein or the bound chromophores, thereby generating excited states or radicals through type I processes. In addition, some proteins bind prosthetic groups such as flavins and hemes, which absorb in the UVA and visible range. For example, catalase a crucial antioxidant enzyme containing heme is very susceptible to UVA (Zigman et al. 1996; Maresca et al. 2006). As a result, indirect photooxidation of proteins may also occur (type II mechanism), which involves singlet oxygen generated by energy transfer from either protein-bound or other endogenous chromophores to oxygen. All these processes have been detailed in Bensasson et al. (1993), Davies (2003), and Pattison and Davies (2006).

58.4.5.1 Protein Oxidation by Direct UV Absorption

The triplet states of Trp, Tyr, and Phe generated by absorption of radiation in the UVB range can undergo electron or hydrogen atom transfer reactions, including with disulfides of cystines and O₂. These reactions result in Trp and Tyr radical cations and then neutral indolyl and phenoxy radicals or benzyl radical in the case of Phe. A well-known end-product of such radicals is the dityrosine cross-link. Thiyl radicals and thiyl peroxy radicals can further lead to sulfonic (RSO₃H) and sulfinic (RSO₂H) acids. Tyr is considered as the ultimate sink for one-electron oxidation, whereas cystine is the ultimate sink for one-electron reduction (Pattison and Davies 2006). Trp, Tyr, Phe, and His side chains, in the ground state, can also undergo direct photoionization processes.

58.4.5.2 Protein Oxidation by Singlet Oxygen

The main ROS produced in cells by UVA is singlet oxygen, which is generated via transfer of energy from an excited chromophore to molecular oxygen. As a result, the majority of UV-induced protein damage appears to be mediated by singlet oxygen (Pattison and Davies 2006). The interaction of singlet oxygen with proteins occurs mostly by reactions, which result in protein modification, rather than by quenching (relaxation to ground-state oxygen). Singlet oxygen reacts preferentially with Trp, His, Tyr, Met, Cys, and cystine side chains. Reaction with Trp gives rise to *N*-formylkynurenine, kynurenine, and 3 α -hydroxypyrrroloindole. The reaction of singlet oxygen with Tyr forms an unstable endoperoxide, which undergoes further reactions resulting in radical formation that may lead to dityrosine and protein cross-links. The products of His oxidation lead to His–His and His–Lys cross-links in free amino acid residues and very likely in proteins too. Disulfides are formed when free Cys reacts with singlet oxygen, probably along with cysteic acid (RSO₃H). UVA is also expected to produce intracellular protein peroxides probably localized on His, Trp, and Tyr residues (Pattison and Davies 2006). Photooxidation of proteins also commonly leads to high-molecular-weight aggregates, which may arise from dark reactions after the end of the light exposure. His residues may have a major role in the generation of these cross-linked proteins, since it has been reported that cross-links are absent from photooxidized proteins that lack His (Balasubramanian et al. 1990). Interestingly, the use of various photosensitizers in combination with UVA has helped in determining photooxidation products of His, either free or in peptides or proteins (Agon et al. 2006). Trp photoproducts have also been used as biomarkers for protein photooxidation and for establishing the molecular mechanism of photosensitization. For example, the pattern of Trp photoproducts differs for methylene blue, a predominant type II photosensitizer, and for naproxen, which belongs to the class of nonsteroidal anti-inflammatory drugs and produces photodamage supposedly through both type I and type II processes (Catalfo et al. 2009).

58.4.5.3 Protein Oxidation Induced by UVA and Biological Significance

Since proteins generally exist in multiple copies, biological effects will tend to be observed only at high doses. However, there is evidence dating back to studies in bacteria that damage to repair enzymes by UVA strongly influenced the biological outcome (Tyrrell and Webb 1973; Tyrrell et al. 1973). Indeed, this work led to a series of studies, which showed strong synergistic lethal interactions between UVA and various DNA damaging agents including shorter wavelength UV in bacteria and human cells (reviewed by Tyrrell 1978). Some years later, *in vitro* studies showed that irradiation of *E. coli lac* repressor with broadband UV (295–400 nm, centered at 325 nm) induces photooxidation of Trp and formation of *N*-formylkynurenine, which abolishes the inducer isopropyl β -D-1-thiogalactopyranoside (IPTG) binding (Spodheim-Maurizot et al. 1985). A continuous sublethal UVA irradiation administered to *E. coli* leads to a change in the activities of oxidative defense enzymes, hydroxyperoxidases, glutathione reductase, and manganese superoxide dismutase. This adaptative response resulted in an increased resistance to a lethal UVA irradiation challenge (Hoerter et al. 2005). Surprisingly, it did not confer increased protection against protein oxidation, as estimated by total carbonyl formation. In human skin cells, the addition of superoxide dismutase does not protect against oxidation of alcohol dehydrogenase and glyceraldehyde 3-phosphate dehydrogenase by UVA irradiation (Hu and Tappel 1992).

It was also shown in human skin cells that in addition to lipid peroxidation, UVA irradiation-induced sulfhydryl oxidation in proteins, which was dependent on iron, singlet oxygen, and hydrogen peroxide (Vile and Tyrrell 1995). Importantly, in melanoma cells, it was observed that UVA considerably increases L-isoaspartyl residues, a marker of protein damage, at doses lower than for induction of lipid peroxidation or DNA damage (D'Angelo et al. 2001). The same group showed that such protein damage is prevented by hydroxytyrosol, a natural antioxidant from olive oil (D'Angelo et al. 2005). In reconstituted epidermis of a different skin phototype, UVA was found more effective than UVB in impairing antioxidant enzyme activities (catalase and superoxide dismutase), and this inhibition correlated with the phototype of the melanocytes. In addition, it was shown that UVA induces a change in catalase levels

in epidermis reconstituted with low phototype melanocytes (Maresca et al. 2006). UVA has been shown to inactivate protein tyrosine phosphatase by a protease calpain-mediated degradation, and modification of tyrosine phosphatase is required to make it a calpain substrate (Gulati et al. 2004). It was later demonstrated that singlet oxygen inactivates protein tyrosine phosphatase-1B by oxidation of the active site cysteine (von Montfort et al. 2006).

Photoaging has been associated with protein oxidation in human skin (Sander et al. 2002) based on several observations. Firstly, the overall expression of antioxidant enzymes, catalase, copper–zinc superoxide dismutase, and manganese superoxide dismutase was elevated in the epidermis, but was low in the dermis. In photoaged skin, a depletion of expression of antioxidant enzymes was observed, as well as an accumulation of protein carbonyls, particularly in the upper dermis. UVA exposure also led to a dose-dependent protein oxidation. Proteosomal peptidases are involved in degrading oxidized proteins, and the activity of several of these peptidases was decreased in human keratinocyte cultures following UVA irradiation (Bulteau et al. 2002). Moreover, it was recently shown that the repair enzyme methionine-S-sulfoxide reductase (MSRA) was expressed in human epidermis and upregulated by low doses of UVA radiation (and H_2O_2), but not by UVB (Ogawa et al. 2006). Its expression was also increased by repetitive exposure of the human skin to simulated sunlight. MSRA reduces the methionine sulfoxide (MetO) to methionine, thus reversing the inactivation of proteins caused by oxidation of critical methionine residues. It is the only enzyme so far identified in human skin that is able to repair oxidative protein damage. Interestingly, MSRA knockout mice that exhibit an increased sensitivity to oxidative stress, leading to accumulation of oxidized proteins, also have a significantly shorter lifespan. Protein oxidation has clearly been correlated with solar elastosis and photoaging in human skin and also in the depigmentation disease, vitiligo. It could also be involved in degenerative disorders, such as cataract. Accumulation of oxidized protein is a hallmark of cellular aging.

Photodynamic cross-linking of proteins was first analyzed *in vitro*, using rose bengal and flavin mononucleotide as photosensitizers (Shen et al. 1996; Spikes et al. 1999). It was found that intermolecular dityrosine cross-linking involve a type I mechanism, whereas singlet oxygen generates His and/or Lys cross-links. An example of covalent photocross-linking is given by the replication and repair protein, proliferating cellular nuclear antigen (PCNA) homotrimer. High-molecular-weight PCNA forms were produced in human cells by photodynamic treatments, which generate singlet oxygen (Bae et al. 2008). PCNA oligomerization of at least tetramer lengths and cross-linking of PCNA with heterologous proteins were observed. Using a proteomic approach, the same authors showed that of the 300 protein spots, only seven were changed by the photodynamic treatment (proflavine plus fluorescent light). Similarly, cross-linking of PCNA trimers was observed in UVA-irradiated cells that have incorporated large amounts of 6-thioguanine (Montaner et al. 2007). UVA irradiation, in the absence of 6-thioguanine, is also able to induce covalent photocross-linking of PCNA, but to a lesser extent (Montaner et al. 2007; Girard and Sage unpublished). Notably, covalent PCNA trimers were found in the chromatin-associated fraction, and at active replication forks. It has not yet been demonstrated whether or not these fractions of cross-linked PCNA interfere with progression of replication. According to the 3D structure at the intersubunit region and the alignment of conserved residues, Montaner et al. proposed that the covalent cross-link involves His153 and Lys77.

Another repair protein that is sensitive to oxidation is the DNA *N*-glycosylase hOGG1, which removes 8-oxoG (Bravard et al. 2006). Interestingly, glutathione depletion of skin fibroblasts and melanoma cells, which increases oxidative stress, causes a strong retardation of repair of 8-oxoG after exposure to non-toxic doses of visible light or UVA radiation (Eiberger et al. 2008). Moreover, the cleavage activity at 8-oxoG residues measured in protein extracts from irradiated cells drops transiently after irradiation. A modification of hOGG1 is suspected, but it is not caused by critical oxidation of Cys such as reported by Bravard et al. (2006). It appears that the base excision repair of oxidized purines is surprisingly sensitive to oxidative stress, while the nucleotide excision that removes bipyrimidine photoproducts is not (Eiberger et al. 2008).

58.4.6 Cell Division, Cell Cycle, and Cell Migration Effects

Using synchronized murine fibroblasts (3T3), Bråthen et al. (2000) showed that cells were most photo-sensitive with respect to formation of multinucleated cells in G2 phase and that the delayed appearance of multinucleated cells in G2 and S phase was due to UVA impairment of cytokinesis. In a study with human transformed fibroblasts and other mammalian cells, Girard et al. (2008) demonstrated a UVA dose-dependent delay in S phase and showed that UVA-irradiated S-phase cells accumulated at the G2/M boundary. Although they confirmed that ataxia telangiectasia mutated (ATM)-, ATR (ATM and Rad3-related protein kinases)-, and p38-dependent signaling pathways are activated by UVA, they were not responsible for the cell cycle delay.

Thorn et al. (2001) showed no effect of UVA (in contrast to H₂O₂) on cell cycle or proliferation in HaCaT cells indicating that cells of epidermal origin may differ considerably from fibroblasts in their response to UVA. However, He et al. (2008) actually showed a UVA-mediated stimulation of cell cycle progression in HaCaT cells, which was dependent on cyclin D1. Inhibitor experiments indicated that UVA stimulated the AKT/cyclin D1 pathway, which in turn upregulated the epidermal growth factor receptor (EGFR) pathway. Interestingly, these authors also showed that the entire EGFR/Akt/cyclin D1 pathway was dependent on the activation of a metalloproteinase (Adam 17). UVA stimulation of growth was also seen by Jean et al. (2007) who showed that low-dose UVA actually reduced the G2/M arrest normally observed in human HaCaT keratinocytes and normal human keratinocytes. Their experiments indicated that following UVA exposure, the EGFR/Akt pathway subverts the G2/M checkpoint.

Shorrock et al. (2004) compared UVA-mediated cell cycle effects in normal human fibroblasts with cells taken from patients heterozygotic for the breast cancer predisposing gene, *BRCA1*. Reentry into S phase was faster in the heterozygotes following G1 arrest indicative of an abnormal cell cycle checkpoint, which could lead to greater levels of unrepaired damage. However, no increases in micronuclei induction were observed following UVA, which would have been indicative of increased chromosomal instability.

Using dermal sheets derived from human skin, Furio et al. (2005) showed that UVA decreased the number of viable dendritic cells that moved out of the dermis and showed that this was related to increased apoptosis. Furthermore, UVA irradiation also prevented the maturation of migrating dendritic cells into antigen-presenting cells, which indicates an additional mechanism by which UVA is immunosuppressive (see also chapter by Reeve, this volume).

58.4.7 Cell Death: Necrosis and Apoptosis

UVA treatment leads to both necrotic and apoptotic cell death, and the relative importance of each pathway depends strongly on the cell type and dose level (reviewed by Pourzand and Tyrrell 1999; Godar 1999a). From a series of experiments, Godar (1999b) concluded that there are two pathways of UVA-induced apoptotic cell death. The primary pathway is an immediate triggering of apoptosis by opening of the cyclosporine A-sensitive mitochondrial megapore and involves singlet oxygen whereas superoxide anions appear to initiate a second cyclosporine A-insensitive final apoptotic pathway.

Apoptosis is believed to be the main pathway to eliminate sun-damaged keratinocytes in skin, and Fas accumulation (Bang et al. 2002) has been consistently observed in human skin epidermal cells following UVA (and UVB) treatment. Interestingly, *in vivo* studies in mice had shown that UVA could actually reduce UVB upregulation of FasL expression in mouse skin (Shen et al. 2000). UVA triggers the DNA damage-dependent ATM kinase activity and the ATM-dependent p53, and JNK pathways have been directly linked to UVA-induced apoptosis (Zhang et al. 2002). The involvement of signaling kinase in apoptosis is further described in Section 58.5.3.

ROS appear to be central to the UVA-induced apoptotic response. Thioredoxin levels increase following UVA irradiation of fibroblasts, and this antioxidant has been implicated in UVA apoptosis (Didier et al. 2001). Strong direct evidence that the sphingomyelin–ceramide signaling pathway is involved in UVA apoptosis was provided by Zhang et al. (2001a). They compared normal lymphoblasts with

lymphoblasts derived from patients genetically deficient in sphingomyelinase (SMase) and showed that UVA-induced acid SMase induction and apoptosis were inhibited in the latter cell type. These authors also linked SMase induction to the upstream activation of JNKs that lead to apoptosis. Induction of the lipid oxidation product and signaling molecule, 4-hydroxynonenal (4-HNE), also appears to be involved in the apoptotic pathway, at least in K562 cells (Yang et al. 2003).

Understanding the specific UV-mediated apoptotic pathways involved is crucial since apoptotic events are central to the carcinogenesis process. For example, the resistance to UVA apoptosis following chronic irradiation treatment of HaCaT cells involves increased Akt signaling and decreased phosphatase and TENSin homolog (PTEN) expression, and this process appears to be linked to malignant transformation (He et al. 2006). Inhibition of JNK leads to a dramatic increase in UVA-induced caspase-dependent apoptotic cell death in HaCaT cells (Silvers et al. 2006). Using mouse NIH 3T3 embryonic fibroblast cells as a model, Ibuki and Goto (2002) showed that unlike apoptosis induced by UVB, UVA apoptosis was independent of the PI3-kinase–Akt pathway. Hirota et al. (2005) showed that the Nrf2–Keap1 pathway is crucial to UVA-induced apoptosis in murine fibroblasts possibly via control of the anti-apoptotic heme oxygenase pathway (see the following).

Induction of singlet oxygen-mediated human T helper cell apoptosis is believed to be one of the central factors involved in UVA phototherapy (see Morita et al. 1997; Krutmann 1998). These authors showed that Malignant T-cell lines as well as CD4+ T cells derived from adult T-cell leukemia are very sensitive to UVA (but not UVB) radiation-induced early and late apoptosis compared with normal CD4+ T cells, and that this is related to the availability of caspases such as caspase 3 (Yamauchi et al. 2004). UVA-induced T-cell apoptosis also appears to be crucial to certain types of phototherapy. For example, phototherapy of atopic dermatitis and other T-cell-mediated inflammatory skin diseases appears to work by UVA-induced Fas ligand-independent activation of Fas death pathways in T helper cells (Zhuang and Kochevar 2003).

Interestingly, malignant human T cells appear to be more susceptible to UVA-induced apoptosis than nonmalignant cells, and this was related to higher levels of pro-caspase 3 activity (Yamauchi et al. 2004).

UVA-induced cell death in cultured human skin fibroblasts is primarily due to necrosis and correlated with intracellular ATP depletion (Zhong et al. 2004). Furthermore, these authors showed that the level of necrotic cell death in both fibroblasts and keratinocytes was directly linked to basal and induced levels of the labile iron pool.

58.5 UVA as a Modulator of Gene Expression

58.5.1 Introduction

UVA is well known to activate expression of a variety of genes at doses relevant to natural sunlight exposure (reviewed in Tyrrell 1996a,b). Of these, the largest and most studied effects are the activation of HO-1 (Keyse and Tyrrell 1987, 1989) and metalloproteinases (Herrmann et al. 1993). However, many other genes have been observed to be activated including intercellular adhesion molecule 1 (ICAM-1) (Krutmann and Grewe 1995) and cyclooxygenase 2 (COX-2) (Hanson and DeLeo 1989). Much has been learnt recently about the UVA-induced signaling intermediates involved and the complex cascades of signaling kinases and phosphatases. The pathways involved are very cell type dependent but a general picture emerges, which is described in the following.

58.5.2 UVA-Generated Signaling Intermediates

58.5.2.1 Singlet Oxygen

Singlet oxygen (see earlier section) was the first ROS to be clearly implicated in UVA activation of gene expression. This was first observed for HO-1 (Basu-Modak and Tyrrell 1993) but the species was soon implicated as a key intermediate in interstitial collagenase (Wlaschek et al. 1995) and ICAM-1 activation (Grether-Beck et al. 1996) by UVA. Singlet oxygen was also implicated in the UVA activation of IL-1 α and IL-6 (Wlaschek et al. 1997), both of which are known to activate HO-1 and interstitial collagenase.

58.5.2.2 Ceramide

Various ROS, including singlet oxygen, will lead to lipid peroxidation, and it is likely that lipid signaling intermediates are responsible for much of UVA modulation of gene expression. Among such intermediates is ceramide, which is known to be a key component of intracellular stress responses and is generated by UVA in a nonenzymatic singlet oxygen-dependent reaction (Grether-Beck et al. 2000). The ceramide is derived from sphingomyelin, and it was clearly demonstrated that this intermediate was involved in the AP-2 (transcription factor activator protein 2)-dependent activation of ICAM-1 expression in keratinocytes (Grether-Beck et al. 1996). Although another group failed to observe the direct (nonenzymatic) cleavage of ceramide (Mazière et al. 2001), Grether-Beck et al. (2005) later showed that both AP-2 activation and ICAM-1 activation were biphasic and the second more sustained peak most likely resulted from a ceramide-mediated autocrine loop since the latter involved activation of the key enzyme in ceramide synthesis, serine palmitoyltransferase. More recently, the same group (Grether-Beck et al. 2008) has shown that the UVA-mediated signaling response involved in ICAM-1 expression is entirely dependent on the ceramide composition of lipid rafts, which are well known to be involved in signaling responses.

58.5.2.3 Lipid Oxidation Products and 4-HNE

Lipid oxidation products have clearly been implicated in the activation of the HO-1 gene by UVA, and from studies using specific lipid antioxidants, it appears that the signaling molecules are derived from internal membrane lipids (Basu-Modak et al. 1996). An important nonenzymatic lipid peroxidation product induced by UVA irradiation of cells is 4-HNE. A role for 4-HNE in UVA effects was first suggested by Basu-Modak et al. (1996) who showed that 4-HNE was an extremely potent inducer of HO-1. 4-HNE production following UVA radiation has been linked to sustained activation of JNK and apoptosis (Yang et al. 2003) in a human myelogenous leukemia cell line (K562) although both are inhibited by a preconditioning dose of UVA. 4-HNE has also been implicated in other signal transduction pathways that affect cell cycle events as well as oxidant-induced apoptosis (Cheng et al. 2001). Cells that overexpress alpha class glutathione S-transferases (GSTs) show reduced intracellular levels of 4-HNE and resistance to apoptosis induced by UVA and other oxidants (Awasthi et al. 2004).

Oxidized phospholipids are known to stimulate a wide range of biological activities. It has been shown that UVA irradiation of fibroblasts can generate oxidized phospholipids from 1-palmitoyl-2-arachidonoyl-sn-glycero-3-phosphorylcholine (PAPC) in a singlet oxygen-dependent fashion and that these intermediates lead to strong expression of HO-1 in skin cells (Gruber et al. 2007). In very recent studies, Gruber et al. (2010) have shown that these oxidized phospholipids act by stimulating the accumulation of Nrf2, redox-regulated transcription factor, and therefore co-induce a series of antioxidant response genes including glutamate-cysteine ligase modifier subunit, aldo-keto reductases-1-C1 and -C2, and IL-8.

58.5.2.4 Phospholipase Metabolites

The phospholipase metabolites diacylglycerol and arachidonic acid were also shown to induce HO-1 mRNA accumulation three- to sixfold above basal levels (Basu-Modak et al. 1996). UVA irradiation of arachidonate-containing phospholipids generated lipid oxidation products including epoxyisopropane-phosphatidylcholine, and these also induce HO-1 expression in dermal fibroblasts or keratinocytes (Gruber et al. 2007), and recently, Nrf2 has again been implicated in this phospholipid-mediated stress response (Gruber et al. 2010).

58.5.3 Protein Kinases and Phosphatases

Protein kinases are essential intermediates in many signaling pathways, which involve a cascade of protein phosphorylation reactions. Activation of a variety of protein kinases by UVA has been frequently observed but is skin cell type dependent and interpretation is often complex. This is further confounded

by laboratory variations in light source and protocols. For example, exquisitely small amounts of contaminating UVB in the broadband sources can cause kinase activation, and there is very often a narrow dose window of activation. Very often, there is no consideration of the target genes involved so that the biological significance is hard to assess. Nevertheless, there are strong arguments to support the notion that the activation of kinase-dependent signaling pathways is involved in skin tumor promotion and progression (Bachelor and Bowden 2004a). UVA radiation has been shown to activate protein kinase C (protein kinase C [PKC], phospholipid-dependent ser/thr kinase) in both murine fibroblasts (Matsui and DeLeo 1990), normal human epidermal keratinocytes (NHEK, Matsui et al. 1994), and rat myeloid leukemia cells (Leszczynski et al. 1995). Inhibitor studies have linked PKC signaling to the UVA activation of MMP-1 (Petersen et al. 1995 and see the following).

In studies by Klotz et al. (1997, 1999), evidence was presented that UVA could activate both p38 and JNK activity but not extracellular-regulated kinase (ERK) activity in human skin fibroblasts by a pathway involving singlet oxygen. However, many more studies have been undertaken in keratinocyte-derived cell lines than fibroblasts since these are considered a better model system for skin cancer. In contrast to the situation in human skin fibroblasts, UVA does activate ERK in mouse epidermal cells (He et al. 2004), and ERK activation by UVA is mediated by PKC in a Ras-dependent pathway. These authors showed that UVA activation of ERK occurs in an EGFR kinase-independent pathway (see the following) quite different to the observations of UVB and UVC activation of ERK. This sustained ERK activation by UVA may provide a cell survival signal crucial to cell transformation and carcinogenesis in human skin subject to sustained UVA irradiation.

Mitogen-activated protein kinases (MAPKs) are a group of phosphorylating enzymes that are activated in response to cytokines and stress. P38 kinases are a class of MAPKs that are involved in cell differentiation and apoptosis. In human dermal fibroblasts, UVA radiation was shown by Le Panse et al. (2003) to activate p38 MAPK but had no effect on ERKs or JNK-stress-activated protein kinase (SAPK). The pathway appears to involve singlet oxygen-dependent ligand-receptor activation or ribotoxic stress or both. In contrast, in HaCaT cells, UVA irradiation led to phosphorylation of both p38 protein and JNK (Bachelor et al. 2002; Silvers et al. 2003) although phosphorylation of ERK was significantly inhibited (Silvers et al. 2003). The activation was clearly linked to AP-1 transactivation and c-Fos expression. Activation of p38 in HaCaT cells has also been clearly implicated in stabilization of the COX-2 message and a consequent increase in COX-2 protein (Bachelor et al. 2002). COX-2, which generates pro-inflammatory intermediates (prostanoids), has been implicated in various pathways of tumorigenesis (e.g., Greenhough et al. 2009). COX-2 has also been heavily implicated in skin cancer, and recent phase 2 trials have indicated that celecoxib (a COX-2 inhibitor) is a potential chemopreventive agent in SCC. UVA activation of p38 mitogen-activated protein (MAP) kinase has also been linked to the UVA-induced expression of Bcl-XL, a crucial anti-apoptotic protein (Bachelor and Bowden 2004b) again highlighting the influence of UVA on cell survival pathways. This appears to occur via a posttranscriptional mechanism involving stabilization of the Bcl-XL messenger by binding of specific proteins to the 3' untranslated region.

In addition to the activation of metalloproteinases (see the following), it has been shown that UVA may stimulate other proteases via activation of p38 kinase in human skin keratinocytes. For example, UVA activation of p38 MAPK in keratinocytes leads to granzyme B (a serine protease) induction via redox-dependent migration inhibitory factor (MIF) release, and this will facilitate degradation of extracellular matrix components (Hernandez-Pigeon et al. 2007). UVA irradiation is known to compromise gap junctional intercellular communication, and this has been associated with hyperphosphorylation and decreased levels of the highly expressed keratinocyte gap junction protein, Connexin 43 (Bellei et al. 2008). Although the authors showed that this was in part mediated by MAPK activation (at Ser 279 and Ser 282) and that this was correlated with the upstream activator of p38 MAPK, they did not directly demonstrate the involvement of p38 in UVA-mediated disruption of gap junctions due to the toxicity of the inhibitors.

Activation of JNK by UVA in both HaCaT cells and primary human keratinocytes has been linked to a cell survival pathway since inhibition of the kinase activity correlates with caspase 3, 8, and 9 activation; cleavage of the caspase substrate polyADP-ribose polymerase (PARP); and apoptotic cell death (Silvers et al. 2006).

58.5.3.1 ATM Kinase

Another important regulator of cell survival and cell cycle checkpoints, the DNA damage-inducible ATM kinase, has also been shown to be stimulated by UVA in an oxygen-dependent fashion (Zhang et al. 2002), and these authors also link ATM-dependent p53 and JNK pathways to UVA apoptosis.

58.5.3.2 PKR

Extracellular stress such as UVA irradiation of mouse epidermal cells (JB6 Cl41) can lead to phosphorylation (Thr 451) of PKR (double-stranded RNA-dependent protein kinase R) via ERK2 (or growth factor-regulated S6 kinase RSK2, p90 ribosomal S6 kinase) but not p38 kinase activation (Zykova et al. 2007). UVA-activated PKR can then cause protein synthesis inhibition by phosphorylating the alpha subunit of protein synthesis initiation factor eIF2, which is involved in both anti-viral and apoptotic pathways.

58.5.3.3 EGFR

The EGFR, a membrane surface receptor, is a member of the ErbB family of proteins, which are tyrosine kinases. It binds to specific ligands such as the epidermal growth factor (EGF) and transforming growth factor alpha (TGF-alpha) so that EGFR undergoes a transition from an inactive monomeric form to an active homodimer with tyrosine kinase activity. The subsequent autophosphorylation elicits downstream activation and signaling via SH2 domains, which in turn initiates several signal transduction pathways, principally the MAPK, Akt, and JNK pathways, leading to DNA synthesis and cell proliferation. Activation of the receptor is important for the innate immune response in human skin. Upregulation of EGFR can lead to various types of cancer, and it is therefore a much-studied oncogene. EGFR activation by UV is a critical event in keratinocyte transformation, but the mechanism that links the EGFR pathway and photocarcinogenesis remains unclear. It has been known for some time that UV and oxidants induce ligand-independent activation of numerous receptor tyrosine kinases including EGFR at the inner side of the plasma membrane (e.g., Devary et al. 1992; Sachsenmaier et al. 1994; Schieven et al. 1994; Coffey et al. 1995) and one pathway by which UVA achieves this is inhibition of tyrosine phosphatase activity (Knebel et al. 1996). Activation of EGFR leads to a cascade of downstream kinase activation. For example, UVA irradiation of EGFR in (murine epidermal) cells can lead to activation of p70(S6K)/p90(RSK) through phosphatidylinositol (PI)-3 kinase and extracellular receptor-activated kinases (ERKs). Results with EGFR^{-/-} cells indicated that that UVA-induced EGFR signaling may be required for activation of p90(RSK)/p70(S6K), PI3 kinase, and ERKs but not JNKs or p38kinase in this mouse cell line (Zhang et al. 2001b). In contrast, Mazière et al. (2003) presented evidence that UVA could inhibit EGF signaling in human fibroblasts (MRC5) and that a high dose of UVA (9 J/cm²) prevented the EGF-induced Tyr phosphorylation of the EGF receptor. However, in human HaCaT keratinocytes, exposure to UVA induces EGFR internalization and downregulation without receptor phosphorylation and ubiquitination (He et al. 2003). This indicates that unlike EGF, UVA can downregulate the receptor in the absence of kinase activity. In contrast to the situation with the EGF ligand, receptor kinase activity appears not to be required for receptor downregulation by UVA. Indeed, it has been considered that EGFR downregulation by UVA may play an important role in the execution of the cell suicide program by attenuating its anti-apoptotic function. Again using human HaCaT keratinocytes as well as normal human keratinocytes, Jean et al. (2007) observed that low doses of UVA irradiation led to EGFR-mediated Akt activation which in turn resulted in increased levels of checkpoint 1 kinase (Chk1) phosphorylation (Ser280). The consequent inhibition of G2/M arrest is again likely to be crucial in UVA photocarcinogenesis since damaged cells may replicate and mutate. He et al. (2008) also showed that low doses of UVA induce dose-dependent cell cycle progression in human HaCaT keratinocytes via PI3 (PI3-OH) kinase/Akt activation and linked it to UVA-induced cyclin D1 accumulation. Importantly, these authors also showed that the activation of the EGFR/Akt/cyclin D1 pathway and cell cycle progression to the S phase are mediated by an ADAM17 metalloproteinase and disintegrin pathway. Another potentially crucial factor in malignant transformation by UVA is that activation of EGFR by UVA irradiation of HaCaT cells potentiates anchorage-independent growth of the keratinocytes and that this is

abrogated by ErbB2 inhibition (Han et al. 2008). Low doses of UVA increases Erb 2 expression in both the skin of hairless mice and in HaCaT keratinocytes via cAMP- and protein kinase-dependent AP-2 α activation. Finally, a recent study by Jean et al. (2009) has linked UVA activation of EGFR with both loss of cell-to-cell contact as a result of beta-catenin/E-cadherin/alpha-catenin dissociation (via beta-catenin phosphorylation at the tyrosine Y654 residue) and the nuclear relocalization of beta-catenin to generate a beta-catenin/T-cell factor 4 (TCF4) complex, which mediates the activation of matrix metalloproteinase (MMP)-1. Both these events are likely to stimulate keratinocyte invasiveness following UVA.

Another protein tyrosine kinase, Abelson-related gene (Arg), is also highly upregulated by UVA in normal human keratinocytes (Klosner et al. 2008).

58.5.3.4 Phosphatases

UVA radiation is known to activate a specific protein tyrosine phosphatase (Keyse and Emslie 1992), which can downregulate protein kinases by dephosphorylation. However, UVA (and UVB) radiations can also degrade and irreversibly inactivate protein tyrosine phosphatases by the combined effect of substrate oxidation and calpain activation (Gulati et al. 2004).

58.5.4 Transcription Factors

58.5.4.1 Nuclear Factor-kappaB

Nuclear factor-kappaB (NFkappaB) is an ubiquitous transcriptional activator intimately involved in a variety of inflammation-related events and which was recognized as redox sensitive in pioneering studies by Bauerle and co-workers (Schreck et al. 1992). This factor would therefore be expected to be responsive to UVA, and indeed, it was shown that relatively low doses of UVA activate NFkB binding to DNA in human skin fibroblasts (Vile et al. 1995). Although activation of NFkB by UVC and UVB radiations has been reported, Vile et al. found that in human skin fibroblasts activation was only observed at very high doses or where there was evidence of significant membrane damage. It was later shown (Reelfs et al. 2004) that the kinetics of appearance of NFkB accumulation in the nucleus was slow and that this was related to labile iron-dependent nuclear membrane damage. Indeed, the work supported the concept that oxidized lipids are a crucial intermediate in UVA-mediated NFkB activation and may underlie the role of UVA in skin inflammation. UVA enhanced NFkB binding to DNA was also observed in keratinocytes (HaCaT, Shang et al. 2002) and a human epithelial cell line (Hellweg and Baumstark-Khan 2007). However, in normal human melanocytes, both negative (Shang et al. 2002) and positive (Larsson et al. 2006) results for activation of this transcription factor have been reported.

58.5.4.2 Signal Transducers and Activators of Transcription

Various extracellular polypeptides are able to activate the signal transducers and activators of transcription (STATs), and these play a crucial role in gene activation. The proteins include a single tyrosine phosphorylation site and, in a dimeric partner molecule, an Src homology 2 (SH2) phosphotyrosine-binding domain, a DNA interaction domain, and a number of protein-protein interaction domains (for review see Darnell 1997). They are now one of the most studied classes of transcription factors because they are often inappropriately activated in cancer and have been implicated in the carcinogenesis process since they regulate genes involved in cell proliferation, survival, differentiation, angiogenesis, and invasion. Many such target genes coding the oncogenic transcription factors are now known (Alvarez and Frank 2004). The promoter (DNA)-binding activity of STAT1 was enhanced by low UVA doses in a keratinocyte cell line (NCTC 2544) but higher doses caused inhibition (Mazière et al. 2000). Inhibitor studies indicated that phosphorylation by both serine/threonine kinases and mitogen-activated protein kinase kinase (MEK) was involved. These authors also observed nuclear transport of STAT 1 after UVA. Using a mouse epidermal cell line (JB6), Zhang et al. (2001c) showed that phosphorylation of STAT 3

(at Ser 727) occurs following UVA radiation, and that this occurs via MSK1 and JNKs but not ERKs or p38 kinase. These phenomena have not yet been linked directly to UVA carcinogenesis but the link between the signal transducers and activators of transcription (STAT) activation and cancer remains intensely studied (e.g., Behera et al. 2010).

58.5.4.3 Nrf2

Nuclear factor (erythroid-derived 2)-like 2 (Nrf2) is the most studied member of a transcription factor family involved in regulating genes involved in the cellular stress response and phase 2 proteins and has been strongly implicated in chemoprevention of carcinogenesis. The Nrf2 protein normally resides in the cytoplasm bound to Kelch-like-ECH-associated protein 1 (KEAP1) and is rapidly degraded by the ubiquitination pathway. Under stress conditions, the protein appears to be stabilized and move to the nucleus where it binds to small Maf proteins (typically MafK) to form a powerful activating transcription factor (ATF) that binds to the Maf-associated responsive element (MARE) present in a number of stress-activated genes. In a classical set of experiments, Gao and Talalay (2004) used retinal pigment epithelial cells derived from mice that had Nrf2 or the repressor KEAP1 (or both) disrupted and showed that these cells became photosensitive (300–400 nm). Hirota et al. (2005) demonstrated that UVA radiation could lead to nuclear accumulation of Nrf2 in human skin fibroblasts and that this appeared to have a protective role against UVA-induced apoptosis. Later, Zhong et al. (2010a) confirmed the UVA stabilization and nuclear accumulation of Nrf2 and using specific short interfering RNA (SiRNA) against Nrf2 demonstrated that this protein was involved in protection against UVA-induced membrane damage and that the response is dependent on heme levels. The UVA-mediated Nrf2 response is also correlated with the UVA generation of oxidized phospholipids (Gruber et al. 2010).

It should be noted that activation of Nrf2 by various agents (e.g., sulforafane and flavonoid antioxidants such as quercetin) has been implicated in photoprotection (e.g., Gao and Talalay 2004; Kimura et al. 2009).

58.5.4.4 Bach1

Bach1 (BTB and CNC homology 1, basic leucine zipper transcription factor 1) like Nrf2 forms a heterodimeric transcription factor by binding to Mafk but the Bach1/Maf complex acts as a negative regulatory protein and binds to the MARE site of HO-1 to prevent transcription (Sun et al. 2004). Heme is crucial to Bach1 activity since it loses DNA-binding activity when bound to heme (Ogawa et al. 2001), and heme also promotes its degradation (Zenke-Kawasaki et al. 2007) and nuclear transport (Suzuki et al. 2004). Bach1 bound to the HO-1 promoter prevents UVA activation of HO-1 under low heme conditions, and knockdown of Bach1 increases the resistance of keratinocytes to UVA-induced membrane damage (Zhong et al. 2010b).

58.5.4.5 ATF3

ATF3 is a member of the Ca²⁺- and cyclic adenosine monophosphate responsive element-binding protein (CREB) family of transcription factors, which are dependent on cyclic adenosine monophosphate (AMP). Transcription of this gene is substantially induced by relatively low (nonlethal) fluences of UVA radiation (Abe et al. 2003). Although the full significance in terms of the CREB-dependent genes has not been fully evaluated, ATF-dependent genes are involved both in immunity toll-like receptors and implicated in cancer biology.

58.5.5 Gene Induction and Significance

58.5.5.1 Heme Oxygenase 1

Induction of HO-1 by UVA radiation was first reported in human skin fibroblasts (Keyse and Tyrrell 1987, 1989) in work that identified a 32 kDa human stress protein that had also been shown to be induced by tumor promoters and heavy metals in various cell types. Lowering of cellular glutathione levels

strongly enhanced basal and induced levels of the gene (Lautier et al. 1992), and as had been shown previously for inactivation of skin fibroblast colony-forming ability, UVA-mediated HO-1 gene activation was shown to involve singlet oxygen (Basu-Modak and Tyrrell 1993). HO-1 induction remains the strongest general mammalian oxidative stress response observed to date (Applegate et al. 1991). It was recognized that the enzyme played an important role in protection against oxidative membrane damage (Vile et al. 1994), and as a crucial anti-apoptotic and anti-inflammatory protein, it has been implicated in numerous pathologies (Otterbein and Zuckerbraun 2005; Soares and Bach 2009).

Iron is one of the important by-products of heme catabolism by HO, and this, iron added to the direct release of labile iron in cells following UVA treatment, leads to a strong induction of the iron storage protein, ferritin (Vile and Tyrrell 1993). This immediate induction of HO-1 and delayed induction of ferritin are crucial to restoring heme and iron homeostasis in cells (see earlier section).

Considerable work in several laboratories has been devoted to elucidating the molecular mechanism of activation of the HO-1 protein. The HO-1 promoter of both the human and rodent gene contains two crucial *cis*-acting elements 4 and 10 Kb upstream of the start site known as Maf-activated response element (MARE) sites. Binding of a heterodimeric activator protein complex such as Nrf-2/MafK to these sites following stress replaces the inhibitory heterodimer, typically Bach1/MafK, to activate transcription (Sun et al. 2004). Recent work has shown that UVA stabilizes Nrf2 in a heme-dependent manner (Zhong et al. 2010a) and that both this pathway and the UVA-mediated heme-dependent release of the Bach1 heterodimer binding to the MARE site of the HO-1 promoter (Raval 2008; Zhong et al. 2010b) are crucial to UVA-mediated HO-1 gene activation.

Although the original observations concerning UVA-inducible HO-1 showed that the enzyme was strongly induced in skin fibroblasts (Keyse and Tyrrell 1989) and melanocytes (unpublished observations and Marrot et al. 2008), there was almost no induction in epidermal keratinocytes (Applegate et al. 1995). However, keratinocytes did express high levels of the constitutive enzyme HO-2, and it was postulated at the time that the lack of expression of induction of HO-1 reflected the low levels of free heme, a consequence of substantial levels of constitutive HO protein expression. It has now been shown that silencing of HO-2 expression (by specific siRNA knockdown) allows a strong basal and UVA-induced expression of HO-1 in epidermal keratinocytes (Zhong et al. 2010b). However, it is Bach1 itself that is the central factor suppressing HO-1 expression in fibroblasts since knockdown of Bach1 unlocks a strong constitutive expression of HO-1, which is not further enhanced by irradiation with UVA. These studies also strongly support the concept that it is the changing level of free heme that is the key to regulation of HO-1 expression and that the latter will be modified whenever HO is induced or constitutively expressed. This also explains the strong refractoriness to UVA induction of HO-1 by a second dose 24–48 h after the first one (Nöel and Tyrrell 1997) since at these times induced HO-1 levels will be high and free heme levels will be very low.

UVA radiation induces HO-1 in rodent skin, although quite unlike the human situation, the strongest response is seen in epidermal keratinocytes (Allanson and Reeve 2004).

58.5.5.2 Metalloproteinases

MMPs are a family of zinc-dependent proteinases (endopeptidases), which are involved in remodeling and degradation of the extracellular matrix proteins. The activity of MMPs is thought to be predominately posttranslationally regulated via proteolytic activation of precursor zymogens or via their naturally occurring endogenous inhibitors (Koch et al. 2009).

A phenomenon known as the “UV response” was first described in the late 1980s (for review see Herrlich et al. 2008) and involved the induction of a series of genes by short-wavelength UV. The earliest event detectable in the nucleus was the posttranslational modification of AP-1 (c-Jun/c-Fos), which was directly linked to the activation of the collagenase gene (MMP-1; Stein et al. 1989) via regulatory elements in the promoter. MMP-1 is known to initiate degradation of collagen type 1 and 2. The enzymes are crucial to cell proliferation, migration (adhesion/dispersion), differentiation, angiogenesis, apoptosis, and host defense and have been implicated in cancer metastasis. Importantly, UVA was shown to

induce both MMP-1 mRNA accumulation and protein synthesis following irradiation of human skin and human fibroblasts (Herrmann et al. 1993) and to mediate this via the generation of singlet oxygen (Wlaschek et al. 1995). Recently, the proteasome has been shown to be an integral part of the UVA stress response (Catalgol et al. 2009). Inhibition of the proteasomal system by UVA-induced protein oxidation led to c-jun phosphorylation and activation of AP-1, a transcription factor central to MMP-1 induction. Furthermore, overexpression of the proteasome or methionine sulfoxide reductase (MsrA), which repairs oxidized proteins, abrogated the UVA activation of MMP-1.

MMP-1 activation in skin fibroblasts has been shown to involve the UVA generation of organic peroxides and lipid peroxidation (Polte and Tyrrell 2004). Repeated (chronic) exposure of human skin fibroblasts to UVA radiation leads to a sustained overexpression of MMP-1 (Naru et al. 2005). In a recent study by Tanaka et al. (2009), UVA has been shown to downregulate the forkhead box gene, group O (FOXO) transcription factor (crucial in regulating insulin/insulin-like growth factor-1 signaling). Interestingly, interfering RNA knockdown of FOXO1A expression led to increased expression of MMP-1 and -2 implying a crucial role of this pathway in regulating metalloproteinase expression. As noted elsewhere, overexpression of phospholipid-hydroperoxide GPx can reduce UVA-induced MMP-1 expression (Wenk et al. 2004) by interfering with NFkB-mediated IL-6 release.

MMP-1 levels were slightly lowered by UVA treatment of epidermal keratinocytes (Scharffetter et al. 1991; Petersen et al. 1992) but later work with a SCC cell line (Ramos et al. 2004) and in HaCaT cells (Wertz et al. 2004, 2005) indicated significant induction of MMP-1 so that the cancer phenotype appears to have changed the induction pattern. Further support for the involvement of singlet oxygen in the response was obtained by Wertz et al. (2004) who modified the response using the natural singlet oxygen quencher, beta-carotene.

Metalloproteinases 1, 2, and 3 were all reported to be induced in human fibroblasts after UVA treatment (Herrmann et al. 1993). Activation of MMP-2 (and reduction in tissue inhibitors of matrix metalloproteinases (TIMPs)-2 activity) has been linked to increased secretion of thioredoxin following UVA treatment. One group (Kawaguchi et al. 1996) did not observe the induction of MMP-2 (type IV collagenase, gelatinase A) by UVA. Although other studies have independently reported UVA induction of MMP-2 in fibroblasts (e.g., Kut et al. 1997; Oh et al. 2004), a study in normal human keratinocytes (Steinbrenner et al. 2003) showed that UVA quite significantly lowered expression of both MMP-2 and MMP-9 (gelatinase B). No change in secretion of these proteins was seen by Onoue et al. (2003) but chronic (18 weeks) re-exposure of HaCaT cells to UVA treatment (He et al. 2006) actually led to increased secretion of MMP-9. In studies with human microvascular endothelial cells, UVA was shown to upregulate MMP-1 but downregulate MMP-2 (Cauchard et al. 2006), and this has been linked to impaired angiogenic phenotype of the dermal endothelial cells. The induction of MMP-3 (stromelysin 1) in fibroblasts by UVA has been the subject of (several) reports and appears to involve promoter activation through an AP-1 site (Sawamura et al. 1996). It is also induced in HaCaT cells (Wertz et al. 2005). Induction of MMP-10 (stromelysin-2) by UVA has been observed in a human SCC line by Ramos et al. (2004) and in HaCaT cells by Wertz et al. (2005).

Cytokines are intimately involved in the induction of MMP-1 by UVA since a rapid posttranslational activation of IL-1 has been shown to be linked to *de novo* IL-6 synthesis and both are involved in the early phase of MMP-1 induction (Wlaschek et al. 1994). Several studies (e.g., Wang et al. 2005) confirm a central role for IL-1 in MMP-1 activation, and this cytokine is excreted from keratinocytes following UVB radiation. Indeed, a second phase of induction of MMP-1 appears to be mediated via transcriptional activation of IL-1 through an autocrine loop. Indirect evidence implicates the UVA-mediated generation of singlet oxygen as the primary ROS involved in MMP-1 activation, and this was later linked to the singlet oxygen dependence of IL-1 and IL-6 activation (Wlaschek et al. 1995, 1997). Metalloproteinase inhibitors (e.g., TIMP-1 and -2) were not activated by UVA. Wlaschek et al. (1995) also directly demonstrated that singlet oxygen released by a thermolabile endoperoxide (disodium salt of 3,3'-(1,4-naphthylidene) dipropionate, NDPO2) strongly activated MMP-1 but not the metalloproteinase inhibitors. It should be noted that other ROS have been clearly demonstrated to activate MMP-1. For example,

Wenk et al. (1999) used fibroblasts overexpressing MnSOD, and these cells were shown to generate hydrogen peroxide as a result of the dismutation and lead to MMP-1 activation via the AP-1 site. More recently, it has been shown that macrophage MIF is involved in the upregulation of MMP-1 by UVA in dermal fibroblasts. Several protein kinase pathways (PKC, protein kinase A [PKA], Src family tyrosine kinase, MAPK, c-Jun, but not p38) have been implicated in this (Watanabe et al. 2004). Furthermore, experiments using MIF- and IL-1-deficient mice (Honda et al. 2008) have confirmed that the IL-1 beta/MIF cytokine network is involved in the upregulation of UVA-induced MMP-1 in dermal fibroblasts but in these studies there was an indication (using inhibitors) that p38 and JNK were also involved.

Ramos et al. (2004) showed involvement of MEK 1 and 2 and p38 in UVA-induced MMP-1 and MMP-10 activation in human SCC cells.

Among agents that have been shown to protect against MMP-1 activation by UVA are flavonoids (Basu-Modak et al. 2006). Beta-carotene can also prevent UVA-mediated MMP-1 activation in skin cells (Wertz et al. 2005), and dietary beta-carotene can suppress MMP-9 activation in mice (Minami et al. 2009). The authors conclude that this systemic effect is due to the prevention of cholesterol peroxidation, which is known to be mediated by UVA and to be a trigger for gene activation.

The influence of endogenous glutathione on UVA-induced gene activation was well established using the HO-1 model (see earlier section). Recently, new findings on redox regulation of MMP-1 have emerged. For example, the antioxidant oxidoreductase thioredoxin-1 (Trx) has been shown to inhibit UVA-induced MMP-1 activation (Buechner et al. 2008). Although these authors concluded that this was an effect on transcription, redox regulation of MMP-1 could occur at the posttranslational level. Koch et al. (2009) showed that reduced thiols such as cysteine or glutathione substantially reduced MMP-1 activity, and this effect was reversed by oxidizing radicals (e.g., the trolox radical). They concluded that these observations reflected redox control via derivatization or oxidation of a glutathione (GSH)–MMP-1 complex.

58.5.5.3 Intercellular Adhesion Molecule 1

ICAM-1 plays an important role in mediating leukocyte/keratinocyte adhesion and is therefore crucial to the inflammatory response. Although UVB radiation can prevent increased expression of ICAM-1 in murine epidermal Langerhans cells (LCs) as well as inhibiting LC function (Tang and Udey 1992), Krutmann and Grewe (1995) showed that both UVB and UVA could induce ICAM-1 in human skin keratinocytes, albeit by different mechanisms. Importantly, the activation of the AP-2 transcription factor on the ICAM-1 promoter of the human keratinocyte *ICAM-1* gene was shown to be the mechanism underlying this response (Grether-Beck et al. 1996), and this model system was used to show the crucial role of ceramide on UVA signaling (see earlier section). Interestingly, ICAM-1 (and E-selectin but not vascular cell adhesion molecule 1 [VCAM-1]) was induced by UVA but not UVB in human dermal microvascular epithelial cells (Heckmann et al. 1994) indicating an important role for these cells in skin inflammation. Further studies from this group (Heckmann et al. 1997) demonstrated that repeated exposure to UVA actually abrogated leukocyte adhesion to endothelial cells. Indeed, studies by Treina et al. (1996) indicated that UVA led to a decrease in ICAM-1 expression in both epidermis and epidermal keratinocytes, and although some increase in ICAM-1 was observed in dermal fibroblasts, ICAM-staining in the dermis was specific for vascular structures, a finding consistent with the data of Heckmann et al.

58.5.5.4 Cyclooxygenase-2

Cyclooxygenases generate the inflammatory mediators known as prostaglandins by breaking down arachidonate. Although such intermediates have been implicated in UVB erythema, studies using indomethacin (a cyclooxygenase inhibitor) indicated that prostaglandins were not involved in UVA erythema (Søndergaard et al. 1985). Nevertheless, cyclooxygenase activity was measured in human and murine skin fibroblasts (Hanson and DeLeo 1989) following UVA irradiation, and activation of COX-2 has been clearly demonstrated in HaCaT cells (Kvam et al. 1999) and in artificial human epidermis (Mahns et al. 2004). Although the latter authors reported that JNK rather than p38 signaling was

involved in COX-2 activation by solar-simulated light in this skin model, activation in keratinocytes appears to be mediated by p38 stabilization of the COX-2 mRNA (Bachelor et al. 2002). These authors conclude that MAPK's, JNK, and p38 are all involved in COX-2 stimulation by UVA activation, and AP-1 is a major factor.

58.5.5.5 NADPH Oxidase

UVA is now known to activate NADPH oxidase, and this is a primary source of UVA-induced ROS generation (primarily superoxide anion) in cells at sublethal doses (Valencia and Kochevar 2008). A direct consequence of this increase in ROS (as shown by Nox1 SiRNA knockdown experiments) is rapid initiation of PGE2 synthesis.

58.5.5.6 Methionine-S-Sulfoxide Reductase

The oxidized protein repair enzyme MSRA is expressed in human epidermis and upregulated by low doses of UVA radiation (and H₂O₂), but not by UVB (Ogawa et al. 2006). Its expression was also shown to be increased by repetitive exposure of human skin to simulate sunlight. MSRA reduces the methionine sulfoxide (MetO) to methionine, thus reversing the inactivation of proteins caused by oxidation of critical methionine residues. It is the only enzyme so far identified in human skin that is able to repair oxidative protein damage.

58.5.5.7 Modulation of Expression of Other Genes by UVA

An interesting preliminary report by Pastila and Leszczynski (2005a) indicated a UVA-mediated upregulation of N-cadherin and a downregulation of E-cadherin in a murine melanoma cell line. This was associated with a decrease in self-adhesion of melanoma cells and an increase in melanoma adhesion to epithelial cells with evident implications for metastatic potential. These authors also demonstrated the UVA-induced metastatic potential of these melanoma cells in mice (Pastila and Leszczynski 2005b). In a study of melanocyte proliferation in hairless SKH-2 mice, van Schanke et al. (2005) found that while a single (but not fractionated) doses of UVB led to a strong enhancement in proliferation, no change in proliferation rate was observed following any type of UVA dose regimen. In a study comparing UVA- and UVB-induced gene expression in primary human melanocytes (Zhang and Rosdahl 2003), proteins involved in cell growth (p73 and Nup88) were notably enhanced by UVA irradiation but induction of expression of these genes has not been noted in other cell types.

Grimbaldeston et al. (2003) showed that UVA irradiation of mouse epidermis or a murine keratinocyte cell line led to the induction of an oxidant-susceptible calcium-binding protein (S100A8) of significance in human psoriasis.

Finally, UVA has been shown (Breuckmann et al. 2004) to induce a reduction in neuron-specific enolase levels in acrosclerosis (a form of auto-immune rheumatic disorder). UVA has been used as an adjuvant treatment in moderately active systemic lupus erythematosus (Polderman et al. 2004). Such treatment has been associated with softening of sclerotic lesions but other UVA-mediated events such as T-cell apoptosis, metalloproteinase induction, and angiogenesis may all also be involved.

58.6 Disease and UVA Sensitivity

A human disease known to be uniquely sensitive to UVA radiation is Smith–Lemli–Opitz (SLO), an autosomal recessive mental retardation syndrome (Anstey and Taylor 1999). The greatest sensitivity was seen at 350 nm although in an examination of all known UK patients, no photosensitivity was observed in 10 out of the 23 people tested (Anstey et al. 1999). The genetic defect involves deficiency of the enzyme 7-dehydrocholesterol-7-reductase. Since cholesterol levels are reduced (and levels of 7-dehydrocholesterol increased), cholesterol supplementation has been used to treat the disease and has achieved limited success in alleviating some of the symptoms including photosensitivity (Azurdia et al. 2001; Starck et al. 2002). Unlike the short-wavelength UV sensitivity of cells from xeroderma pigmentosum

patients, sensitivity to UVA was not observed in skin cells derived from SLO patients. However, in a model system, exposing keratinocytes containing high 7-dehydrocholesterol levels and low cholesterol to UVA strongly enhanced ROS levels compared to nonsupplemented keratinocytes, and this was associated with enhanced UVA-induced cell death (Valencia et al. 2006; Valencia and Kochevar 2006). There is limited evidence that the extreme photosensitivity observed in Pellagra may be a UVA phenomenon (Wan and Anstey in preparation).

58.7 Conclusions

UVA has multiple effects on cells and tissues. In addition to causing damage to DNA which can lead to mutation, UVA damages other cellular macromolecules and triggers a series of stress responses indicative of wider damage. Damage to lipids in particular cannot only cause loss of membrane integrity at relatively low fluences but also lead to lipid intermediates, which have been heavily implicated in signaling and modulation of gene expression. UVA has been implicated as a human carcinogen for many years but it also plays a role in acute inflammatory skin damage as monitored by the dramatic HO-1 response. Furthermore, UVA activation of several types of proteinases causes both short- and long-term destruction of skin components that will contribute to the photoaging process. While we have not considered protection in the current review, the overwhelming evidence for the short- and long-term damaging consequences of UVA have already stimulated considerable scientific endeavor to find ways of preventing this damage and will continue to be a focus for the future.

59.1 Introduction

Vitamin D is a hormone, with a chemical structure closely related to that of cortisol. It is often called the “sunshine vitamin” as it is synthesized in the skin following exposure to the ultraviolet B (UVB) in solar radiation. There are two forms of vitamin D, with only vitamin D₃ (cholecalciferol) being photochemically produced in the skin, while vitamin D₂ (ergocalciferol) is formed from ergosterol in plants, through a similar process. Both require metabolism to produce the active hormone. Humans can obtain both vitamin D₃ and D₂ through diet, although several recent surveys confirm that the average diet contains low amounts. There is currently considerable controversy regarding the amounts of vitamin D required for human health and how these may best be obtained. While it is well known that vitamin D is essential for calcium metabolism and that deficiency causes the severe bone disorders of rickets and osteomalacia, there are also associations with systemic and malignant disorders where cause and effect are not firmly established.

59.2 Cutaneous Synthesis

59.2.1 Contribution of Sunlight to Vitamin D Levels

Vitamin D synthesis is the best known beneficial effect of ultraviolet radiation (UVR) on the skin. It is often quoted that around 90% of the body's source of vitamin D is obtained by this route, with only approximately 10% gained through diet. However, while sunlight is in most circumstances likely to be the larger contributor (Ashwell et al. in press), this statement is dependent on specific latitudinal, seasonal, and personal conditions and cannot be applied generally.

59.2.2 Biosynthetic Pathway

Precursor molecule, 7-dehydrocholesterol (7-DHC; provitamin D), is stored in the skin. On exposure of skin to UVB radiation, a photochemical reaction occurs, converting 7-DHC to pre-vitamin D₃. This is subsequently converted through a comparatively slower thermal isomerization step to vitamin D₃, which is released into the circulation where it is transported by vitamin D-binding protein. It is known that sunlight as well as initiating vitamin D₃ synthesis in the skin also regulates the process (Figure 59.1), and that this involves a role for ultraviolet A (UVA) wavelengths in addition to UVB (Norval et al. 2010). Prolonged sun exposure results in reversible photoconversion of pre-vitamin D₃ to alternative, inactive metabolites tachysterol and lumisterol, limiting the total amount of pre-vitamin D₃ that will form and be available for conversion to vitamin D₃. Sunlight (UVA) also degrades formed vitamin D₃ present in the skin to photoproducts 5,6-transvitamin D₃, suprasterol I, and suprasterol II (Webb et al. 1989). This photochemical regulation explains why hypervitaminosis D is only reported to occur when excess vitamin D is ingested, and not from sun exposure, and why short exposures to sunlight are most efficient in vitamin D production.

FIGURE 59.1 The formation of vitamin D and its metabolites. The long box (down the left side) shows the path from 7-DHC to the active metabolite 1,25(OH)₂D₃. The top box indicates reactions that occur in the skin. Products outside the long box are inert isomers or degradation products. With the exception of the slow heat isomerization (dotted arrow), all reactions (continuous straight arrows) are driven by UVR, predominantly UVB for formation and UVA for degradation. Curved arrows indicate transport in the blood.

59.2.3 Action Spectrum

The wavelengths of radiation most effective in transforming 7-DHC to pre-vitamin D₃ were identified to fall between 295 and 300 nm, with a maximum around 297 nm (Figure 59.2; MacLaughlin et al. 1982). This and earlier works were examined by the Commission Internationale de L'Eclairage (CIE) in defining a standardized action spectrum for vitamin D synthesis (CIE 2006). However, *in vivo* studies are lacking and further research is required to confirm the action spectrum (Norval et al. 2010); as described in the preceding paragraph, the cutaneous processes prior to the release of vitamin D into the bloodstream are more complex than the initial production of pre-vitamin D₃, with the involvement of UVR at more than one step.

59.2.4 Latitude and Season

The quantity of UVB reaching the earth's surface is highly dependent on latitude, season, and time of day. The solar zenith angle (SZA), that is, the angle between the local perpendicular and the location of the sun in the sky, determines the path length of radiation through our attenuating atmosphere and

FIGURE 59.2 The action spectrum for the formation of pre-vitamin D₃ from 7-DHC. Top (linear scale): Data measured in human skin (MacLaughlin et al. 1982). Bottom (logarithmic scale): The CIE action spectrum based on the measured data (dots) and extrapolated (dashed line) to the regions with no data (CIE 2006).

also the angle at which radiation strikes the surface. As SZA increases, path length increases and the direct beam reaches the surface at a more oblique angle, both of which decrease the radiation at the surface. SZA increases with latitude, in autumn and winter, and outside noon hours. Maximum vitamin D production occurs at low latitudes, in the summer months and around midday, and there is no effective vitamin D production in winter time at higher latitudes such as in Northern Europe, Canada, and northern states of the United States (Webb et al. 1988; Webb and Engelsen 2006).

59.2.5 Atmospheric Factors

Cloud, pollution, and ozone affect the amount and type of UVR reaching the earth's surface (Webb and Engelsen 2006). Ozone changes result in spectral differences at the surface, since it absorbs most strongly at UVB (vitamin D producing) wavelengths. Low ozone therefore enhances potential vitamin D₃ production while having little effect on the rest of the solar spectrum. Cloud on the other hand generally decreases radiation at all wavelengths, by amounts that vary depending on cloud type, depth, and sky cover; in broken cloud conditions, radiation can even be enhanced for short periods of time. Pollution too results in overall reduction of solar radiation at the surface, though some pollutants absorb in particular wavebands, for example, sulfur dioxide, as well as ozone in the troposphere, absorbs at UV wavelengths.

59.2.6 Skin Pigmentation

Skin color affects vitamin D production as UVR is partially absorbed by melanin, reducing the amount reaching the chromophore 7-DHC (Webb and Holick 1988). Studies show that people with darker skin (skin phototypes V and VI) are capable of synthesizing vitamin D in their skins, but higher absolute UV doses are required (see Section 59.2.9). This puts people with darker skins living at higher latitudes at particular risk of low vitamin D status.

59.2.7 Age

Older people are in general at greater risk of low vitamin D levels, due to factors including lower 7-DHC levels in the skin and, potentially, decreased mobility reducing the time spent outdoors. In an *in vitro* study using skin samples from people aged 8–18 and 77–82 years, ability to produce pre-vitamin D₃ following UV exposure was decreased by more than twofold in the older group (MacLaughlin and Holick 1985), while an *in vivo* study showed a reduced seasonal boost in vitamin D levels in those living in nursing homes compared with independently living older people (Webb et al. 1990).

59.2.8 Impact of Photoprotective Measures

Shade, clothing, and sunscreens are employed to reduce the risk of sunburn and longer term hazards of UVR on the skin. Sunscreen, when applied according to the manufacturer's testing conditions, that is, an even application with surface density of 2 mg/cm², provides a barrier to UVB and to a lesser extent to UVA. Accordingly, it has been calculated that a sunscreen with sun protection factor (SPF) 15 could reduce vitamin D synthesis by up to 99.9% (Holick 2004). However, studies consistently show that in practice, sunscreen is applied less rigorously and in much lower densities, even by people with photosensitivity conditions (Azurdia et al. 2000; Thieden et al. 2005), and while sunscreens tend to be used to protect during the intense conditions of sunny holidays, they are less frequently used during outdoor pursuits at other times (Bourke et al. 1995). Shade can also be deceptive since much of our UV exposure is to diffuse or scattered radiation that is incident from all directions. Shade provides protection from the direct beam but not all the scattered radiation. Thus, unknowns regarding behavioral factors and UVB exposure patterns as well as target vitamin D status complicate this issue.

59.2.9 Artificial UVR Sources

Lamps emitting UVB, as used in the medical treatment of skin disorders, are known to raise vitamin D levels (Armas et al. 2007; Sayre et al. 2007). UVR lamps with peak emission at 310 nm fitted to the ceiling in a nursing home also increased vitamin D status in the elderly residents, in whom hands and face were exposed (Chuck et al. 2001). Elsewhere, people with both black and white skin responded to a 6 week course of total body irradiations with UVB, dosed according to their individual erythema sensitivity, that is, their minimal erythema dose (MED) (Brazier et al. 1988). Baseline vitamin D status was lower in the black subjects and remained lower following treatment. However, on the higher absolute UV dose regime (with longer irradiation times), the black subjects showed a similar gain in vitamin D status over the course. Commercial sunbeds, as used for indoor tanning, have been increasingly marketed as providing health benefit. Thieden et al. (2008) compared two groups of women given treatment courses with sunlamps containing primarily UVA with 0.5% or 1.4% UVB and a group given no intervention. The lower UVB group increased their circulating 25-hydroxyvitamin D (25(OH)D) by approximately 5 ng/mL while the increase was approximately double this in the higher UVB group, and no change was seen in the untreated group; however, the levels showed a plateau after four treatments. As the emission spectrum of commercial lamps varies, and the use of sunbeds increases the risk of skin cancer (IARC 2008), they are not recommended for use by the public for any perceived health gain. Thus, the U.S. Food and Drug Administration (FDA) states that sunbeds are for tanning purposes only and no health benefit claims can be made (Lim et al. 2005).

59.3 Dietary Sources

59.3.1 Natural and Fortified Foods

Few foods naturally contain significant amounts of vitamin D. Fatty fish, for example, herring and mackerel, contains the highest concentration, while meat, eggs, and dairy products (milk, butter, and cheese) contain moderate–low concentrations. Food fortification has enhanced the vitamin D content of some foods, particularly margarine, cereals, and milk, although countries vary in the degree to which this occurs. For example, in the United States, legislation has made milk fortification mandatory, although in the United Kingdom presently only margarine undergoes mandatory fortification and this is only to the (low) level found naturally in butter (Margarine Regulations 1967). Problems can occur with food fortification, for example, in controlling the dose within each portion when adding vitamin D to milk, resulting in overfortification of some portions and underfortification of others (Holick et al. 1992; Chen et al. 1993).

59.3.2 Recommended Intake

Guidelines on the daily oral requirement of vitamin D vary, but generally there has been an assumption that most is obtained via cutaneous exposure to sunlight and that relatively little is required orally. Some authorities are considering revising these recommendations upward in the light of recent reports of widespread low vitamin D status. The World Health Organisation (WHO 1998) currently recommends 5 µg (200 IU) per day for most adults, 10 µg for 50–65 years, 15 µg for >65 years, and 10 µg for pregnant and lactating women. In the United States and Canada, the Institute of Medicine, Food and Nutrition Board (1997) advised 5 µg for adults <50 years, 10 µg for 51–70 years, and 15 µg for 70+ years. Authorities in several European countries also recommend 5 µg per day for healthy adults (Doets et al. 2008). In the United Kingdom, there is no recommended nutrient intake for vitamin D for most adults and children aged 4–64 years, while older people, along with the housebound, pregnant, or lactating women, and those with pigmented skin, are identified as at risk and advised to take 10 µg daily, and children 0–6 months are recommended 8.5 µg daily, and 6 months–3 years, 7 µg daily (Department of Health, COMA 1998; Food Standards Agency 2003).

59.3.3 Actual Dietary Levels

Studies have revealed that the average dietary intake in Europe is low (Andersen et al. 2005). The U.K. National Diet and Nutrition Survey (NDNS) found that the mean daily intake from diet alone was only 2.8 µg in women and 3.7 µg in men. Fish and fish dishes were the main dietary sources, with most vitamin D provided by oily fish (Henderson et al. 2003). A survey in Ireland confirmed a daily vitamin D intake below 5 µg per day from all sources (diet and supplements) in the majority of men and women aged 18–64 years (Hill et al. 2004); however, the impact on bone health is currently unknown. Oily fish meals and use of fish oil supplements could explain the modestly higher vitamin D levels tending to be found in Scandinavia (Zittermann 2003). In Finland, the mean daily intake is 4.7 µg for women and 5.6 µg for men (Lamberg-Allardt et al. 2001).

59.4 Metabolism

Once in the circulation, vitamin D (both D₃ and D₂ forms) undergoes hydroxylation, first in the liver to form 25(OH)D, calcidiol, and second in the kidney to produce the active hormone, that is, 1,25 dihydroxyvitamin D (1,25(OH)₂D, calcitriol). Formation of 1,25(OH)₂D is tightly regulated and only small amounts occur in the bloodstream. Key target organs for the vitamin D hormone are those involved in calcium homeostasis and bone turnover, that is, the intestine, where vitamin D regulates the transport of calcium across the intestinal mucosa, and in the bone, kidney, and parathyroid glands (Shipley et al. 2002). However, many other organs including ovary, breast, and uterus are now known both to be able to synthesize 1,25(OH)₂D locally and to possess vitamin D receptors, thus accommodating wider biological roles of the hormone (Dokoh et al. 1983).

59.5 Role in Bone Health

59.5.1 Rickets and Osteomalacia

It is well known that severe vitamin D deficiency causes rickets in children, and osteomalacia in children and adults; these involve the development of severe bone deformity through a failure of bone mineralization (Lips 2006). Rickets was common particularly in cities at higher latitude in the nineteenth century, and it was discovered early in the twentieth century that this could be cured by sunlight exposure. However, it would be incorrect to regard rickets as a disease of previous times. Cases continue to be reported, particularly in the increasing populations of darker skinned people living at higher latitude, and in instances where total infant nutrition is through breast feeding, as breast milk can be a poor source of vitamin D, depending on the status of the mother (Specker et al. 1985; Kreiter et al. 2000; Hollis and Wagner 2004).

59.5.2 Other Aspects of Musculoskeletal Health

As well as the aforementioned severe bone disorders, relatively low vitamin D status is associated with the bone-thinning condition, osteoporosis, along with bone fracture and muscle weakness (Lips 2006). Low vitamin D status results in reduced resorption of intestinal calcium, and to a lesser extent, phosphorus. The parathyroid glands respond by increasing parathyroid hormone (PTH) secretion, with higher PTH levels resulting in increased calcium resorption from bone. Elevated levels of PTH also result in increased renal production of 1,25(OH)₂D, which then binds to and increases the activity of the bone-forming cells (osteoblasts) in the bone. However, phosphorous is lost, causing mobilization of minerals and matrix from bone and a negative effect on bone mineral density (Bischoff-Ferrari et al. 2004). These observations have led to expectations that higher vitamin D status may help achieve optimal bone health. Indeed, while studies are not completely consistent, results of a number of randomized

controlled intervention studies with vitamin D supplements suggest a reduction in bone fractures in those actively treated, and a protective effect of higher vitamin D levels is supported by biochemical and radiological data (Veith 2005; Bischoff-Ferrari et al. 2005; Wolpowitz and Gilchrest 2006).

59.6 Potential Role in Malignant and Systemic Disorders

59.6.1 Cellular Effects of Vitamin D

Evidence from experimental models supports that $1,25(\text{OH})_2\text{D}$ has chemopreventive properties, including its role as a differentiating agent and modulator of apoptosis (Colston and Hansen 2002; Mehta and Mehta 2002; Ingraham et al. 2008). It is also an immunomodulatory agent, capable of influencing aspects of both innate and adaptive immunity (Deluca and Catorna 2001; Kamen and Tangpricha 2010). These roles could be facilitated by the presence of vitamin D receptors in many cells, with most tissues also capable of locally producing the active vitamin D hormone from circulating $25(\text{OH})\text{D}$. Thus, potentially low vitamin D status might contribute to increased risk of malignancy and disorders of immunity. Currently, while there is a wealth of evidence associating low vitamin D status or proxies for this with several malignancies, diabetes, multiple sclerosis, and other conditions, there is very little direct evidence to confirm cause and effect.

59.6.2 Malignant Conditions

Mortality from prostate, colon, and breast cancer is reported to be inversely associated with ambient UVB, and this has been attributed to low vitamin D status (Holick 2006). The expert panel of the International Agency for Research on Cancer reviewed multiple strands of evidence and supported a protective role for vitamin D in colon cancer, but found insufficient evidence for a protective effect in other malignancies (IARC 2008). In epidemiologic studies, ambient UVR data are used as a proxy for vitamin D status, but it is known that behavioral factors can confound this assumption. Moreover, comparisons of age-standardized incidence and mortality rates for colorectal and prostate cancers in Northern Europe with those in Australia and New Zealand reveal lower incidence of both cancers in Northern Europe, despite the lower ambient UVR (Ferlay et al. 2004; Diffey 2006). In the case of colon cancer, several studies do report a reduction in risk of colorectal cancer with higher circulating levels of $25(\text{OH})\text{D}$ (Giovannucci 2005). Luscombe et al. (2001) examined the effect of UVR exposure on prostate cancer development by comparing recall of sun exposure levels in men with prostate cancer versus a control group with benign prostatic disease. They found that lower reported frequency of childhood sunburn, fewer foreign holidays, and low UV exposure correlated with the development of prostate cancer; however, this does not establish vitamin D as the protective factor. Epidemiological data conflict concerning potential protection in melanoma (Millen et al. 2004; Ingraham et al. 2008; Asgari et al. 2009).

59.6.3 Systemic Disorders

Further evidence exists of an association with beneficial effects in a range of other diseases, including multiple sclerosis, tuberculosis, diabetes, hypertension, and cardiac failure (Hypponen et al. 2001; Muray et al. 2003; Stene and Joner 2003; Zittermann et al. 2003), although confounding factors and data limitations frequently pose challenges in defining a clear link between vitamin D and reduced incidence of such diseases.

59.7 Defining Vitamin D Levels for Health

59.7.1 Vitamin D Status

The active hormone $1,25(\text{OH})_2\text{D}$ is tightly regulated, and the measurement of its levels has limited value. On the other hand, $25(\text{OH})\text{D}$ is the major circulating form of vitamin D and more responsive to the effects of sunlight exposure and dietary intake. Thus, there is international consensus that it is the most

appropriate marker of vitamin D status (Expert Group on Vitamins and Minerals 2003; Institute of Medicine 1997). However, there is much debate concerning the circulating 25(OH)D levels that should be reached.

59.7.2 Deficiency

It is well established that circulating levels of 25(OH)D below 5–10 ng/mL (12.5–25 nmol/L) can cause the severe bone conditions of rickets and osteomalacia, and hence, it is agreed that values below these levels are deficient (DoH, COMA 1998; NRPB 2002; Ashwell et al. in press). Some authors recently suggest regarding levels of <20 ng/mL (50 nmol/L) as being in the frankly deficient category (Holick 2009) but the evidence is weaker and the proposal is not generally accepted by investigators or government bodies (Ashwell et al. in press).

59.7.3 Sufficiency

Circulating 25(OH)D levels of above 20 ng/mL (50 nmol/L) are generally considered to be vitamin D sufficient, with good evidence for levels below this being associated with secondary hyperparathyroidism and increased risk of osteoporosis (Vieth 1999; Holick 2002). Many clinical biochemistry laboratories, including several in the U.K., regard 25(OH)D levels of 20 ng/mL and above as “normal.” It was recently proposed that a level of 21–29 ng/mL is regarded as insufficient (Holick 2009), but this is based on biochemical rather than clinical evidence, including levels of 25(OH)D associated with maximal PTH suppression, which is not established to be beneficial to health.

59.7.4 Optimal Levels

Several researchers support that the optimal vitamin D level for bone health is much higher than previously thought, that is, 30–32 ng/mL (70–75 nmol/L) and above (Dawson-Hughes et al. 2005; Heaney 2005; Hollis 2005; Veith and El-Hajj Fuleihan 2005; Bischoff-Ferrari et al. 2006). Bischoff-Ferrari et al. (2006) reviewed evidence for optimal levels of vitamin D in multiple health parameters and concluded that these start at around 30 ng/mL. The optimal level of vitamin D for bone health might be defined as one providing maximal suppression of PTH level, peak intestinal calcium absorption, and maximum bone mineral density. However, there is no universal consensus, and others believe there is insufficient evidence that these high levels are physiological or required (Barger-Lux et al. 1998; Lim et al. 2005; Ashwell et al. in press).

59.7.5 Toxicity

Toxicity can occur through oral sources of vitamin D, that is, from an excessive dose of supplements and/or food fortification. However, quite high doses appear to be tolerated. The U.S. Food and Nutrition Board stated that the upper tolerable level for vitamin D is 2000 IU (50 µg) daily (1997), although this may be an underestimate (Heaney et al. 2003; Veith 2004). In a clinical setting, much higher doses are sometimes provided, for example, in treating osteoporosis, but this is different to regular self-administration of a supplement. Based on current evidence, vitamin D toxicity could be defined as a circulating 25(OH)D level of >150 ng/mL; this is accompanied by increased urinary excretion of calcium (hypercalciuria) and if prolonged there may also be increased blood levels of calcium (hypercalcemia), vomiting, weakness, and confusion (Veith 1999).

59.7.6 Vitamin D Status in the General Population

The groups particularly at risk of low vitamin D status were discussed earlier in this chapter. However, there is increasing evidence that low vitamin D status may occur across populations generally. A recent study examined a large cohort of white, British adults aged 45 years and found that around half the

study sample had 25(OH)D levels <40 nmol/mL (16 ng/mL) (Hypponen and Power 2007), and findings were broadly similar in the NDNS of British adults aged 19–64 years (Hirani et al. 2009). Furthermore, a recent partially published study indicated that 20%–25% women assessed in the north of Scotland had levels in the frankly deficient range (<10 ng/mL) in winter (Ashwell et al. in press).

59.8 Recommendations on Sunlight Exposure Levels

59.8.1 Skin Cancer Avoidance

Skin cancer has high incidence in countries with large populations of white Caucasians including in Northern Europe, the United States, and Australia, and the incidence continues to rise, with UVR the principal etiological agent in the majority of skin cancers (NRPB 2002; Elwood and Jopson 1997). Thus, national and international authorities advise summer sunlight limitation in these populations (Ziegelberger et al. 2006). Exposure to solar UVR is the principal cause in the majority of cases of the three main types of skin cancer, that is, basal cell carcinoma and squamous cell carcinoma [both are types of nonmelanoma skin cancer (NMSC)] and malignant melanoma. The NMSCs are the most commonly occurring, and while they infrequently cause death, they can cause high morbidity (NRPB 2002). Malignant melanoma occurs less frequently but is fatal in 25% of cases (<http://www.sunsmart.org.uk/skin-cancer-facts/about-skin-cancer>). People of the fairest skin coloring, freckled and with tendency to sunburn, that is, those in phototypes I and II, are the most prone to melanoma and NMSC.

59.8.2 Current Guidance

Policy recommendations and public health strategies to limit summer sunlight exposure in order to prevent skin cancer have generated considerable international debate in recent years. The “SunSmart” campaign originating in Australia has been emulated or paralleled elsewhere, with focus on providing the public, particularly those of phototypes I and II, with information on the relationship of skin cancer to sunlight and advice on how to reduce the risks. A particular emphasis is to avoid sunburn, as sunburn is a risk factor for both melanoma and NMSC (NRPB 2002). In Australia, the SunSmart campaign was associated with a slowing of the rate of rise of melanoma incidence in younger adults (Giles and Thursfield 1996), while elsewhere campaigns have generally not been running consistently for a sufficient period to assess impact on the longer term incidence of skin cancer. However, concerns have been raised, as advice to seek shade at noon hours, to cover up with clothing, and to use sunscreens may reduce opportunities for the skin to synthesize vitamin D, particularly at latitudes further from the equator. This concern is strengthened by the recognition that higher vitamin D levels may be required than previously realized for optimal health.

59.8.3 How Much Sunlight Is Needed?

Our group recently performed an *in vivo* study to examine the impact on vitamin D status of a casual summer’s sunlight exposures, following an interpretation of the U.K. national recommendations on sun exposure levels (Rhodes et al. 2010). This national guidance is fairly general, with uncertainty regarding the specification and impact of following the recommendations, based as they are on data derived from *in vitro* and theoretical models (National Radiological Protection Board 2002; Ziegelberger et al. 2006). The U.K.’s SunSmart campaign is consistent with many countries in its recommendations to limit personal summer sunlight exposure levels (<http://www.sunsmart.org.uk/skin-cancer-facts/about-skin-cancer>), while the U.K.’s Health Protection Agency, in line with countries of similar latitude, advises that casual exposures to summer sunlight containing UVB are sufficient for attaining vitamin D (National Radiological Protection Board 2002) albeit at the levels required to avoid rickets. A population-justified sample of U.K. white Caucasians was given a simulated summer’s UVR exposures of known dosage,

equivalent to <30 min exposure of unshaded skin to Manchester noon sun on a cloudless day. This was performed in the winter months, when ambient UVB could not confound the data, and to skin areas (35% total surface area) routinely exposed when wearing casual summer clothing (Rhodes et al. 2010). We showed this regime would produce a vitamin D sufficient status, that is, 25(OH)D of at least 20 ng/mL, in 90% of the population, whereas only approximately a quarter (26.2%) would reach the proposed optimal level, that is, 25(OH)D of at least 32 ng/mL. The findings were very similar to the vitamin D status acquired naturally following a British summer in the same population of white Caucasians (Webb et al. 2010). Thus, repeated sub-erythral UV exposures while casually dressed can produce sufficiency at summer end. On the other hand, sufficiency (25(OH)D \leq 20 ng/mL) was maintained during winter only in those reaching optimal levels (25(OH)D \leq 32 ng/mL) at summer end, in the natural summer exposure study (Webb et al. 2010). These data can be utilized when considering how best to achieve and maintain vitamin D status, although clearly a consensus is required on the level of 25(OH)D that should be targeted for the population.

59.9 Future Directions

Human vitamin D requirements for optimal health may be greater than previously stated, when avoiding rickets was the main goal, and research is ongoing to both clarify the needs and establish feasible ways for attaining these. While vitamin D supplements could potentially satisfy needs and avoid health risks of UVR, questions to be addressed in this respect include: Will whole populations be prepared to take supplements? Are dietary sources handled in an equivalent manner to the cutaneous source? If high circulating 25(OH)D levels are required, should these be maintained year-round, thus removing the naturally occurring seasonal pattern seen at mid-high latitudes? Sunlight provides a natural, regulated source of vitamin D at sub-erythral doses, and as people gain pleasure from this, they are likely to continue to expose their skin. However, sunlight appears more effective as a source in some individuals than others; hence, what biochemical and genetic differences influence vitamin D status gained? What factors influence effective storage of vitamin D into the winter months? An examination of the action spectrum for vitamin D synthesis *in vivo* may provide information regarding how to maximize benefits while avoiding the hazards of sun exposure. Research is also needed into other potential benefits of sunlight exposure, and how the overall optimal benefit/risk ratio for health can be gained in different population groups.

60.1 Introduction

Terrestrial solar ultraviolet radiation (UVR) is a major environmental hazard and is the cause of the majority of skin cancers, especially in sun-sensitive white-skinned people. There is considerable evidence that nonmelanoma skin cancers are due to UVR-induced DNA damage (Ziegler et al., 1994). UVR also causes photoaging. The effects of UVR on the skin, whether acute such as sunburn or long term, are caused by damage to target molecules. This can be done in two ways: (1) Direct absorption of UVR by the target molecule such as DNA or urocanic acid. In such cases, the target molecule is the chromophore. One of the most important types of DNA damage formed in this way is the cyclobutane pyrimidine dimer (CPD), which has been implicated in erythema, immunosuppression, mutagenesis, and skin cancer (Yarosh, 2004). Alternatively (2) the target molecule can be damaged indirectly when UVR is absorbed by another chromophore, which generates reactive oxygen species (ROS), such as the superoxide anion, hydrogen peroxide, the hydroxyl radical, and singlet oxygen. ROS can interact with cellular proteins, membranes, and DNA to alter their functions. Consequently, excessive ROS may arrest the cell growth cycle and cause inflammation, immunosuppression, skin aging, DNA damage (Cadet et al., 2009), mutation, and cancer.

The specific chromophores that generate ROS are largely undefined. As an approximate rule of thumb, it can be said the minor ($\leq 5\%$) UVB ($\sim 295\text{--}320\text{ nm}$) component of solar UVR is responsible for direct UVR effects and the majority ($\geq 95\%$) of UVA component ($320\text{--}400\text{ nm}$) is responsible for the indirect effects. However, there are many exceptions to this rule.

The skin has natural defense mechanisms against UVR. The most obvious is melanin, which attenuates UVR. The amount and type of melanin in the skin are genetically determined as is the melanogenic response to UVR. More important is DNA repair capacity, without which the skin is extremely prone to skin cancer. The classic example of this is in the genodermatoses xeroderma pigmentosum (XP), which lack nucleotide excision repair. The skin also has natural antioxidants.

60.2 Natural, Oral, and Topical Antioxidants

Low-molecular-weight antioxidants, naturally present in skin, provide endogenous protection by binding to and neutralizing ROS before oxidation can cause damage to healthy cells. These natural antioxidants are nonenzymic (e.g., ascorbic acid, α -tocopherol, ubiquinol, and glutathione) or enzymic (e.g., catalase, superoxide dismutase, thioredoxin reductase, glutathione peroxidase, and glutathione reductase) (Pinnell, 2003). Antioxidants are present in the epidermis and the dermis (Shindo et al., 1994); overall activities of the enzymatic antioxidants, and the concentrations of nonenzymatic antioxidants, are higher in the epidermis.

The majority of nonenzymatic antioxidants are obtained through the diet and then transported to skin, where they may be depleted by UVR exposure. For example, in a model of human skin exposed to high doses of UVR, ubiquinol levels were reduced significantly, and α -tocopherol was depleted in a linear fashion with increasing UVR doses (Podda et al., 1998).

After UVR exposure, skin cannot protect itself as well against further ROS because of its diminished antioxidant levels. The excess ROS generated overwhelms the antioxidant system; the imbalance between ROS and endogenous protective mechanisms is known as "oxidative stress."

Since some of the adverse consequences of UVR are due to ROS production, it is logical to consider antioxidant supplementation as a defense against their generation, leading to a reduction in ROS's damaging effects. Moreover, since antioxidants are depleted as they shield the skin from oxidative stress, it would seem beneficial to add to the skin's supply. Antioxidants can be added to skin through diet, oral supplements, and topical application.

Direct application is advantageous because it adds antioxidants directly to skin surfaces which require defense and may also penetrate to the dermis. Oral antioxidants are appealing because they are simple and convenient and homogeneously give the whole skin a basic UVR shield.

Much of the research on antioxidant photoprotection has been done on the mouse (Reeve et al., 2005, 2010) but this chapter will focus on human studies. Antioxidant micronutrients that enhance endogenous photoprotection in humans include carotenoids, vitamins E (α -tocopherol) and C (ascorbate), and polyphenols. A summary of these studies and their outcomes is given in [Table 60.1](#).

60.2.1 Carotenoids

60.2.1.1 Structures and Characteristics

The carotenoids' antioxidant abilities are due to their structure: a long conjugated double bond chain. They efficiently quench ROS, especially excited singlet oxygen (Krinsky, 1998; Cantrell et al., 2003). Several carotenoids are precursors to Vitamin A. The two major carotenoids in humans are β -carotene and lycopene (Stahl et al., 1993), as shown in [Figure 60.1](#).

60.2.1.2 β -Carotene

β -Carotene is a fat-soluble antioxidant commonly consumed from carrots, spinach, sweet potatoes, and cantaloupe.

60.2.1.2.1 Photoprotective Properties

A meta-analysis of the literature up to 2007 on oral supplementation with dietary β -carotene in humans showed that it effectively prevents sunburn (Kopcke and Krutmann, 2008), with a maximum sun protection factor (SPF) of 4. However, this photoprotection was only provided once the individual had been taking at least 24 mg β -carotene daily for over 10 weeks with the protective effect increased by 0.5 standard deviations with each extra month of taking supplements.

60.2.1.2.2 Mechanism of Action

The mechanism by which β -carotene provides photoprotection is unknown; it is presumed that this is due to its antioxidant properties, possibly by interfering with the cell signaling pathways through which UVB exerts its damaging effects (Kopcke and Krutmann, 2008).

TABLE 60.1 Summary of Photoprotective Effects of Antioxidants in Human Skin

Antioxidant	Daily Dose	Duration	ROA	UVR Source	Outcome	References
Carotenoid						
β -Car	24 mg/day	12 weeks	OS	SSR	a ↓ (~20%)	Heinrich et al. (2003)
	30–90 mg/day	24 weeks	OS	SSR	MED ↑ dose dependently (50% with 90 mg/day)	Lee et al. (2000)
	90 mg/day	3 weeks	OS	SSR	No protection: erythema or SBC	Garmyn et al. (1995)
	180 mg/day	10 weeks	OS	Sun	MED ↑ slightly	Mathews-Roth et al. (1972)
	15 mg/day	8 weeks	OS	Philips TL12	No protection: MED or oxidative stress	McArdle et al. (2004)
	16 mg/day	10 weeks	Tomato paste (40 g)	SSR	Δa ↓ 30%	Stahl et al. (2001)
Lyc	10.2 mg/day	12 weeks	Synthetic lyc capsules (2)	SSR	Δa ↓ not significant	Stahl et al. (2006)
	16 mg/day	12 weeks	Tomato paste (55 g)	Philips TL12	MED ↑ 16% (eye) and ~40% (reflectance), MMP-1 ↓, mtDNA damage	Rizwan et al. (2010)
β -Car + lyc	5.1 mg β -car + 10 mg lyc/day	12 weeks	Carrot juice (2 × 200 mL)	SSR	Δa ↓ 45%	Stahl et al. (2006)
	0.4 mg β -car + 9.8 mg lyc/day	12 weeks	OS	SSR	Δa ↓	Stahl et al. (2006)
	0.4 mg β -car + 8.2 mg lyc/day	12 weeks	Lyc drink (2 × 250 mL)	SSR	Δa ↓ 50%	Stahl et al. (2006)
β -Car + lyc + lutein	24 mg (8 mg each)/day	12 weeks	OS	SSR	a ↓ (~15%)	Heinrich et al. (2003)
Carotenoid mixture	150 mg β -car + canthaxin (2:3)/day	4 weeks	OS	UVA and UVB	No protection: MED and UDS with UVB	Wolf et al. (1988)
	25 mg (13.0 mg all-trans- β -car, 10.5 mg 9- <i>cis</i> β -car, 0.3 mg other <i>cis</i> isomers of β -car, 0.75 mg α -car, 0.18 mg cryptoxanthin, 0.15 mg zeaxanthin, 0.12 mg lutein)/day	12 weeks	OS	SSR	Δa ↓ 35%	Stahl et al. (2000)

(continued)

TABLE 60.1 (continued) Summary of Photoprotective Effects of Antioxidants in Human Skin

Antioxidant	Daily Dose	Duration	ROA	UVR Source	Outcome	References
β -Car + lycopene + α -toc + selenium	6 mg α - and β -car + 6 mg lyc + 10 mg α -toc + 75 μ g selenium/day	7 weeks	OS	SSR	MED \uparrow 20%, SBC, p53 and lipoperoxide \downarrow	Cesarini et al. (2003)
Carotenoids + α -toc	25 mg carotenoids (13.0 mg all- <i>trans</i> - β -car, 10.5 mg 9- <i>cis</i> β -car, 0.3 mg other <i>cis</i> isomers of β -car, 0.75 mg α -car, 0.18 mg cryptoxanthin, 0.15 mg zeaxanthin, 0.12 mg lutein) + 500 IU RRR- α -toc/day	12 weeks	OS	SSR	Δa \downarrow 32%	Stahl et al. 	2000 mg/day	1 week	OS	Phototherapy lamp	No protection: MED	Mireles-Rocha et al. (2002)
	5% Vitamin C	1 day	Topical	Westinghouse FS20	No protection: a	Dreher et al. (1998)

α-Toc + asc	1000 IU α-toc + 2000 mg asc/day	8 days	OS	Philips TL20	MED ↑ 20%, cutaneous blood flow ↓	Eberlein-König et al. (1998)
	1200 IU α-toc + 2000 mg asc/day	1 week	OS	Phototherapy lamp	MED ↑ 40%	Mireles-Rocha et al. (2002)
	2000 mg α-toc + 3000 mg asc/day	7 weeks	OS	SSR	MED ↑ ~80%	Fuchs and Kern (1998)
α-Toc + asc + ferulic acid	2% Vitamin E + 5% vitamin C	1 day	Topical	Westinghouse FS20	a ↓	Dreher et al. (1998)
	1% α-Toc + 15% L-asc + 0.5% ferulic acid	4 days	Topical	SSR	Erythema ↓, CPD ↓, p53 ↓, cytokine mRNA ↓	Murray et al. (2008)
α-Toc + asc + melatonin	2% Vit E + 5% Vit C + 1%–2.5% melatonin	1 day	Topical	Westinghouse FS20	a ↓	Dreher et al. (1998)
Flavanols	3 mg EGCG/100 μL acetone/2.5 cm ²	1 day	Topical	Westinghouse FS20	Erythema ↓, leukocytes ↓, PG ↓	Katiyar et al. (1999)
	3 mg GTP/2.5 cm ²	1 day	Topical	Westinghouse FS20	Erythema ↓, CPD ↓	Katiyar et al. (2000)
	0.2 mL of GTPs dissolved in ethanol/water vehicle (0.25%–10%)	1 day	Topical	SSR	Erythema ↓ GTP dose dependent; LC ↑, SBC and DNA damage ↓	Elmets et al. (2001)
	326 mg flavanol dissolved in 100 mL water/day	12 weeks	Cocoa drink	SSR	a ↓ 25%	Heinrich et al. (2006)

Abbreviations: α-car, α-carotene; α-toc, α-tocopherol; asc, ascorbate; β-car, β-carotene; EGCG, epigallocatechin-3-gallate; GTP, green tea polyphenols; Lyc, Lycopene; CPD, cyclobutane pyrimidine dimer; MED, minimal erythema dose; MMP-1, matrix metalloproteinase-1 (marker of photoaging); mtDNA, mitochondrial DNA; OS, oral supplement; PG, prostaglandins; ROA, route of administration; SBC, sunburn cell (marker of apoptosis/DNA damage); SSR, solar-simulated radiation; UDS, unscheduled DNA synthesis (a measure of DNA damage). In some cases, erythema was measured by a reflectance device where units are given as a ↓ or Δa ↓ values. The latter is the difference between a test and a control site.

FIGURE 60.1 Structures of the major dietary carotenoids (a) lycopene and (b) β -carotene.

60.2.1.2.3 Side Effects

While β -carotene has significant photoprotective properties, for it to be marketed as an endogenous photoprotectant, it needs to be nontoxic at the recommended dose and over a long time period. However, two intervention trials have shown that β -carotene supplements given to individuals at a high risk for lung cancer increased their cumulative risk (Omenn et al., 1996; Alpha-Tocopherol Study, 1994; Goodman et al., 2004). Therefore, the use of β -carotene as an oral supplement may not be practical; further studies are required to determine the side effects of long-term use.

60.2.1.3 Lycopene

Lycopene is a major dietary carotenoid in tomatoes with the reddest strains having the highest levels; it is also present in apricots, guava, and watermelon (Stahl et al., 2006). Its bioavailability from tomato paste is greater than tomato juice or fresh tomatoes (Gartner et al., 1997). Of all the carotenoids, lycopene is the most efficient singlet oxygen quencher (Di et al., 1989).

The effectiveness of lycopene has been demonstrated (Stahl et al., 2001). Individuals who ingested 40 g of tomato paste (equivalent to 16 mg of lycopene) with 10 g of olive oil per day for 10 weeks had 40% less erythema exposure to a solar-simulated radiation (SSR) compared with controls who consumed olive oil only ($P = 0.02$). Individuals who consumed the test products with high lycopene content on a daily basis for 10–12 weeks had decreased skin erythema in response to UVR in comparison with the start of the study. These results have been confirmed in a more recent human study (Rizwan et al., 2010), which also found that oral lycopene could protect against UVR-induced dermal matrix metalloproteinase-1 (MMP-1) induction and mitochondrial DNA damage; the latter two endpoints have been implicated in photoaging. Overall, these data suggest that lycopene has potential as a photoprotecting agent.

60.2.1.4 Future Implications for Carotenoids

Should β -carotene's risks prove to be insignificant, sunscreen application and carotenoid supplementation could be used as complementary methods to provide photoprotection (Kopcke and Krutmann, 2008). The combination of carotenoid supplementation and topical sunscreens provides synergistic defense against UVR's damaging effects. β -Carotene intake would offer a complete, always present defense against UVR, while sunscreen would provide extra protection when the individual requires higher photoprotection requirements, such as while outdoors or on summer vacations.

Additionally, β -carotene should be combined with other oral antioxidants, thereby enabling lower β -carotene doses to be used and consequently decreasing the risk of β -carotene supplementation. A daily oral supplement consisting of β -carotene, lutein, and lycopene (8 mg each) efficiently reduces the degree of UVR-induced erythema at levels similar to those obtained with 24 mg daily β -carotene supplements (Heinrich et al., 2003).

60.2.2 Vitamin E (Tocopherols) and Vitamin C (Ascorbate)

The body already uses vitamins E and C for protection against UVR, making them ideal candidates for antioxidant supplementation (Pinnell, 2003). The main sources of dietary vitamin E are vegetable oils, cereal grains, green leaves, egg yolk, liver, milk fat, and nuts. Vitamin C is found in a wide variety of fruit and vegetables. Good sources include peppers, broccoli, Brussels sprouts, sweet potatoes, oranges and kiwi fruit.

60.2.2.1 Structures and Characteristics

Vitamin E is the generic name for a group of tocol and tocotrienol derivatives, that is, α -tocopherol. These compounds are lipophilic and present in cell membranes (Bendich and Machlin, 1988). Vitamin C is a water-soluble compound present in several tissues and is the most abundant antioxidant in the skin (Shindo et al., 1994). It acts as a cofactor in enzymatic reactions necessary for collagen synthesis; thereby, it helps in wound healing and maintenance of normal connective tissue. The structures for vitamin E and C are shown in Figure 60.2.

60.2.2.2 Photoprotective Properties

60.2.2.2.1 Oral Intake

High oral intake of α -tocopherol and ascorbate does not have serious side effects (Bendich and Machlin, 1988). One week of supplementation with 2000 mg/day of ascorbic acid and 1000–1200 IU/day of D- α -tocopherol reduced sunburn reaction (Eberlein-Konig et al., 1998; Mireles-Rocha et al., 2002). Oral combination therapy with a much lower dose of α -tocopherol and for a longer period— α -tocopherol (2 g/day) and ascorbate (3 g/day) for 50 days—also decreased the erythema produced from high doses of SSR (Fuchs and Kern, 1998). These studies resulted in an SPF of 1.4–2.

Several studies have determined that oral monotherapy with 400 IU α -tocopherol does not provide significant levels of photoprotection or affect the UVR-induced erythema response (Werninghaus et al., 1994; McArdle et al., 2004). However, minimal erythema dose (MED) was increased with 1200 IU α -tocopherol daily (Mireles-Rocha et al., 2002).

Numerous studies have illustrated that oral vitamin C supplementation does not have photoprotective properties (Fuchs and Kern, 1998; Mireles-Rocha et al., 2002; McArdle et al., 2002).

FIGURE 60.2 Structures of nonenzymatic antioxidants (a) α -tocopherol and (b) ascorbate.

60.2.2.2.2 Topical Application

Humans must obtain L-ascorbic acid from the diet. Since physiological mechanisms in the body restrict the amount of L-ascorbic acid that can be absorbed and transported to skin, topical L-ascorbic acid application is the sole method of further increasing skin concentrations (Pinnell, 2003). Vitamin E is appealing as a topical agent because its lipophilic nature enables easy absorption into skin.

Topical application of 2% vitamin E alone or 5% vitamin C alone 30 min before sun exposure provided modest or no inhibition of erythema, respectively (Dreher et al., 1998). However, topical application to swine skin of 15% L-ascorbic acid alone is photoprotective, as is 1% α -tocopherol (Lin et al., 2003). This suggests that topical application of vitamin C is not effective unless at high concentrations.

The combination of 15% L-ascorbic acid and 1% α -tocopherol over 4 days provides the best protection against erythema, and CPD in swine skin (Lin et al., 2003).

Because vitamins C and E are inherently unstable, modifications have been developed to increase their stability and effects. The addition of 0.5% ferulic acid, a potent antioxidant, to 1% α -tocopherol and 15% L-ascorbic acid was shown to improve the vitamins' stability and photoprotective properties (Murray et al., 2008). This combination reduced erythema, sunburn cells (SBC; apoptosis), and CPD as well as proinflammatory and immunosuppressive cytokines.

60.2.2.3 Mechanism of Action

Ascorbate scavenges ROS and protects the skin by neutralizing the superoxide radical anion, hydrogen peroxide, the hydroxyl radical, and singlet oxygen. Vitamin E inhibits oxidative damage to lipids and scavenges lipid peroxyl radicals. In the process, α -tocopherol is oxidized to the tocopheroxyl radical such that combination therapy is effective and synergistic because ascorbate regenerates α -tocopherol from its radical form (Packer et al., 1979; Fuchs and Kern, 1998).

60.2.2.4 Future Implications for Vitamins E and C

60.2.2.4.1 Oral Supplementation

The prevalence of melanoma has been found to be inversely correlated with serum α -tocopherol levels (Knekt, 1992). Additionally, individuals with basal cell carcinoma (BCC) have significantly lower ascorbic acid and α -tocopherol plasma levels (Vural et al., 1999). It has been suggested that regular consumption of supplemental vitamins, especially vitamins C and E, reduces the risk of BCC (Wei et al., 1994). Thus, systemic photoprotection with combination therapy may be a convenient adjunct to sunscreens in improving photoprotection.

60.2.2.4.2 Topical Application

Using a topical mixture containing vitamins E and C in addition to using sunscreen may provide effective protection against the adverse effects of UVR (Lin et al., 2003). In swine skin, combination therapy added to a UVA sunscreen (oxybenzone) provided greater than additive levels of photoprotection (Darr et al., 1996). Combining both antioxidants with ferulic acid and a broad-spectrum sunscreen is hypothesized to provide the most substantial photoprotection (Lin et al., 2005).

60.2.3 Polyphenols

Tea polyphenols are more potent than vitamins C and E (Pinnell, 2003). They are also the most common dietary antioxidants with intake as much as 1 g/day. They are found in tea, coffee, red wine, fruit juice, vegetables, cereals, chocolate, and dry legumes (Scalbert et al., 2005).

60.2.3.1 Structures and Classification

There are thousands of plant-derived molecules with the polyphenol structure; hydroxyl groups on aromatic rings (Manach et al., 2004). Based on their number of phenol groups, they are divided into

FIGURE 60.3 Structure of flavanols.

subgroups. The flavanoid subgroup has a structure of two aromatic rings united by three carbon atoms, which make up a heterocycle. Depending on the type of heterocycle in the structure, the flavonoids are further divided into different subclasses: flavonols, flavones, isoflavones, flavanones, anthocyanidins, and flavanols. The latter exist as monomers (catechins) and polymers (proanthocyanidins). Their structures are shown in Figure 60.3. While flavanols are abundant in numerous fruits and vegetables, the richest sources are green tea (GT) and chocolate.

60.2.3.2 Green Tea

GT produced through fermentation of fresh tea leaves, is one of the most commonly consumed drinks worldwide. The leaves of *Camellia sinensis* are fermented to produce GT such that the plant's polyphenols are not oxidized or polymerized (Yusuf et al., 2007). The chief polyphenols in GT are (–)-epicatechin (EC), (–)-epicatechin-3-gallate (ECG), (–)-epigallocatechin (EGC), and (–)-epigallocatechin-3-gallate (EGCG), as shown in Figure 60.4.

60.2.3.2.1 Photoprotective Properties

60.2.3.2.1.1 Oral Intake Chronic oral intake of green tea polyphenols (GTPs) (0.1%, w/v) significantly protects against developing UVR-induced skin cancer in mice in comparison with controls drinking normal water ($P < 0.01$) (Wang et al., 1991). This group also showed that treating mice with GT for 4–10 weeks caused partial regression or greater than 90% inhibition of growth of established skin papillomas,

FIGURE 60.4 Structures of major polyphenols in GT (a) (–)-EC, (b) (–)-ECG, (c) (–)-EGC, and (d) (–)-EGCG.

and complete regression in 4% (Wang et al., 1992b). Further studies showed that a 1.25% GT extract as the only source of drinking water 10 days before and during UVB radiation, and for 7 days after, inhibited photocarcinogenesis (Wang et al., 1992a). Another study showed that GTPs in the drinking water (2 g/L) of mice decreased UVB-induced tumor incidence (35%), multiplicity (63%), and growth (55%) (Mantena et al., 2005). Furthermore, the intensity and area of red sunburn lesions in mice were decreased dose dependently with brewed GT consumption (at concentrations similar to human intake: 1.25% or 2.5%) for 2 weeks before and during UVB radiation (Wang et al., 1992a).

In humans, GT intake provided photoprotection: following exposure to 12 min of UVA radiation, peripheral blood cells taken after consumption of three cups of GT (totaling 540 mL) had less DNA damage (assessed by comet assay) in comparison with those taken before consumption (Morley et al., 2005). It has been suggested that drinking 5–6 cups (1 cup = 150 mL) of GT (1 g GT leaves/150 mL) daily may provide significant photoprotection (Mantena et al., 2005).

60.2.3.2.1.2 Topical Application

Tumor Formation, DNA Photodamage, and Apoptosis

Topical GTP application protected mice from UVB-induced tumors (Wang et al., 1991), as did EGCG in hydrophilic cream, which reduced tumor incidence (60%), multiplicity (86%), and growth (95%) ($P < 0.001$) (Mittal et al., 2003). In mice, topical application of GTPs in hydrophilic cream also prevented UVB-induced depletion of glutathione peroxidase, catalase, and glutathione (Vayalil et al., 2003).

Topical GTP application to human skin *in vivo* significantly inhibited CPD after UVR exposure (Katiyar et al., 2000; Elmetts et al., 2001). Protection against DNA photodamage has also been demonstrated *in vitro*. Preincubation of human skin fibroblasts with 250 μ M EGCG significantly reduced DNA damage, assessed by the comet assay, after UVR exposure (Morley et al., 2005). In addition, EGCG treatment to the human keratinocyte line (HaCaT) decreased UVA-induced single-strand DNA breaks assessed by the comet assay (Tobi et al., 2002). DNA damage is a trigger for apoptosis, observed as SBCs in the epidermis. Topical GTP application decreased SBC by 66% (Elmetts et al., 2001). This was most effective when applied immediately before UVR but protection was still observed with application 4 h before UVR.

Lipid Peroxidation/Oxidative Stress

Application of EGCG (~ 1 mg/cm²) to human skin before four MED inhibits UVR-induced oxidative stress, with decreased production of hydrogen peroxide, nitric oxide, epidermal lipid peroxidation, and inflammatory leukocyte infiltration (Katiyar et al., 2001). The latter may be due to the ability of EGCG to inhibit signaling pathways triggered by oxidative stress (Baliga and Katiyar, 2006). EGCG pretreatment also protected glutathione peroxidase and Langerhans cells in human skin (Elmetts et al., 2001; Katiyar et al., 2001). The inhibition of the different adverse effects may inhibit photocarcinogenesis and photoaging (Baliga and Katiyar, 2006).

Erythema

Preapplication of GTPs to human skin (3 mg/2.5 cm²) decreases UVB-induced erythema (Katiyar et al., 1999). In another study, skin treated with 0.2 mL GTP (concentrations ranging 1%–10%) immediately before UVR exposure dose dependently decreased the erythema response. A 10% solution provided nearly total protection at 48 and 72 h, while a 2.5% solution afforded excellent protection; even a 0.5% solution significantly protected some individuals from sunburn ($P < 0.01$). The polyphenols EGCG and ECG were much more effective than EGC and EC at inhibiting erythema (Elmetts et al., 2001).

60.2.3.2.1.3 Oral vs. Topical Treatment

GTPs provide greater photoprotection when administered topically than orally, possibly because this allows for greater bioavailability, penetration, and absorption into skin (Vayalil et al., 2003). Despite this, oral GTPs' photoprotective effects are significant, and perhaps more relevant because GT is a popular drink (Mantena et al., 2005).

60.2.3.2.2 Modes of Action of the GTPs

Of the GTPs, EGCG is the most potent in preventing photocarcinogenesis in mouse. *In vitro* and *in vivo* experiments show that GTPs or EGCG are photoprotective via several mechanisms: GTP induces the immunoregulatory cytokine interleukin (IL)-12, inhibits UVR-induced immunosuppression and angiogenesis that supports tumor growth and metastasis, and promotes apoptosis of carcinogenic cells. Through these mechanisms, GTP therapy may prevent tumors and cause regression of existing tumors (Mantena et al., 2005; Katiyar et al., 2007).

60.2.3.3 Cocoa

The effect of regular consumption of cocoa containing high levels of the flavanol monomers epicatechin and catechin on human photoprotection has been studied. By the 12th week, those who drank the high flavanol drink had 25% less UVR-induced erythema after skin exposure to 1.25 MED compared with when they had begun the study (Heinrich et al., 2006). Another study found that better photoprotection was provided with consumption of high flavanol content chocolate in comparison with conventional dark chocolate (Williams et al., 2009). Both studies concluded that dietary flavanols increased endogenous photoprotection.

60.2.3.4 Future Implications for Polyphenols

Polyphenols in GT and cocoa/chocolate are ideal supplements because of their numerous photoprotective properties and because they are more pharmacologically safe, nontoxic, and easily obtained. For these reasons, the food and nutrition supplement companies have recently increased interest in promoting and producing polyphenol-rich products.

In addition to oral supplementation, GTP supplementation to sunscreens and skin care products is another strategy for reducing photocarcinogenesis and various skin disorders. In contrast to sunscreens, GTPs do not absorb UVR. Therefore, their addition to sunscreens should provide a synergistic photoprotection, stronger than the application of GTPs or sunscreens alone. Consequently, several companies have begun including *C. sinensis* plant extracts in their skin care products. GTPs may also be beneficial for individuals with sunscreen allergies or intolerance.

Clinical trials are required to determine the effectiveness of GTPs, both alone and in combination therapy, in preventing skin damage and cancer in high-risk individuals. Using GTPs should not be the only method of preventing photodamage but may be an effective adjunct to current strategies.

60.3 Conclusions

There is evidence that natural antioxidant defenses in humans can be enhanced by oral and topical supplementation. Table 60.1 shows that all studies have used erythema as an endpoint. It would be difficult to conclude a long-term benefit from these studies, and it is clear that more sophisticated techniques should be developed to assess long-term protection. Some groups have started to do this (Rizwan et al., 2010). The SPF provided by dietary and topical antioxidants is very much less than that provided by sunscreens, typically less than 2.

Many of the studies listed in Table 60.1 have used “SSR”; however, few authors have defined their UVR emission spectra, and it is quite likely that many sources, whether “SSR” or not, contained nonsolar UVR. This is important because some antioxidants, for example, vitamin E, absorb in the nonsolar and solar UVB range, which makes it impossible to exclude a small sunscreensing effect (bearing in mind that photoprotection is typically very modest). This is an aspect that is often neglected by authors but has been considered in the case of GT polyphenols (Elmets et al., 2001), which do not absorb in the UVB range.

In general, oral route studies have required several weeks of daily intervention. While this may demonstrate a point of principle, it is unlikely to be of great use in practice where compliance is less likely. Nonetheless, it can be argued that systemic administration enhances photoprotection when sunscreens are not being worn. The topical route seems much more promising for the development of new intelligent

photoprotection strategies. Some studies have shown antioxidant protection against CPD (in particular thymine dimers). This is perhaps surprising because it is widely believed that CPD induced by solar UVR is formed by direct UVR absorption of UVB. However, there is some debate about the role of direct absorption or photosensitization reactions in the formation of UVA-induced CPD (Mouret et al., 2010).

61.1 Introduction

The term electromagnetic spectrum is used to encompass a broad range of radiation, from cosmic rays to radiowaves. Each type of radiation is made up of a range of wavelengths, and each wavelength comprises photons. Ultraviolet (UV) radiation, visible light, and infrared are specific terms for separate wavelength ranges within the electromagnetic spectrum and have been defined by Commission Internationale de l'Eclerage (CIE). In order to discuss the in vivo effects of radiation, it is necessary to understand one of the first principles of photobiology, that is, in order to have biological effect, a photon must be absorbed by a molecule termed “a chromophore” (Figure 61.1). Each chromophore has an individual absorption profile. The in vivo effects of radiation, or the “biological efficacy,” depend on which wavelength is absorbed. This “action spectrum” has been defined for a number of different endpoints,

FIGURE 61.1 Absorption profile of chromophores in the skin. (a) oxyhaemoglobin, (b) melanin, (c) protoporphyrin IX, (d) bilirubin, and (e) riboflavin.

FIGURE 61.2 Action spectrum for erythema (continuous line) and photocarcinogenesis (broken line)—Commission Internationale de l'Eclairage (CIE).

which include erythema, thymine dimer formation, and skin cancers (Figure 61.2). UV radiation has both acute and chronic effects on the skin, the eye, and the immune system.

61.2 UV Radiation

The wavelengths of UV radiation can be subcategorized into UVC, UVB, UVA, and CIE has given definition to these wavelengths: UVC radiation includes wavelengths of less than 280 nm, UVB between 280 and 315 nm, and UVA ranging between 315 and 400 nm [1]. UVA can further be subdivided into UVA-1 (340–400 nm) and UVA-2 (315–340 nm). The difference between UVA-1 and UVA-2 being that

the shorter UVA wavelengths have been shown to have more photobiological activity, and therefore, UVA-2 and UVB are more closely related and exert a similar biological effect. Environmental factors can have a significant effect on solar UV exposure. Terrestrial UVR is derived from the sun and is scattered, reflected, or absorbed in the medium through which it travels. One's behavior, location (latitude and altitude), time of day, and the season all have an impact on the amount of ambient UV exposure to an individual [2]. It has been shown that a close proximity to the equator, a higher altitude, and the summer season all increase exposure to UV, as UVR is absorbed by the earth's atmosphere. Therefore, when the angle of the sun is high, the distance UVR travels through the earth's atmosphere is shortest, resulting in less UVR absorption. Conversely, when the angle of the sun is low, UVR travels a greater distance through the earth's atmosphere, and greater UVR is absorbed. White surfaces and rippling water reflect UVR in the earth's atmosphere, resulting in scatter. When the sky is blue, up to 50% of UV incident on the skin derives from scatter UVR. Thus, in light shade, a very significant amount of UVR may be received.

61.3 UV Effects on the Skin

UV radiation exerts its effects on the skin in one of two ways, either through direct DNA damage or indirectly through free radical formation. Epidermal DNA seems to be the most important chromophore in the skin resulting in inflammation, DNA photoproducts, and immunosuppression. DNA is only one of several endogenous chromophores that absorbs UV. Other chromophores include urocanic acid, melanin, protoporphyrins, and bilirubin. UVB and UVA act by forming pyrimidine dimers in DNA which, if not repaired, result in negative cutaneous effects that will be later discussed. There are also well-understood immunosuppressive effects due to UV, but is probably best to divide the effects of UVR, as well as those effects of visible light and infrared into acute and chronic photodamage.

61.4 Acute Effects on Normal Skin

Acute photoeffects broadly encompass inflammation and erythema, tanning, skin hyperplasia, immunosuppression, and vitamin D production. There are also acute abnormal photoeffects; namely the photodermatoses and phototoxic effects of drugs. The photodermatoses are skin conditions due to an abnormal immune-mediated response to UV radiation. This includes conditions such as polymorphous (polymorphic) light eruption (PLE), solar urticaria, actinic prurigo, chronic actinic dermatitis, and hydroa vacciniforme. Numerous other skin conditions, including atopic eczema, lupus erythematosus, rosacea, and bullous pemphigoid, can be aggravated by UV radiation [3]. Endogenous chemicals, the porphyrins, are also potent photosensitizers. In defects of porphyrin metabolism, that is, porphyrias, build up of excessive porphyrin products can result in cutaneous photosensitizing effects. Drugs can act as exogenous potent photosensitizers, such as seen with amiodarone and its hyperpigmentation effects [4]. Psoralens, a plant-derived photosensitizing agent, are frequently used in a therapeutic setting in combination with UVA to treat a variety of UV-sensitive skin conditions. The list of photosensitizing agents is extensive and will probably continue to grow.

61.5 Inflammation and Erythema

It has already been mentioned that DNA is a major chromophore for UVR. DNA damage occurs directly as a result of the effects of UVB and UVA [5] leading to cytokine production, inflammatory cell infiltration, and the release of inflammatory mediators such as interleukin-1 (IL-1) and tumor necrosis factor-alpha (TNF- α) from keratinocytes. The release of these cytokines results in the generation of reactive oxygen species (ROS), prostaglandins, and inflammatory mediators [6].

Studies carried out *in vivo* have demonstrated that ROS also develop secondary to UVB and UVA exposure [7]. Endogenous photosensitizers respond to both UVB and UVA and then react to form ROS such as superoxide anion radicals. The effects of UVA (particularly UVA-1) are mainly oxygen dependent but UVA (particularly UVA-2) also has the capacity to cause DNA photoproducts directly.

The CIE erythema action spectrum indicates that most sunburn is UVB induced as UVB is biologically 1000-fold more active than UVA. Erythema develops clinically as a result of inflammation causing vessel dilatation. UVA and visible light may also cause erythema [8]. The minimum dose of radiation to induce erythema is known as the minimal erythema dose (MED). The MED varies by wavelength, with shorter wavelengths being more biologically active [9]. The development of UVB-induced erythema has a delayed onset occurring hours (peaking at 24 h) and lasting up to days after the initial insult. The effects of this can be widely variable ranging from mild reddening of the skin to severe blistering. The histology of UVB erythema has been clearly delineated [10], with the molecular basis of UV-induced effects on human skin, *in vivo*, also being well described [11]. Apoptosis is an error free method of eliminating UV-induced DNA damage and will be discussed further in relation to its role in skin cancer.

61.6 Tanning

Tanning is triggered by DNA damage, which occurs as a response to UV radiation. It appears that not only are DNA photoproducts catalysts for tanning but formed DNA repair products, specifically the excised DNA fragments, so-called oligomers, are also able to induce tanning [12]. Endogenous pigmentation is a protective mechanism against skin cancer. The tanning response is an adaptive mechanism [13]. Tanning can be classified as immediate, persistent, and delayed [14]. Immediate tanning is of a rapid onset and has a short duration lasting only a few hours while persistent tanning is up to 24 h in duration [15]. Both immediate pigment darkening and persistent pigment darkening occur as a result of the oxidation and redistribution of preexisting melanin [14]. Both are the result of UVA exposure. Delayed tanning is mostly due to UVB, but UVA is also responsible to a lesser extent [16]. It occurs as a result of increased melanin synthesis and a redistribution of melanin in similar melanosomes [17]. Delayed tanning does not occur in the absence of DNA damage [12].

61.7 Skin Hyperplasia

Hyperplasia, much like tanning, occurs as a protective response mechanism to UV radiation. Hyperplasia of the epidermis leads to thickening of the stratum corneum layer, following UVB and UVC exposure. This happens due to an increase in cellular mitoses and occurs up to days to weeks after exposure. UVB induces transforming growth factor alpha production, which in turn leads to epidermal hyperplasia [18].

61.8 Immunosuppression

UV radiation is well known to be a potent immunosuppressant. Margaret Kripke demonstrated this phenomenon in a series of seminal experiments in mice. Kripke transplanted UV-induced tumors into the skin of mice that were either exposed to UV radiation or not. The tumors in the mice that were exposed to UVR continued to grow, and the tumors in the mice that were not exposed were rejected by the host. She also demonstrated that immunosuppression could also be transferred from the lymphocytes of irradiated mice into the nonirradiated mice by injection [19].

The mechanism of UV-induced immunosuppression is complex. One mechanism is the action of UVR on Langerhans cells. These Langerhans cells are both phagocytic and dendritic cells and specifically function as antigen-presenting cells (APCs) that play a role in the immune system. UV radiation has been demonstrated to deplete Langerhans cells, even at low doses [20]. There is a definite genetic

basis to this that determines the ability of UV radiation to deplete Langerhans cells, as this can be demonstrated in patients with the photodermatosis, PLE, who are genetically able to resist UV-induced Langerhan cell depletion [21].

The second major effect is on urocanic acid [22]. Urocanic acid is another major chromophore for UV within the stratum corneum where it is produced. The interaction of UVB induces isomerization of urocanic acid from a *trans* to *cis* formation, and this *cis*-isomer has a potent systemic immunosuppressant effect.

61.9 Vitamin D Production

The skin is a major source of vitamin D, which to a lesser extent can be derived from the diet [23]. The direct effects of specific UVB wavelengths on 7-dehydrocholesterol lead to cholecalciferol, or vitamin D3. This in turn is metabolized by both the liver and kidneys to its active form, 1 α -hydroxyvitamin D. Vitamin D3 is more potent than the dietary form of vitamin D, ergocalciferol, and vitamin D2 [24]. Very little exposure to UVB leads to vitamin D formation—10 min seems sufficient as daily exposure for white skin [25].

61.10 Chronic Effects

61.10.1 Photoaging

The process of photoaging should be clearly distinguished from chronological aging. Photoaging refers to progressive degradation of the skin due to prolonged or repetitious UV exposure. Photoaging is superimposed on a background of natural degenerative skin changes, or chronological aging [26–28]. The extent and depth of UV penetration depend on the active wavelength, and both the epidermis and dermis are affected. UVA has longer wavelengths that penetrate deeply into the dermis and is most credited with photoaging [8]. UVA is also prevalent all year and for most of the day. Despite this, both UVB and UVA contribute to the effects, resulting in the degeneration of elastic tissue and the degradation of collagen. Collagen is a significant structural protein found in the dermis, by matrix metalloproteinases which are induced by the effects of UV radiation [29]. This manifests itself cutaneously with skin dryness, loss of tensile strength, wrinkles, skin laxity, as well as blotchy hyper and hypopigmentation and pseudoscarring [30–32].

61.10.2 Skin Carcinogenesis

UV radiation is a known cutaneous carcinogen. UV radiation when absorbed by DNA results in the formation of cyclobutane pyrimidine dimers [33]. There are several intrinsic repair mechanisms within the skin to combat UV-induced DNA damage. The primary intrinsic repair mechanism of the skin whereby DNA is uncoiled, the damaged DNA (a cross-linked thymine dimer) is excised, and the DNA is reinstated into its original shape [34]. This excision repair mechanism, known as nucleotide excision repair, is essential to maintain the integrity of the DNA helix. Without this, mutations within DNA occur, and errors in transcription of DNA result. Accumulation of mutations in damaged DNA ultimately results in carcinogenesis [35]. UVB is more effective at inducing carcinogenesis than UVA. UVA has also been shown to produce similar effects and has been shown to contribute between 10% and 20% of sunlight-induced carcinogenesis [36,37]. The effect of repeated exposures to both UVA-1 and visible light has also been studied and shown to increase the number of p53-positive cells, but this is only true to a lesser extent when referring to visible light [38]. The World Health Organization (WHO) has declared all UVR to be a Class I carcinogen [39]. Apoptosis, or programmed cell death, of heavily DNA-damaged cells is another protective mechanism against skin cancer [40]. This involves a complex cell signaling cascade that is most importantly regulated by p53 (referred to as the “guardian of the genome”) and the caspase system. UV radiation has a dual effect

on the work of p53. UV radiation induces p53, which enables cell cycle arrest in the S1 phase and DNA repair occurs. Concomitantly, UV radiation also induces the MDM2 protein that paradoxically inhibits the function of p53 [11]. UV radiation also leads to mutations of p53 leading to alteration of its function from a tumor suppressor gene to a tumor-promoting protein, or oncogene.

61.11 Visible Light and Infrared

The range of visible light is from 400 to 800 nm; hence, visible light lies between UVA-1 and infrared radiation on the electromagnetic spectrum. Visible light has acute and chronic effects on the skin and eyes [41,42]. This is clinically relevant as visible light has been implicated in the pathogenesis of some diseases but has also been exploited therapeutically in the treatment of skin disease. Visible light is recognized to be responsible for adverse effects in several photodermatoses, including chronic actinic dermatitis, solar urticaria, porphyria, and pseudoporphyria. Conversely, visible light has a therapeutic role and is used in the treatment of actinic keratosis, Bowen's disease, and superficial forms of basal cell carcinomas when used in photodynamic therapy (PDT). PDT uses a chromophore derived from the heme biosynthetic pathway—protoporphyrin IX. Lasers utilize many wavelengths to produce very specific effects depending on the chromophore targeted (i.e., port wine stains—pulsed dye laser, ruby laser—pigmentation).

Infrared radiation has many effects on the skin [43]. A link between infrared radiation (heat, wavelength >800 nm) and carcinogenesis has also been demonstrated previously both in experiments and epidemiological models [44–46]. In recent years, this has been highlighted with particular significance in the context of climate change and ozone depletion. Both ozone depletion and the rising ambient temperature have been demonstrated to be linked to an increased risk of skin carcinogenesis [47].

61.12 Acute and Chronic Effects of Visible Light and Infrared Radiation

Visible light has a role in the development of erythemas and inflammation. Visible light has been shown to result in free radical formation [48]. Although we have described that most erythemas is due to UVR exposure, visible light can also produce vascular dilatation resulting in erythema within the deep dermis [8]. In a study by Porges et al., visible light was demonstrated to have effects of immediate tanning as well as delayed tanning [49]. The effect of repeated exposures to visible light has also been studied and shown to increase the number of p53-positive cells, but this is only true to a lesser extent when referring to visible light [38].

61.13 Effect of UVR and Visible Light on the Eye

Similar to the skin, ocular tissue is extremely sensitive and is also vulnerable to the effects of UV and visible light. The three main structures vulnerable to UV radiation and visible light are the cornea, lens, and the retina [50]. As with skin, the depth of penetration within the eye is dependent on the wavelength. The cornea transmits wavelengths only above 295 nm, with the anterior ocular structures of the eye absorbing most UV radiation. This limitation of transmission by the cornea means that in the adult eye, less than 1% UVR reaches the retina [50]. It is therefore the longer wavelengths of UV (>295 nm) that penetrates deeply into the eye reaching the lens [51]. Similarly, the longer wavelengths of visible light and infrared can also penetrate the retina [52].

61.14 Acute Ocular Effects

In terms of ocular exposure to UV, ground reflection is the major determinant of UVR exposure. Highly reflective ground surfaces include snow, while sand is moderately reflective and grass is of very low reflectance [53]. Rippling water acts as a mirror, reflecting the sun and skylight directly onto the cornea.

Both UVB and UVA play an important role in acute ocular effects. Epidemiologically, UVB has been shown to play a role in acute ocular damage [54]. The lens, as mentioned earlier, is exposed to significantly more UVA than UVB, although the effects of UVA on DNA damage are much less than that of UVB [50].

Photokeratitis describes the acute response of the cornea to UV radiation, with direct involvement of the corneal keratinocytes within the epithelium. It is also known as “snow blindness,” “arc eye,” or “welders flash.” Symptoms of photokeratitis include gritty eyes, photophobia, and tearing. The onset of this is usually several hours after exposure but the cornea is able to reestablish itself and symptoms resolve within 48–72 h [55]. Both the angle of reflection and the highly reflective surface of snow explain why photokeratitis has such a high incidence of occurrence in skiers. Other acute responses of the cornea to UVR include transient haze, swelling, and corneal opacification [55]. The retina is relatively well protected from the effects of UVR, as most of it is filtered out by the lens, but acute injury from visible light can result in retinal burns. This usually occurs in the context of staring at the sun during an eclipse where macular burns may be sustained and even blindness may occur.

61.15 Chronic Ocular Effects

Chronic ocular effects include cataracts, pterygium, age-related macular degeneration (AMD), and pinguecula. The incidence of cataract and pterygium is much more prevalent at latitudes with greater UVB exposure [50]. Cortical cataract formation has been shown to be associated with UV radiation, particularly with exposure to UVB [54]. Visible light has not been shown to have this same association [42]. Structures like the cornea and conjunctiva are particularly vulnerable to direct UVR exposure due to their prominent anterior location.

Pterygium is another corneal response to chronic UVR exposure, and epidemiological studies have demonstrated a strong causal relationship linking pterygium to UVR [55–60]. In pterygium, there is formation of a fibrovascular tissue sheet that invades the corneal tissue. As pterygium is a disorder that is associated with sun exposure, it occurs commonly in tropical regions receiving more sun exposure. It has been linked to both UVB [57–60] and UVA [61,62], and strong associations between cumulative UVR exposure and the development of pterygium have also been shown [42]. Exposure to short-wavelength visible light, or blue light, has also been demonstrated to carry an increased risk in development of pterygium [42].

The development of other corneal disorders including climatic droplet keratopathy (CDK) is associated with both visible light (blue light) and UVR [42,59,63–65]. CDK is associated with intense climate conditions (i.e., Arctic). The prevalence of CDK also increases with age, similar to that of pterygium. Other corneal disorders worth mentioning include pinguecula and AMD. The development of pinguecula, a mass growing on the conjunctival surface adjacent to the cornea, is associated with UVR [60] but its association with UVR is much weaker than with pterygium. Taylor et al. found a strong association with the incidence of AMD and blue light or visible light exposure [42]. However, the causal relationship between AMD and both visible light and UVR remains a contentious issue. Acute intense light can cause macular damage, even blindness.

Ocular and periocular carcinomas have been associated with chronic UVR exposure. This includes an association between squamous cell carcinoma (SCC) of the eye, of both cornea and conjunctival surfaces, and UVR exists [55,56]. In addition to an association with SCC, basal cell carcinoma of the eyelid has also been demonstrated [66,67].

61.16 Photoprotection

The negative effects of UV radiation are clearly widespread and involve not only the skin but also the immune system and ocular tissue. The development of sunscreens has afforded protection against UV radiation, mostly against UVB, but the newer broad coverage sunscreens are also now affording

coverage against UVA. Sunscreens reflect or absorb UV radiation. However, the critical factor that affects how well a sunscreen works is the amount of sunscreen applied, the frequency of applying sunscreens, and the evenness of the application. It has been well demonstrated that most people who do not apply sufficiently meet these criteria [68].

Additional sun protection is afforded through the use of sunglasses and protective clothing. Sunglasses should be chosen to provide adequate protection against UV transmission to ocular structures while permitting normal vision [52]. European Standards have been formulated to act as guidelines in this [69]. The use of protective clothing, such as a brimmed hat, can provide additional ocular protection as well as protection to the scalp and ears, and to a lesser extent, the face and neck [70]. Clothing can be an excellent protectant against UVR. The UV protection factor (UPF) has been developed to provide guidelines to choose UV protective clothing. Fabric, thickness, weave, color, and composition all critically affect the amount of UV protection afforded by clothing [71–73]. Wet fabric can have a variable effect on the UPF of clothing [74,75]. The correct choice in clothing, hat, and sunglasses is crucial in providing optimal protection against UVR and its many consequences.

62.1 Introduction

Phototherapy is the use of nonionizing [ultraviolet (UV), visible, or infrared], electromagnetic radiation in the treatment of skin diseases. In dermatology, phototherapy commonly refers to UV phototherapy. Its goal is to suppress ongoing disease processes via the prevention, modulation, or abrogation of pathogenic mechanisms that cause the disease itself [1].

Natural UV from sunlight (heliotherapy) has been employed in the treatment of several dermatoses in Egypt and India since 2000–1200 B.C. In the present chapter, we will concentrate on clinical applications of artificial radiation sources. The carbon arc lamp was used as first man-made therapeutic UV source from the mid-1800s. At the beginning of the twentieth century, medium- and high-pressure mercury arc lamps became available. A variety of metal halides added to these mercury lamps improved their emission in certain regions of the UV and visible spectra. Fluorescent lamps became available in the late 1940s and, since then, multiple phosphors and envelope materials have been used to produce lamps with modified emission spectra in the UV region [2]. Finally, in the mid-1970s, the combination of artificial UVA (320–400 nm) radiation with psoralens (PUVA; photochemotherapy) was introduced into clinical practice [3,4]. In the following decades, phototherapies including photochemotherapy have been used at a constantly increasing rate in the management of multiple skin diseases and are an essential part of today's dermatologic therapeutic armamentarium. At the same time, advances in photoimmunology and molecular biology have improved our knowledge of many actions of UV radiation on the skin, although many aspects still remain to be clarified.

62.2 Light Sources and Dosimetry

Artificial light sources for phototherapy are characterized by three primary properties:

1. Irradiance is a radiometry term for the power per unit area of the total amount of electromagnetic radiation incident on a surface. The relevant SI unit is Watt per square meter ($\text{W} \cdot \text{m}^{-2}$) but in clinical practice $\text{mW} \cdot \text{cm}^{-2}$ is often used. The light dose is the irradiance multiplied by the application time, measured in $\text{J} \cdot \text{m}^{-2}$ (Joule = $\text{W} \cdot \text{s}$) or $\text{mJ} \cdot \text{cm}^{-2}$.
2. The emission spectrum, the plot of irradiance at each wavelength is measured in $\text{W} \cdot \text{m}^{-2} \cdot \text{nm}^{-1}$.
3. The 3D distribution of the emission field. Variations of light intensity at the skin level are caused by variations in the output along vertical and horizontal axes of the lamps as well as by their arrangement in the irradiation units.

Two main groups of radiation sources are used in phototherapy today: metal halide lamps and fluorescent lamps that emit variable proportions of UVA and UVB (290–320 nm) wavebands. The former contain mercury vapor at high or medium pressure within a quartz envelope. They have a high output throughout the whole UV spectrum, and the emission is confined to the desired range by suitable optical filters. Fluorescent tubes contain mercury vapor at low pressure, and the emission spectrum is modified by the inner phosphor coating of a thin glass tube.

Broadband UVB (BB-UVB; UV21) fluorescent lamps have a broad spectral emission (10%–20% of the total output) in the UVB range and some emission below 290 nm (i.e., within the UVC waveband). BB fluorescent UVB lamps with relatively little UVC emission (UV6) are available. Narrowband (NB) UVB lamps have more than 80% of the output concentrated in a narrow emission peak around 312 nm and only 0.1% below 290 nm. UVA sources for PUVA therapy have 98%–99% of the UV emission in the UVA waveband. For UVA-1 phototherapy, the high intensity emission of high-pressure metal halide lamps is strictly confined to the 340–400 nm range by special glass filters.

Recently, XeCl excimer lasers have become available for dermatological phototherapy. In such laser, a pseudo-molecule called an excimer is created, which can only exist in an energized state. Upon relaxation, monochromatic radiation at 308 nm is emitted, typically in 60 ns micropulses at a 200 Hz rate. Pulse trains (macropulses) deliver a fluence of 3–4 $\text{mJ} \cdot \text{cm}^{-2}$. The spot size is maximally 3.2 cm^2 . Excimer lamps with a continuous emission at 308 nm at high energy are available at lower cost and offer the clinical advantage of a larger field of irradiation, but they are not monochromatic.

Careful dosimetry is essential to ensure efficacy and safety of phototherapy, because relatively small variations in the photophysical parameters may cause major changes in the biological activity. Irradiance in a given spectral range, for example, UVA or UVB, can be measured with inexpensive, practical BB dosimeters. However, their response spectrum must match the emission spectrum of the UV source and should be calibrated annually with a spectroradiometer, measuring the UV emission at 1–5 nm intervals.

62.3 BB- and NB-UVB Phototherapies

62.3.1 Action Mechanisms

Therapeutic effects of UVB phototherapy are caused by a cascade of biological events that begins with the absorption of a photon by an endogenous chromophore. The biologically most relevant target is DNA. Excited nucleotides give rise to various DNA photoproducts, notably cyclobutane-type pyrimidine dimers and (6-4) adducts. The amount of photoproducts is directly related to a decrease in synthesis of DNA, RNA, and proteins [5]. Oxidative damage to DNA (8-hydroxy-2'-deoxyguanosine) as well as to cellular membranes and surface receptors leads to activation of intracellular signaling pathways that contribute to the biological response. These effects are seen in all exposed cell populations. Until relatively recently, it was believed that UVB phototherapy improves hyperproliferative diseases,

such as psoriasis, mainly by interfering with keratinocyte proliferation and by inducing apoptosis. This assumption has been challenged by experimental evidence focusing on UVB effects on T lymphocytes [6]. Indeed, *in vitro*, UVB is antiproliferative and cytotoxic toward both T cells and keratinocytes, but T cells are 10 times more sensitive [1]. If UVB-induced DNA lesions are not repaired, C → T and CC → TT transitions can occur that are characteristic for UV exposure (“UVB signatures”). These DNA mutations may occur in biologically relevant genes such as tumor suppressor genes or oncogenes and thus represent initial events of the multistep UV carcinogenesis in keratinocytes and Merkel cells, whereas UV-induced cancers of other cutaneous cell populations have not been reported so far [7].

The depletion of the skin-resident T-cell population may be due to a combination of UVB-induced apoptosis (via direct activation of death receptor and upregulation of its ligand, CD95L on the keratinocytes) [1] and decreased recruitment from the circulation due to reduced expression of adhesion and homing molecules [6]. UVB upregulates transcription and release of anti-inflammatory interleukins (IL-3, IL-4, IL-6, IL-10, and IL-20), granulocyte macrophage colony-stimulating factor (GM-CSF), transforming growth factor-beta (TGF-β), nervegrowth factor (NGF), pro-opiomelanocortin (POMC), alpha-melanocyte stimulating hormone (α-MSH), and prostaglandins (PG)E₂ and PGF_{2α}. UVB suppresses the Th1 (pro-inflammatory) axis as defined by IL-12, interferon (IFN)-γ, and IL-8, and other proinflammatory cytokines, that is, IL-1β, IL-2, IL-5, and tumor necrosis factor-α (TNF-α) [1,8,9]. The number and activity of Langerhans cells (LHC) and dendritic cells are downregulated [1,9]. In addition, the reduced expression by LHC of costimulatory molecules, such as CD86 and intercellular adhesion molecule-1 (ICAM-1), may result in a tolerogenic, rather than an immunogenic signal [1,9]. The induction of regulatory T cells [10] offers a mechanism to suppress the immune system in a rather specific fashion. UVB-induced isomerization of *trans*- to *cis*-urocanic acid in the stratum corneum plays an additional role in suppressing antigen presentation by LHC and complex immune responses such as contact hypersensitivity [1]. Vitamin D converted by UVB in the skin from 7-dehydrocholesterol has potent immunomodulatory properties as well. The active form of vitamin D has been shown to inhibit T-cell proliferation and major histocompatibility complex (MHC) class II expression on antigen-presenting cells, and to suppress LHC activity [11]. In addition, UVB stimulates keratinocytes and melanocytes to express α-MSH that besides its role in skin pigmentation also suppresses cutaneous inflammation [11]. Importantly, the suppression of delayed hypersensitivity reactions and immunosurveillance against skin tumors are seen already at UVB doses below the erythema threshold in human skin [6]. Finally, antimicrobial UV effects and alteration of the skin flora [12] may contribute to the therapeutic activity of UVB in some clinical applications.

62.3.2 Treatment Principles

Sensitivity of human skin to the erythemogenic activity of UVB can vary widely, and individual ranges are only roughly predictable by skin phototyping. The individual photosensitivity level may be determined by assessing the minimal erythema dose (MED). This is the lowest UVB dose that induces a well-defined perceptible redness of the skin 24 h after exposure. It is measured by exposing a set of small (1–4 cm²) areas of untanned skin (e.g., on the buttocks) to an incremental series of UVB doses. A variable portion of the MED (35%–70%)—depending on the aggressiveness of the protocol—is used as starting dose [5]. Subsequent increments are determined according to the cutaneous reaction and, in most regimens, range from 10% to 40%. Some protocols use fixed dose increments rather than a relative portion of the previous exposure. The number of weekly treatments varies from two to five. Daily irradiations are possible because peak erythema occurs at 8–24 h following UVB exposure, and thus, cumulative toxicity can be avoided. A treatment cycle ends, when complete clearance (or improvement without further amelioration with 3–6 subsequent exposures) is obtained. A maximum number or cumulative dose of NB-UVB exposures has not been set so far. Repeated phototherapy usage depends not only on objective estimates of skin cancer risk but also on factors, such as whether or not the face is shielded during phototherapy, the frequency of repeated treatment courses, and each patient's attitude to the known risks of treatment [5]. Contraindications to UVB phototherapy are detailed in [Table 62.1](#).

TABLE 62.1 Absolute and Relative Contraindications to UVB, UVA-1, PUVA and Bath-PUVA Phototherapy Treatments

	UVB	UVA-1	PUVA	Bath-PUVA
Absolute contraindications to treatment				
Pregnancy			Yes	
Breast feeding			Yes	
Lupus and autoimmune diseases	Yes		Yes	Yes
Xeroderma pigmentosum	Yes	Yes	Yes	Yes
Porphyrias	Yes	Yes	Yes	Yes
Albinism	Yes	Yes	Yes	Yes
Dysplastic nevus syndrome	Yes	Yes	Yes	Yes
Previous melanoma or nonmelanoma skin cancer (NMSC)	Yes	Yes	Yes	Yes
Severe cardiopathy	Yes	Yes	Yes	Yes
Liver or kidney insufficiency			Yes	
Therapy with phototoxic drugs	Yes	Yes	Yes	Yes
Relative contraindications (to be evaluated in the single case)				
Age less than 18 years	Yes	Yes	Yes	Yes
Melanoma in relatives	Yes	Yes	Yes	Yes
Anti nuclear (high titer) anti-extractable nuclear antigen (ENA) antibodies	Yes		Yes	Yes
High cumulative UV dosage	Yes	Yes	Yes	Yes
Therapy with ionizing radiation	Yes	Yes	Yes	Yes
Previous exposure to arsenic or nitrogen mustard	Yes	Yes	Yes	Yes
Cataract or aphakia			Yes	
Poor compliance	Yes	Yes	Yes	Yes

Note: Yes = Contraindicated.

62.3.3 Clinical Indications

62.3.3.1 Psoriasis

Both BB(UV21)-UVB and NB-UVB phototherapies have shown high efficacy in the treatment of psoriasis but the latter is associated with higher remission rates, lower number of exposures, lower cumulative UV dose (in terms of multiples of the MED), longer remission, and better tolerability with fewer phototoxic reactions [5]. Results are even better (fewer treatments, better long-term efficacy) when more aggressive protocols are used [13]. However, it is still a matter of discussion, whether NB-UVB is superior to BB(UV6)-UVB in clearing psoriasis [14]. Following clearance, the treatment cycle is terminated. In order to avoid high cumulative UVB doses, maintenance treatments are only suggested for selected patients, who are at high risk of early relapse. Combination therapies with other antipsoriatic agents proved effective to reduce cumulative UV doses and to enhance clearance of psoriatic lesions [7]. However, use of systemic corticosteroids is not favored because of adverse effects and risk of early relapse. Combinations with cyclosporin A or methotrexate should be avoided because of the risk of additive carcinogenesis. In contrast, the combination with acitretin improves efficacy, particularly in the treatment of thick plaques, erythrodermic, and pustular psoriasis, and potentially reduces long-term hazards [7]. A few sessions of UVB phototherapy before or during the first weeks of a treatment cycle with efalizumab or etanercept shorten the time to remission and increase clearing rates [15,16].

62.3.3.2 Atopic Dermatitis

NB-UVB phototherapy of atopic dermatitis (AD) of both childhood [17] and adulthood [18] is effective but, in comparison to protocols for psoriasis, more cautious dosimetry and prolonged maintenance are advisable. NB-UVB phototherapy was found as effective as bath-PUVA without differences in

the duration of remission [19]. In comparison to medium-dose UVA-1, NB-UVB is more effective for chronic AD but less effective to control acute flares [20].

62.3.3.3 Polymorphic Light Eruption and Solar Urticaria

Polymorphic light eruption (PLE) and solar urticaria (SU) represent an indication for photoprophylaxis, the prevention of recurrences by increasing the patient's tolerance to sunlight using controlled UV exposures. This effect is likely due to reduced UV penetration because of thickened epidermis, particularly stratum corneum, enhanced pigmentation, and immunomodulation. UVB hardening significantly promotes UV-induced LHC depletion, which is defective in patients with PLE [21]. Randomized controlled clinical trials have shown that BB-UVB is less effective than NB-UVB, and the latter is as effective as PUVA in managing photosensitive conditions [5,22,23]. UV treatment should be always preceded by photoprovocation testing to determine the pathogenic waveband and the minimal dose that triggers the disease. A treatment cycle should start at least 4 weeks before expected sun exposures.

Several case reports have also supported NB-UVB phototherapy in the treatment of other photosensitive disorders, such as erythropoietic protoporphyria, actinic prurigo, hydroa vacciniforme, and drug-induced photosensitivity (see for review Refs. [5,22]).

62.3.3.4 Vitiligo

NB- or BB-UVB are widely used for vitiligo in adults and children, with NB-UVB appearing more effective with up to 75% repigmentation in about two-thirds of patients after at least 1 year of treatment [7,24,25] (Figure 62.1a and b). Initial doses and increments are chosen cautiously to avoid excessive erythema. Response rates depend on anatomic location (face, neck, and trunk > distal extremities and genitals), duration (recent > older lesions), and skin type (darker > lighter phototypes) [5,7]. Phototherapy inhibits T-cell-mediated toxicity to melanocytes and stimulates by an unknown mechanism inactive melanocytes in the outer root sheath of hair follicles to proliferate and migrate into vitiligo patches.

62.3.3.5 Cutaneous T-Cell Lymphoma

BB-UVB and NB-UVB are effective for early stages of cutaneous T-cell lymphoma (CTCL), limited by the lesion thickness in relation to UVB penetration depth. Phototherapy is also a useful adjunct to other modalities such as IFNs, retinoids, and electron beam therapy. Induction of apoptosis of neoplastic T cells is the most likely therapeutic mechanism [26].

62.3.3.6 Other Indications

Open, uncontrolled studies, case series, and case reports have reported successful treatment with BB-UVB or NB-UVB of a broad range of dermatoses, including subcorneal pustular dermatosis (Sneddon–Wilkinson disease), acquired perforating disorder, pruritic folliculitis of pregnancy, prurigo

FIGURE 62.1 (See color insert.) Vitiligo of the face treated with NB-UVB: (a) before treatment and (b) after treatment.

nodularis, lichen planus, hand dermatitis, alopecia areata, granuloma annulare, pityriasis rubra pilaris, pigmented purpuric dermatosis (Schamberg's disease), mastocytosis, lymphomatoid papulosis, pityriasis lichenoides, eosinophilic folliculitis, scleromyxedema, and pruritus in polycythemia vera, hepatic, and renal disease (see for review Refs. 5, 7, 27). However, current evidence allows no definitive conclusions as to whether NB- or BB-UVB would be preferable to competing phototherapeutic options such as UVA-1 and PUVA.

62.3.4 Adverse Effects

Burns, dryness, pruritus, and reactivation of herpes simplex virus are common acute cutaneous side effects of UVB phototherapy. Lesional blistering of psoriatic plaques is uncommon, and the hazard of activation of HIV infection is still debated [28]. Data quantifying the carcinogenic risk of NB-UVB and BB-UVB are limited. Recently, a small increase in basal cell carcinoma among those NB-UVB patients also receiving PUVA was registered, without increase in squamous cell carcinoma (SCC) and melanoma rates [29]. One argument favoring NB-UVB was its hypothetically reduced carcinogenic risk compared to BB-UVB; this still remains to be demonstrated at the clinical level [5].

62.4 Excimer UVB Phototherapy (308 nm)

Excimer lasers or lamps deliver large fluences of 308 nm NB-UVB selectively to cutaneous lesions within reasonable time and without hazards to uninvolved skin. However, as it can only expose one small body area after the other, it is only practical for limited skin involvement. Biological and immunological effects are presumably the same as NB-UVB at 312 nm. Excimer light appears to be effective and safe for palmoplantar pustular psoriasis, vitiligo, plaque-type psoriasis, chronic atopic and non-AD of the hands, and alopecia [30].

62.5 UVA-1 Phototherapy

Unlike UVB and UVA-2 (320–340 nm), UVA-1 is poorly erythemogenic and penetrates into the dermis. Its biological effects are due to oxidative damage of proteins, lipids, and DNA (preferentially guanosine) [6,31]. UVA-1 induces apoptosis via the early (<20 min after the exposure) preprogrammed death pathway that depends on singlet-oxygen generation and is activated by the expression of Fas-ligand molecules on the cell surface. These mechanisms markedly differ from the delayed programmed pathway after anaerobic PUVA and UVB-induced DNA damage, and that is p53 dependent and requires synthesis of new proteins [32]. Apoptosis of normal and neoplastic T helper cells plays a central role in the therapeutic effects of UVA-1 [31,33]. In addition, UVA-1 radiation has the capacity to significantly increase mRNA and protein expression of IL-1, IL-6, IL-8, IL-10, and α -MSH, and to downregulate IFN- γ and TNF- α [26]. UVA-1-induced production of PG (prostaglandins), particularly PGE₂, in epidermal keratinocytes and dendritic cells may also contribute to immunosuppression by affecting costimulatory molecule expression on the surface of antigen-presenting cells and thereby preventing T-cell activation [26]. The number of LHC and dendritic cells is not changed by UVA-1, but their activity is downregulated. In fibroblasts, UVA-1 upregulates the synthesis of the collagen-degrading enzyme collagenase I (or matrix metalloproteinase I) [31,33].

62.5.1 Principles of Treatment

UVA-1 phototherapy may be delivered at low (10–30 J/cm²), medium (40–60 J/cm²), and high (80–120 J/cm²) doses with 2–5 weekly exposures. Unlike other phototherapies, it is delivered at fixed dosages without further increments, and MED assessment is not required because even high doses are lower than the erythema thresholds.

62.5.2 Clinical Indications

62.5.2.1 Atopic Dermatitis

Several controlled studies indicate that UVA-1 is effective for AD of both adults and children. Medium-dose UVA-1 may be most cost-effective and safest when compared to low-dose and high-dose regimens. UVA-1 is more effective than BB-UVB and ultraviolet A-B but it is superior to NB-UVB and PUVA only for acute flares (see for review Ref. 20). Clinical improvement is accompanied by apoptosis of skin-infiltrating T cells, epidermal IgE bearing LHC, dermal mastocytes, and circulating eosinophils. In situ expression of IFN- γ , IL-2, and IL-4 is reduced, as are serum levels of the eosinophilic cationic protein [20,34].

62.5.2.2 Lupus Erythematosus

Controlled, randomized, double-blind studies suggest a beneficial effect of low-dose UVA-1 for skin lesions of acute and subacute lupus erythematosus. In addition, systemic symptoms such as arthralgia and malaise improve and elevated circulating inflammation markers and leukopenia normalize [35]. Nevertheless, uncritical treatment of this UV-sensitive disease may put patients at risk for systemic exacerbation [32].

62.5.2.3 Scleroderma and Other Sclerosing Conditions

UVA-1 softens localized scleroderma and cutaneous involvement in systemic scleroderma. Sonography shows a significant decrease in lesional skin thickness [31,36]. Activity on fibroblasts and stimulated apoptosis of autoreactive T cells are involved in the improvement of lichen sclerosus et atrophicus, polyneuropathy, organomegaly, endocrinopathy, monoclonal gammopathy, and skin changes (POEMS) syndrome, keloids, and hypertrophic scars [31,37].

62.5.2.4 CTCL and Other T-Cell-Mediated Diseases

Because of its proapoptotic effect on T lymphocytes, UVA-1 phototherapy has also been introduced successfully in the treatment of patients with early-stage CTCL, acute and chronic pityriasis lichenoides, and lymphomatoid papulosis [38].

62.5.2.5 Mastocytosis

Induction of apoptosis of mast cells infiltrating the skin has been postulated as mechanism of the beneficial effect of UVA-1 phototherapy on cutaneous mastocytosis. Moreover, serum and urine values of mast cell-derived mediators, such as histamine and serotonin, returned to normal levels [39].

62.5.2.6 Other Indications

Medium- and high-dose phototherapy was found effective for dyshidrotic hand eczema and a heterogeneous group of skin diseases characterized by dermal inflammatory infiltrates, including follicular mucinosis, sarcoidosis, granuloma annulare, and necrobiosis lipoidica. Its use for psoriasis in HIV+ patients remains controversial (see for review Ref. [31]). UVA-1 is useful for managing both lichenoid and sclerodermoid cutaneous graft-versus-host disease [37].

62.5.3 Adverse Events

Short-term adverse effects (erythema, pigmentation, induction of PLE or other UVA-sensitive photodermatoses, and herpes simplex reactivation) are uncommon and usually mild and transitory (less than 10% of patients). The major chronic side effects might be photoaging and skin cancer, although epidemiological studies do not support this concern so far [31,33].

62.6 PUVA Photochemotherapy

62.6.1 Mechanisms of Action

Biological effects of photochemotherapy are caused by a cascade of molecular effects triggered by the photoactivation of exogenous chromophores, usually psoralens.

8-Methoxypsoralen (8-MOP), 5-methoxypsoralen (5-MOP), and 4,5',8-trimethylpsoralen (TMP) are bifunctional linear furocoumarins that are widely used worldwide. They have no systemic toxicity in the dark even at doses much higher than those used for PUVA therapy. Psoralens intercalate in the dark between DNA helices and induce their unwinding. Upon absorption of a photon, pyrone- and furan-side monoadducts are formed and, upon absorption of a second photon, the furan-side adduct only can further photoreact with a base of the opposite DNA strand to form an interstrand cross-link [40]. The DNA-psoralen cross-link blocks DNA polymerase progression and consequently DNA and RNA synthesis [22,40]. Psoralens also photoreact with proteins (DNA-protein cross-links, protein-protein cross-links), leading to damage of cell membranes and the microsomal P450 system, and inactivation of enzymes. Photoaddition of unsaturated fatty acids inhibits the activation of protein kinase C signaling [22]. In addition, activated psoralens may also modify proteins and lipids via generation of singlet oxygen, superoxide anion, or radicals and strongly decrease mitochondrial functions and activate caspase-3, -8, and -9 [41]. The significance of photochemical reactions other than DNA adducts in a clinical setting is unclear.

Cell death of CD4⁺ lymphocytes may be responsible for the anti-inflammatory effects of PUVA and for the beneficial therapeutic effects of PUVA in lymphoproliferative diseases, such as CTCL. Whether PUVA at clinical dose levels inhibits gene transcription, which ultimately results in a shut-down of cytokine release and expression of accessory surface molecules, is unclear at this point. Suppression by PUVA of the release of the proinflammatory cytokines IL-1, IL-6, IL-8, and TNF- α has been reported. These results were obtained in vitro at high 8-MOP concentrations and may not be therapeutically relevant [33]. Systemic PUVA in vivo suppressed the induction of contact hypersensitivity responses in a systemic fashion and also led to a marked increase in regulatory T-cell subpopulation (CD4 + CD25 + FoxP3 + Treg) in peripheral blood [42]. PUVA decreased the number of cutaneous T lymphocytes, macrophages, dendritic cells, and epidermal LHC with a diminished expression of CD86 and human leukocyte antigen-DR (HLA-DR) [43].

Keratinocytes are much more resistant to PUVA-induced apoptosis than T cells. Inhibition of cell proliferation, however, is observed at PUVA doses that do not affect cell viability. This indicates that the amount of DNA-psoralen photoadducts required for impairing cell replication and proliferation is much lower than that resulting in cell death [44]. An additional PUVA effect on keratinocytes is downregulation of ICAM-1 expression, while it has no significant effect on urocanic acid isomerization [33].

62.6.2 Principles of Treatment

Standard PUVA regimens consist of the psoralen ingestion followed by a delayed exposure to UVA. 8-MOP is administered at a standard dosage of 0.6–0.8 mg · kg⁻¹ body weight and 5-MOP at 1.2 mg · kg⁻¹ in partial compensation for its much lower intestinal uptake [22]. Low psoralen doses may be completely metabolized by the liver at first-pass and thus be nontherapeutic [45]. UVA exposures are given when the tissue psoralen concentration is highest. This happens after 2 h with pulverized or micronized crystalline preparations and after 1 h with liquid preparations in soft gelatin capsules [22]. Different irradiation protocols are available, and they vary in four parameters: the initial UVA dose, the frequency, the UVA dose increments, and maintenance therapy. The choice of the starting UVA dose has a crucial importance because of wide inter-individual variability in psoralen skin levels and photosensitivity following oral intake. UVA doses that are predetermined based on skin phototype may be too low and ineffective

or too high and hazardous. The initial UVA dose can be better determined by assessing the minimal phototoxic dose (MPD) via exposure of a series of small skin areas of untanned skin to incremental UVA doses after psoralen intake [45].

The number of weekly treatments ranges from 2 to 4 and is limited by the risk of cumulative phototoxicity because PUVA erythema peaks at 48–96 h. A high number of weekly treatments reduces the overall treatment duration but can only be delivered after careful MPD determination. UVA dose increments are necessary in order to maintain the therapeutic effect despite progressive pigmentation and thickening of the skin. Increments are calculated empirically either as fixed dose or as percentage of the previous irradiation [22,45]. Upon complete clearing, patients may discontinue the treatment or enter maintenance therapy with the latest UVA dose and gradually reduced frequency. Patients undergoing maintenance therapy remain longer in remission but prolonged maintenance is time consuming and carries higher risk of long-term adverse effects [22,45]. Unlike creams, ointments, or lotions, bath water delivery of psoralens results in uniform drug delivery, very low psoralen plasma levels, and quick elimination of unbound psoralens from the skin, thus reducing the hazard of accidental burns. Once a domain of TMP, bath-PUVA now largely includes 8-MOP. Bath-PUVA consists of 15–20 min whole body immersions in 0.5–10 mg of 8-MOP per liter of bath water. Photosensitivity increases in this dose range linearly with increasing psoralen concentrations, albeit to a lower extent, that is, a 10 times higher 8-MOP concentration resulted in a less than threefold stronger photosensitivity [46]. Dosimetry for bath-PUVA must take into account that—unlike in oral-PUVA—the phototoxic threshold declines during the early treatment phase [47].

Contraindications to both oral- and bath-PUVA are detailed in [Table 62.1](#). It is noteworthy that bath-PUVA is more user-friendly because it lacks the hazards for internal organs and eye.

62.6.3 Clinical Indications

General treatment parameters are based on the response of psoriasis, where therapeutic effects can easily be quantified. No greater effort was spent on therapeutic development for any other indication. Thus, psoriasis is the model disease for dosimetry, and other indications follow similar regimens.

62.6.3.1 Psoriasis

There is no international consensus on the practical aspects of oral PUVA therapy. Protocols basing the initial irradiation on the individual MPD are preferable because they are as efficient in clearing psoriasis as protocols using a skin type-dependent fixed initial dose but the latter requires a 2.5-fold higher cumulative UVA dose until remission is achieved and therefore has a long-term safety disadvantage [22,30,45]. PUVA should be continued until complete remission or partial remission without any further improvement during the following 2 weeks. In general, maintenance therapy should be avoided [30,45]. Some authors argue that patients with recalcitrant disease should receive maintenance therapy once weekly for 2 months to avoid early relapses [22].

5-MOP is as effective as 8-MOP but at higher cumulative UVA doses because of its lower phototoxicity and higher melanogenic potential after ingestion [47]. The advantages of 5-MOP are its much better gastro-intestinal tolerability and reduced phototoxic side effects [22]. When comparing bath-PUVA with oral PUVA, similar clearing rates were found, but bath-PUVA achieved remissions with fewer treatment sessions and lower cumulative UVA doses [48] ([Figure 62.2a](#) and [b](#)).

Combination therapies may be useful in disease management. Topical vitamin D analogues enhance PUVA, whereas topical steroids have given conflicting results.

Acitretin is effective in treating hard-to-treat cases of psoriasis. The combination reduces cumulative UVA requirements and decreases long-term risks [30,45]. Combinations with cyclosporin A and methotrexate also work well, but they raise concerns of added carcinogenicity. In analogy, caution is advised for combination with biologicals, such as anti-TNF- α therapies.

FIGURE 62.2 (See color insert.) Psoriasis of the trunk treated with PUVA: (a) before treatment and (b) after treatment.

In studies comparing PUVA and NB-UVB, PUVA seems to be more effective, particularly for the most severe cases, for palmoplantar pustulosis and pustular psoriasis [49,50]. However, considering the convenience of NB-UVB units and because no psoralen is required, NB-UVB can be considered the first choice in phototherapy [5].

62.6.3.2 Atopic Dermatitis

PUVA and bath-PUVA are effective in the treatment of AD of both children and adults, but the use in children and adolescents has to be carefully weighed. Low initial doses with cautious increments help prevent exacerbation, and prolonged maintenance is usually needed. Bath-PUVA was found to be as effective as NB-UVB (see for review Ref. [7]).

62.6.3.3 Vitiligo

PUVA is used for vitiligo because it stimulates migration of melanocytes and melanogenesis, and it has immunosuppressive effects. Low initial UVA doses and cautious increments are delivered until a faint erythema is attained in the vitiligo patches and then maintained by careful UVA dose adjustments.

In comparative trials, PUVA therapy has not been found superior to NB-UVB and due to a higher hazard ratio is now considered a second-line therapy [24]. PUVA seems to be safe in this indication with respect to photocarcinogenicity, as only two vitiligo patients have been reported so far, who developed SCC after prolonged PUVA therapy [7].

62.6.3.4 Cutaneous T-Cell Lymphoma

PUVA is considered a first-line therapy for patch- and plaque-stage CTCL. Long-term remissions have been reported. In the majority of cases, maintenance therapy was necessary. No consensus exists on the duration of treatment courses and frequency of exposures. Combinations of PUVA with IFN- α or bexarotene have shown to improve efficacy, safety, and tolerability for both early and advanced disease. PUVA is also a useful component for combined maintenance regimens [27].

62.6.3.5 Idiopathic Photodermatosis

PUVA can prevent relapses (photochemoprophylaxis) of idiopathic photodermatoses via the stimulation of pigmentation, thickening of the stratum corneum, and immunomodulation. Initial UVA doses are

given according to the MPD, and dose increments are cautious. Three weekly exposures for 4 weeks are sufficient in preventing relapses in up to 90% of patients with PLE.

PUVA is also quite useful for the photochemoprophylaxis of SU. The irradiations must be lower than the minimal urticarial dose (MUD) for UVA, and dose increments must be very small at least for the first few exposures. For accelerated regimens, two or more treatment sessions can be delivered on the same day. The first few exposures may be combined with oral antihistamines or corticosteroids to avoid complications from systemic histamine effects.

In order to speed up the achievement of a protection, a rush hardening protocol with multiple UVA (without psoralen) irradiations at 1 h intervals per day was proposed and allowed to achieve a good protection within 3 days [33]. For both, SU and PLE, the protective effect lasts generally during the whole summer as long as the “hardening” is maintained by repeated exposures to sunlight.

62.6.3.6 Other Indications

Oral PUVA and bath-PUVA have been used successfully in the treatment of a broad range of inflammatory skin diseases encompassing the indications that were listed above with UVB and UVA-1 (with the only exception of lupus erythematosus). However, for most indications, comparative clinical trials are unavailable (see for review Refs. [22,30,45]), and optimal treatment protocols are uncertain. The action mechanisms for different disorders may vary based on their pathogenesis and need further clarification.

62.6.4 Adverse Effects

Oral PUVA is generally well tolerated but one or more episodes of excessive phototoxic reactions and itching occur in 10%–20% of patients, who usually recover spontaneously. Gastrointestinal symptoms (nausea and vomiting) are not uncommon with 8-MOP but can be improved by intake of some food with the drug. Skin pain, blisters, acneiform eruptions, facial hypertrichosis, onycholysis, and subungual hemorrhages are uncommon. Increase of transaminases is rare unless there is preexisting liver damage. PUVA in the long term leads to photoaging with elastosis, poikiloderma, and prominent lentigines. PUVA-treated patients have a higher risk of nonmelanoma skin cancer, and the risk is higher for patients, who were previously treated with arsenic, BB-UVB, or methotrexate. It is uncertain if PUVA causes malignant melanoma [51,52]. However, patients with dysplastic nevus syndrome and those with a history of melanoma should not be treated. Because psoralens bind to the proteins in the ocular lens, there is a theoretical risk for accelerated cataract formation under PUVA therapy. However, PUVA does not increase cataract risk among persons using eye protection for at least 12 h after treatments [53]. Bath-PUVA has the same short-term cutaneous adverse effects as oral PUVA. However, because of minimal percutaneous absorption of psoralens, bath-PUVA has no systemic toxicity. In addition, hazards of skin cancers have not been reported with bath-PUVA so far.

63.1 Introduction

Photoimmunology has its origins in the landmark studies around 25 years ago that demonstrated the immunogenic nature of UV radiation-induced skin tumors taken from mice by the failure of their growth when fragments of these tumors were transplanted into naïve syngeneic recipient mice (Kripke 1974; Daynes and Spellman 1977). That the tumor rejection was immunological was shown by the reversal of the rejection by immunosuppressive drugs. Furthermore, if the recipient mice were pre-exposed to a subcarcinogenic dose of UV radiation, transplanted tumors again survived and grew, indicating for the first time that UV radiation could be immunosuppressive (Fisher and Kripke 1978). It was later observed that this inhibited anti-tumor immunity could be transferred to recipient mice with splenic T lymphocytes from such UV-irradiated donor mice, and thus, the dependence of the development of skin cancer on UV-induced defective T cell-mediated immunity was revealed (Fisher and Kripke 1982; Ullrich and Kripke 1984).

It is now understood that UV radiation is a complete carcinogen that not only mutates the DNA of epidermal cells to initiate cancer, but also suppresses the immunological recognition and rejection of this genetic damage in a specific manner that facilitates survival and progression of the initiated tumor cell. The early data arose from studies in mice, but all mammals appear to be susceptible to photoimmune suppression, including humans (Cooper et al. 1992; Kelly et al. 1998), with fair skin and sensitivity to sunburn in humans being associated with greater susceptibility to immune suppression by sunlight, measured by the contact hypersensitivity reaction (Kelly et al. 2000). Chronic overexposure

to sunlight is a universal precursor in otherwise healthy non-melanoma skin cancer patients and is reflected in their greater susceptibility to immune suppression by UVB radiation than normal subjects (Yoshikawa et al. 1990; Czarnecki et al. 1995). In addition, in patients receiving long-term immunosuppressive drug therapy such as organ transplant recipients, there is a highly significantly increased and often intractable metastatic skin cancer development that may prove to be manageable only by withdrawing the immunosuppressive drug (Berg and Otley 2002; Euvrard et al. 2006; Gutierrez-Dalmau and Campistol 2007; Veness et al. 1999).

The relentless increase in human skin cancers, particularly in fair-skinned populations worldwide, has made it urgent to understand the pathways by which solar UV radiation acquires its immunosuppressive property. Strategies for the protection of the immune system from UV damage are potentially helpful in preventing skin cancer development, but depend on the elucidation of the cutaneous photoreceptors that are activated to suppress immunity, and the relevant downstream cellular and molecular targets that result in the immunological defect. There has been much progress in identifying the mechanisms, gradually revealed to comprise a very complex multipathway network. Murine models have been a major contribution to this field, but important controversies currently persist that need clarification before the cutaneous immune response in humans can be targeted to advantage. Numerous excellent reviews have regularly charted the advances (Clydesdale et al. 2001; Ullrich 2005, 2007; Schade et al. 2005; Hanneman et al. 2006; Norval 2006; Loser and Beissert 2009; Schwarz 2008). In this chapter, the current state of knowledge will be summarized and updated with the newer observations.

63.2 Measurement of Immune Function

Photoimmune suppression is mediated primarily by T lymphocytes, and this arm of the immune system is conveniently modeled by the delayed-type or contact hypersensitivity (DTH or CHS) reactions. These T-cell-mediated reactions are relevant for laboratory rodents, marsupials (*Monodelphis domestica*), other mammals, and humans, and studies of these reactions in laboratory animals have been very fruitful in supplying the evidence for the critical pathways involved. The two reactions differ in the nature and route of administration of the sensitizing antigen, with sensitization for DTH usually being parenteral, whereas this is topical or epicutaneous for CHS (Reeve 2002). Commonly used sensitizers for DTH are injectable pathogens such as *Candida* or *Mycobacterium*, and for CHS are simpler topically applied chemicals such as oxazolone, 2,4-dinitrochlorobenzene, or 2,4-dinitrofluorobenzene. If sensitization is directly via UV-irradiated skin, the subsequently elicited reaction at a second site will reveal local UV-induced immune changes; if sensitization is via distant unirradiated skin, the elicited reaction at another site will reveal systemic UV-induced immune changes. Following sensitization, which is normally innocuous, the hypersensitivity reaction will be elicited by challenging the animal with the same sensitizing agent at another site, commonly the footpad (DTH) or the ear (CHS), resulting in an inflammation in the next 24–48 h that can be measured by the swelling. Local photoimmune suppression of CHS in the UVB-irradiated skin can be observed as soon as 24 h postirradiation, whereas systemic suppression develops more slowly and can be observed by 3–5 days postirradiation, but the UV dose to induce both defects is the same (Noonan and De Fabo 1990).

A well-used assay for photoimmune changes in humans is the elicitation of the nickel recall antigen response (Damian and Halliday 2002). The serendipitous prior sensitization to this metal in affected humans provides a population of potential human volunteers who will not require exposure to other chemical sensitizers, and the contact allergic reaction is readily elicited by topical application of a nickel salt solution. The suppressive effect of UV radiation will be measured by the local erythema and records the effect on the elicitation arm of the CHS response rather than on the primary sensitization.

In mice and humans, the immune defect after a single UV treatment is transient, and normal immune function will be restored within days or a few weeks. However, chronically repeated UV exposures result eventually in chronically suppressed skin immunity, when the animal or human can no longer be

successfully resensitized against the initial sensitizing agent, and this condition of immune tolerance is associated with the increased risk of carcinogenesis. The mechanisms underlying local and systemic suppression are different, as will be seen in the following.

63.3 Photoreceptors

63.3.1 DNA

The induction of a biological reaction to radiation requires a receptor that has an absorption spectrum matching the action spectrum for the biological reaction. The earliest attempt to produce an action spectrum for photoimmune suppression in mice was a heroic study (De Fabo and Kripke 1979) that indicated a peak in the UVB waveband between 290 and 320 nm. An immediately obvious potential receptor with UVB absorption encompassing this waveband was the DNA, and evidence began to accumulate showing that UVB-induced DNA lesions were the cause of the immunological dysfunction. Repair of the predominant UVB-induced DNA lesion, the cyclobutane pyrimidine dimer (CPD), either by switching on the endogenous photoreactivating enzyme pathway in the marsupial *M. domestica* (Applegate et al. 1989) or by treating mice with encapsulated T4N5 endonuclease to initiate nucleotide excision repair (Kripke et al. 1992; Yarosh et al. 1994) also repaired the immune defect. Furthermore, these strategies also resulted in a reduction in the photocarcinogenic outcome in both experimental species (Bito et al. 1995; Ley et al. 1991; Yarosh et al. 1992), emphasizing the connection between photoimmune suppression and the risk of skin cancer. Recently, patients with the hereditary disease *xeroderma pigmentosum*, who lack the DNA repair mechanism specific for UV-induced genetic damage and who suffer greatly exacerbated sunlight-induced immune suppression and skin cancer development, have been successfully treated with encapsulated DNA repair enzymes (Yarosh et al. 2001).

It has not been immediately clear in which cells the critical DNA damage with the immunosuppressive outcome occurs. The nuclei of all epidermal cell types are in the target range for genetic damage by UVB radiation, and there is good evidence that both the dendritic Langerhans cells (LCs) and the keratinocytes have roles to play. These will be addressed in the following.

63.3.2 *trans*-Urocanic Acid

DNA is not the only UVB-absorbing cutaneous molecule. It has transpired that a second potential photoreceptor for immune suppression is *trans*-urocanic acid (deaminated histidine). This molecule, the product of the enzyme histidase, is a catabolite of the amino acid histidine and is present in most body tissues where it is further degraded by urocanase activity, and is so-named for its original extraction from the urine of the dog, *Canis canis*. It occurs in relatively high concentrations in the upper epidermis and *stratum corneum*, due to the absence in the skin of urocanase. Urocanic acid has an UV absorption peak between 280 and 310 nm (McLoone et al. 2005), and the natural *trans* isomer is UV dose dependently photoisomerized to the *cis* form, equilibrating at the photostationary state of approximately equal concentrations of each isomer. *cis*-Urocanic acid, but not the *trans* isomer, is immunosuppressive, and many studies have tracked its actions in the skin, utilizing the ready responses of mice to topically applied or injected urocanic acid solutions (De Fabo and Noonan 1983; Noonan and De Fabo 1992). A neutralizing antibody to *cis*-urocanic acid prevents its immunosuppressive activity in mice (Moodycliffe et al. 1996), and more recently was shown to also inhibit photocarcinogenesis in the mouse (Beissert et al. 2001). This finding is consistent with an earlier demonstration that topically applied *trans*-urocanic acid daily to hairless mice during photocarcinogenesis induction resulted in an exacerbated tumorigenic outcome (Reeve et al. 1989). It is evident that the *cis* isomer is not the only urocanic acid photoproduct. A number of urocanic acid photooxidation products have been identified in UVB-irradiated human *stratum corneum*, which are also immunosuppressive in mice, and in combination may be more potently suppressive than *cis*-urocanic acid alone (Kammeyer et al. 2004). The contribution of such oxidized products to the immune defect in humans remains to be defined.

Urocanic acid has been isolated from the skin of many animals including reptiles, marsupials, rodents, and man, and the molecule appears to be very well conserved across the animal species (Ley et al. 2000). This suggests that it has a positive function of broader consequences in the skin than the immunosuppressive property of the *cis* isomer, perhaps in limiting the inflammatory immune reaction to photoantigens that could potentiate an autoimmune rejection of damaged skin cells. Several comprehensive reviews have followed the progress of understanding the activity of *cis*-urocanic acid (Gibbs et al. 2008; Mohammad et al. 1999; Norval et al. 1995; Norval and El-Ghorr 2002), but considerable uncertainty prevails as to its mode of action.

Because of its UVB absorption properties and location in the *stratum corneum*, it was originally thought that urocanic acid functioned as a natural endogenous sunscreen for the UV protection of the epidermal basal cells. However, calculations of its very low sun protection factor in humans from a cream containing more than 20 times the concentration of cutaneous *trans*-urocanic acid later seemed to rule out such a function (De Fine Olivarius et al. 1996). Nevertheless, cosmetic products were formulated with the inclusion of urocanic acid, but experimental application of one of these products was revealed to significantly increase the suppression of CHS in mice following their subsequent exposure to solar-simulated UV radiation (Reeve and Mitchell 1991). In contrast to these early experiments, a very recent report has provided evidence of significantly fewer CPDs induced in the skin of mice genetically deficient in histidase, and therefore deficient in *stratum corneum* urocanic acid, indicating that a photoprotective action for endogenous urocanic acid remains a possibility (Barresi et al. 2011).

The molecular and functional dissimilarity between the two molecules, DNA and urocanic acid, proposed as the receptors for photoimmune suppression led initially to much controversy. The possibility that *cis*-urocanic acid might bind to DNA or produce CPD-like dimers was examined and later refuted (IJland et al. 1998; Morrison et al. 1983), leading to the conclusion that two separate pathways to photoimmune suppression must exist. Today, the downstream targets of *cis*-urocanic acid remain somewhat controversial, and the critical cell population(s) bearing the immunosuppressive DNA damage are only recently becoming apparent.

63.3.2.1 Downstream Targets of *cis*-Urocanic Acid

Early evidence that histamine receptor antagonists could inactivate the immunosuppressive effects of urocanic acid indicated a role of the H1 and H2 histamine receptors (Gilmour et al. 1993), but as the cells involved did not appear to be the keratinocytes (Mitra et al. 1993), the relevant cell population, whether cutaneous or distantly localized, remains unclear. It has since been reported that UV irradiation clinically results in an approximately fivefold increase in the *cis/trans* ratio of urocanic acid in the urine, strongly indicative of a systemic distribution of this photoproduct (Kammeyer et al. 1997; Sastry et al. 2005). Therefore, it is relevant that oral, rather than topical, treatment of hairless mice with the H2 receptor antagonist cimetidine during photocarcinogenesis induction significantly reduced the skin tumor outcome (Matheson and Reeve 1991), and in a model of allergic respiratory inflammation in mice, suppression by UVB radiation has implicated a mediating role for histamine H2 receptors in the lung-draining lymph node (McGlade et al. 2007). Obviously, distant organ effects of *cis*-urocanic acid via this pathway remain a possibility.

More recent evidence based on its molecular structural similarity with 5-hydroxytryptamine (5-HT; serotonin) reports that the 5-HT(2A) receptor functions as the *cis*-urocanic receptor and is supported by studies in mice treated with various receptor antagonists (Walterscheid et al. 2006). *cis*-Urocanic acid, but not the *trans* isomer, was found to be a competitive inhibitor of 5-HT for this receptor (Shen and Ji 2009); a selective 5-HT receptor antagonist blocked the binding of *cis*-urocanic acid, and furthermore, the neutralizing antibody to *cis*-urocanic acid or blockade of the 5-HT(2A) receptor both prevented the suppression of DTH by UV radiation, *cis*-urocanic acid, or 5-HT. It was therefore consistent to find that 5-HT(2A) receptor blockade also reduced the photocarcinogenic outcome in chronically irradiated mice (Sreevidya et al. 2008). In contrast to these studies have been reports that do not find that *cis*-urocanic acts via the 5-HT(2A) receptor in either primary human keratinocytes (Kaneko et al. 2009)

or in peripheral human blood monocytes (Woodward et al. 2006). Whether human keratinocytes actually express the 5-HT(2A) receptor is controversial, since the mRNAs of several 5-HT receptors were identified in these cells by Slominski et al. (2003), but not in the later study (Kaneko et al. 2009). Further research is needed to clarify this issue.

Another target for *cis*-urocanic acid consists of the peripheral sensory nerves, which have been shown to release neuropeptides in response to this photoproduct, but not to the *trans* isomer (Khalil et al. 2001). Both substance P and calcitonin gene-related peptide (CGRP) were released, compounds that are known to induce the degranulation of mast cells to release many mediators, particularly histamine, which then can activate prostaglandin synthesis by the keratinocytes. The neuropeptides may also bind to the LCs and induce immunosuppressive interleukin (IL)-10 production (Lambert and Granstein 1998).

63.3.3 Cell Membrane Lipids

UV irradiation of the skin results in oxidative stress that indirectly damages additional epidermal molecules. Cell membrane lipids are oxidizable targets and provide a source of the potent phospholipid mediators, platelet-activating factor (PAF) and related compounds, that are now known to have inflammatory and immune modulating activity via the PAF receptor on keratinocytes (and various other cell types). The synthesis of PAF is believed to be one of the first responses to UV irradiation and can be detected within minutes (Barber et al. 1998; Marathe et al. 2005). Activation of the PAF receptor results in a cascade of cytokine and eicosanoid release that contributes to the inflammatory sunburn response (Pei et al. 1998; Ullrich et al. 2007), and this reaction is independent of any genomic or nuclear events (Simon et al. 1994). Significantly, PAF receptor antagonists in mice inhibit photoimmune suppression as well as *cis*-urocanic acid suppression of DTH (Walterscheid et al. 2002), and these actions were confirmed in the failure to induce photoimmune suppression in PAF receptor gene knockout mice (Wolf et al. 2006). Furthermore, PAF receptor antagonism in mice was demonstrated to inhibit photocarcinogenesis (Sreevidya et al. 2008).

On the other hand, more recent studies in primary human keratinocytes provide conflicting data (Kaneko et al. 2009). Treatment with *cis*-urocanic acid was reported to activate the secretion of relevant immunosuppressive factors, but this was not inhibited by a PAF receptor antagonist, nor was there evidence of *cis*-urocanic acid binding to the PAF receptor. It was earlier shown that *cis*-urocanic acid induced oxidative stress in primary human keratinocytes that could be anticipated to stimulate the PAF receptor (Kaneko et al. 2008), and antioxidants were found by others to inhibit *cis*-urocanic acid immunosuppression in mice (Steenvoorden and van Beijersbergen 1999). Nevertheless, the human keratinocyte does not appear to be the cell in which PAF signaling mediates photoimmune suppression, and further studies are needed to identify the role of alternate cell populations.

63.4 UV-Responsive Mediators

63.4.1 Cellular

63.4.1.1 LCs and T Lymphocytes

LCs are dendritic antigen-presenting cells that form a suprabasal interdigitating network in the epidermis, thus providing the surveillance against environmental and invading pathogens in order to protect the susceptible basal cells below. Their role is to capture and process exogenous antigens, to migrate to the regional lymph node, and there to present the processed antigen to T helper-1 (Th-1) lymphocytes. A population of specifically activated T cells is then generated, sensitized to that antigen. However, in the case of UV irradiation, this sequence fails to occur, and the failure can be partially attributed to the UV-induced DNA damage of the resident LC (Schwarz 2005). Increased numbers of LC with identifiable UV-DNA damage accumulate in the regional lymph nodes (Schwarz et al. 2005), viable but unable to present antigen normally, and instead causing the generation of a population of

regulatory T cells (Treg cells) associated with Th-2 function and immunological tolerance. Meanwhile, in the LC-depleted epidermis, it has been suggested that antigens can be taken up by nonspecific antigen-presenting cells like macrophages, thus avoiding specific sensitization and also resulting in the development of an aberrant population of T cells subsequently unable to recognize the antigen. Either mechanism may be involved; however, recent studies in which the reversal of the immunosuppressed state in mice was achieved by injecting IL-12 indicated that this cytokine both prevented the UV-depletion of the epidermal LC and unexpectedly also resulted in repair of their DNA lesions, apparently by stimulating the endogenous nucleotide excision repair (NER) enzymes (Schwarz et al. 1996, 2005; Schwarz 2005).

The target T cells were originally known as T suppressor cells (Ts cells), and populations of lymph node or splenic cells that included these Ts cells could adoptively transfer the defective immunosuppressed response to naïve recipient mice (Fisher and Kripke 1978, 1982; Elmetts et al. 1983). For some years, the actual existence of the Ts cell was much debated, as it proved impossible to purify or clone such a cell population, but more recently their role in modulating the skin immune system has been confirmed, and they are now known as Treg cells and have been characterized as CD4+CD25+ (reviewed in Schwarz 2008). Another population of UV-induced suppressor T cells that plays a critical role in tumor rejection, while present in small numbers, is the unique natural killer T cell (NKT cell) that is CD3+CD4+ (Moodycliffe et al. 2000).

The photoantigenic defect induced by UV radiation in the skin cells may be the altered DNA, RNA, protein, or lipid components of the epidermal cells. UVB radiation is known to induce specific lesions directly in the DNA, predominantly the CPD, as well as alterations in the aromatic amino acids, and oxidation products of cell membrane lipids. These primary lesions have each been demonstrated to result from the initial interaction of the UV radiation with epidermal photoreceptors that results in the immune suppression and, as will be seen in the following, suggest that there are multiple pathways that can be activated by UV radiation to produce the immunosuppressed state. Treg cells in the periphery are important under normal conditions in tissues as they are required to terminate active immune responses when the antigen has been sequestered and removed, and provide important protection against the development of autoimmunity. Their continued presence is dependent on the expression of costimulatory molecules such as CD80 and CD86 of the B7 family (Loser et al. 2005), and receptor activator of NF- κ B ligand (RANKL) of the tumour necrosis factor (TNF) family (Loser et al. 2006). When activated by the specific antigen, the Treg cells release the immunosuppressive cytokine IL-10, which then enables general immune suppression that can be local or systemic because of the soluble and systemically dispersible nature of this cytokine, and can be directed nonspecifically to other unrelated antigens encountered by the body at that time.

63.4.1.2 Mast Cells

The degranulation of mast cells in UV-irradiated skin releases many inflammatory and immune modulating factors that can contribute to UV-induced erythema and immune suppression, but TNF α and histamine have been identified as the critical molecules for immune suppression and involve the synthesis of inflammatory prostaglandins like PGE2. Degranulation is not mediated directly by *cis*-urocanic acid, but is dependent on neuropeptides such as CGRP released from sensory dermal fibers, that is, *cis*-urocanic acid dependent (Hart et al. 2001, 2002).

There is a correlation between dermal mast cell prevalence and susceptibility to immune suppression by UV radiation or *cis*-urocanic acid in mice, and mouse strains have been categorized according to their mast cell numbers for the dose of UV radiation, high or low, by which they can be photoimmune suppressed experimentally (Hart et al. 1999). In humans, mast cell numbers in chronically sun-exposed skin sites are significantly greater than in protected skin (Grimbaldeston et al. 2003) and may lead to predisposition for basal cell carcinoma (Grimbaldeston et al. 2006). Mast cell-depleted mice proved to be unresponsive for systemic immunosuppression by either UVB or *cis*-urocanic acid; therefore, these cells infiltrating the UV-irradiated skin sites are contributors to photoimmune suppression.

63.4.1.3 Macrophages/Monocytes

It has long been recognized that there is an inflammatory cellular infiltrate that appears in the UV-irradiated skin 3–4 days after exposure that includes macrophages, neutrophils, and mast cells. Because activated human macrophages can be potent sources of IL-10, it was consistent to find that CD11b+ macrophages appearing in the UV-irradiated skin of humans contained elevated levels of IL-10 protein (Kang et al. 1994). The macrophage is now recognized as a major contributor to epidermal IL-10 and photoimmune suppression. Furthermore, enhanced UV-induced tumor growth in mice could be attributed to the influx of CD11b+ and other inflammatory cells into the epidermis (Sluyter and Halliday 2000). In more recent studies, dendritic cells including macrophages from UV-irradiated mice were shown to be unable to secrete functional immunoprotective IL-12 (IL-12p70), but instead secreted an IL-12p40 homodimer that acts as an antagonist of biologically active IL-12, thus suppressing the Th1 cell inflammatory and immunological activity (Schmitt and Ullrich 2000).

63.4.1.4 B Cells

Studies of the crucial lymph nodes draining the UV-irradiated skin have provided new evidence that not only activated dendritic cells were present, but a population of B cells also responded by increasing in size and expressing antimajor histocompatibility complex II but not costimulatory molecules, a phenotype suggestive of immune suppression (Byrne and Halliday 2005). The B cells inhibited antigen presentation by the dendritic cells and could transfer the UVB-induced immunosuppression to naïve recipient mice in a manner that was inhibited by a PAF receptor antagonist (Matsumura et al. 2006). Furthermore, UV-stimulated infiltrating mast cells were attracted to the lymph node B cells by an upregulated ligand on the B cell specific for the CXCR4 receptor on the mast cell. Treatment with a CXCR4 antagonist prevented photoimmune suppression, confirming the immunoregulatory importance of the lymph node B cells (Byrne et al. 2008).

63.4.2 Molecular

63.4.2.1 Cytokines and Eicosanoids

The release of specific cytokines by different cell populations in response to the UV damage plays an important role in photoimmune suppression. The balance of Th-1/Th-2 cytokines becomes deranged in UV-irradiated skin, with an abnormal predominance of the suppressive Th-2 cytokines, primarily IL-4 and IL-10 at the expense of the pro-inflammatory Th-1 molecules IL-2, IL-12, and IFN- γ (El-Ghorr and Norval 1997; Rivas and Ullrich 1994). Immunohistochemical staining reveals these soluble mediators are present diffused throughout the UV-irradiated mouse epidermis (Shen et al. 1999), and it is thought that they are released from the UV-damaged keratinocytes, which have been described as “bags of cytokines” susceptible to environmental damage. The repertoire may include IL-12, IL-10, IL-7, IL-15, IL-18, as well as several costimulatory molecules, which contribute to the direction of either Th-1 or Th-2 helper cell responses, but whether human skin responses are the same as those observed in mouse skin remains unclear at present (reviewed in Halliday and Rana 2007).

It is not clear whether *cis*-urocanic acid itself can affect cytokine production in the skin. In murine keratinocytes, there was no evidence of cytokine induction at the protein level by *cis*-urocanic acid, although mRNA for IL-10 and TNF α was induced (Redondo et al. 1996; Zac-Prelich et al. 2001). Certainly, *cis*-urocanic acid has been shown to initiate the transcription of genes for TNF α , IL-6, IL-8, as well as the pro-inflammatory transcription factor NF κ B, and enzymes of lipid peroxidation, in primary human keratinocytes (Kaneko et al. 2008). Serum levels of various cytokines are also modulated following UV exposure in mice, although this may not be true for humans (McLoone et al. 2004; Shreedhar et al. 1998).

The hallmark of the photoimmune suppressed state is the upregulated Th-2 cytokine IL-10 (Rivas and Ullrich 1992, 1994). This cytokine is known to mediate immune suppression in many tissues and

to play an important natural role in the conclusion of inflammatory reactions in the body. However, when overexpressed, or not counterbalanced by Th-1 expression such as functional IL-12, immune suppression prevails. It is relevant that exogenous IL-12 can prevent photoimmune suppression in mice (Schmitt et al. 2000; Schwarz et al. 1996). Importantly, it is also apparent that IL-12 can induce DNA repair (Schwarz et al. 2002), and this is via nucleotide excision repair because it does not occur in NER-deficient mice (De Vries et al. 1995; Schwarz et al. 2005). Possibly, the LCs are the targets for IL-12, because DNA-damaged LC numbers migrating to the regional lymph nodes were reduced by IL-12 injection in mice (Schwarz et al. 2005).

In addition to the altered cytokine profile, there is a major contribution to photoimmune suppression by the inflammatory prostaglandins such as PGE₂. Synthesis of such eicosanoids is activated by UV irradiation, following the rapid production of the oxidized phospholipid product and inflammatory mediator PAF, the upregulation of phospholipase A, and the release of the precursor arachidonic acid from cutaneous cell membrane phospholipids. The production of IL-4 and IL-10 follows with the outcome of immunosuppression from this cascade (Shreedhar et al. 1998). In mice, treatment with PAF antagonists, or with nonsteroidal anti-inflammatory drugs that inhibit the cyclooxygenase that catalyzes PGE₂ synthesis from arachidonic acid, also inhibits immunosuppression by UVB or *cis*-urocanic acid (Jaksic et al. 1995; Walterscheid et al. 2002), and reduces the severity of photocarcinogenesis induced in mice (Fischer et al. 1999; Pentland et al. 1999; Reeve et al. 1995; Sreevidya et al. 2008).

63.4.3 Convergence of DNA Damage and *cis*-Urocanic Acid Pathways

It has been pointed out (Sreevidya et al. 2010) that repairing UV-induced CPDs with exogenous T4N5 endonuclease, neutralizing *cis*-urocanic acid, blocking the PAF receptor, and blocking *cis*-urocanic acid binding to the 5-HT receptor, all prevent photoimmune suppression in mice. In contrast, treating mice with PAF, 5-HT, or *cis*-urocanic acid, each induces immunosuppression. When PAF or 5-HT pathways were blocked with receptor antagonists in UV-irradiated mice, and the major DNA lesions induced by the UV were assessed, it was found that there was a delayed and significant reduction in the numbers of CPDs, in the second most relevant DNA lesion, the 6,4-photoproduct, and in the oxidized lesion 8-oxo-dG. This finding was the first evidence that UV-induced immunosuppressive factors, PAF and *cis*-urocanic acid, can inhibit DNA repair, apparently by inducing oxidative stress, and it also provides a mechanism for the established protection against photocarcinogenesis by the inhibition of *cis*-urocanic acid activity. However, these new data must be considered together with the also new but contrary evidence that endogenous urocanic acid may photoprotectively inhibit epidermal DNA damage in the mouse (Barresi et al. in press). Obviously, there is a need for clarification here.

63.5 Wavelength Dependence

63.5.1 UVA versus UVB

Terrestrial solar UV radiation has been arbitrarily divided into the UVB (290–320 nm) and UVA (320–400 nm) wavebands, with UVA further defined as UVAI (340–400 nm) and UVAII (320–340 nm). Experimental UV sources can be used to produce selected spectral regions by the use of optical filters, and even narrow bandwidth regions that have been used to establish action spectra, or the critical wavelengths, for various UV-induced pathologies like erythema, DNA damage, and cancer induction. However, defining the wavelengths responsible for photoimmune suppression remains a controversial issue. While there is no argument that the UVB waveband is immunosuppressive, the role of the longer wavelength UVA is less clear. In mice and humans, there is much conflicting evidence as to whether UVA is immunosuppressive, and several reviews have attempted to rationalize the data but without overall success (Damian et al. 2001; Halliday et al. 2004; Phan et al. 2006; Reeve and Tyrrell 2007; Ullrich 2005). The issue for humans is important from a sun protection perspective, since the design

of an ideal sunscreen depends on the knowledge not only of the inflammatory burning wavelengths (agreed to be UVB), which do match the action spectrum for cancer induction at least in mice, but also those causing immunosuppression. Many studies in mice and humans have compared photoimmune responses after irradiation through sunscreens of different UV-absorbing properties, and there is general consensus that sunscreen protection from UVA as well as UVB radiation is necessary for optimal inhibition of immunosuppression (Damian et al. 1997; Fourtanier et al. 2008; Moyal and Fourtanier 2008). However, there exists significant contrary evidence from mice and humans that, in fact, UVA may not be immunosuppressive.

The recall antigen responses in nickel-sensitive UV-irradiated humans were reported to differ according to waveband, UVB being dose dependently suppressive, while UVA suppression was detected only transiently (Damian et al. 2001). In mice, the UVA content of minimally erythemogenic solar-simulated UV radiation did not suppress CHS or DTH, although fractionating the UVA dose unexpectedly acquired suppressive properties that are difficult to explain (Byrne et al. 2002, 2006). Interestingly, when the activation of lymph node B cells was the measure of immune response in mice, UVB was suppressive but UVA remained innocuous (Byrne et al. 2005). Recent mouse studies attribute UVA immunosuppression to the UVAI band and claim that the longer wavelength UVAI is immunologically innocuous (Ullrich 2007). This observation is consistent with evidence in human volunteers showing that while UVB suppressed LC-mediated antigen presentation, UVAI was innocuous (Dittmar et al. 1999), and these studies raise the question of the accuracy of experimental divisions into UVA and UVB regions of what is a continuous solar UV spectrum. Further problems arise from the demonstrated genetic dependence in wavelength-dependent immune response observed between mouse strains (Byrne et al. 2002), and the different methods for assessing immune function, which may target different phases of the immune response that need not all be affected in the same manner.

63.5.2 UVA/UVB Interactions

Interesting waveband interactions have been observed in mice to modulate the photoimmune response. In an early report in haired C3H mice, it was observed that the power of different broadband laboratory UV radiation sources to suppress CHS was reduced as the UVA content of these sources increased (Roberts et al. 1996). The UVA and UVB wavebands were separately shown to induce the expression of different cytokines in human keratinocytes (Kondo 1999) and also in the hairless mouse epidermis, in which an immunohistochemical study found that the UVB-induced upregulation of IL-10 was reversed if an exposure to UVA followed (Shen et al. 1999). This was later correlated with the modulation of immune function by UVA radiation, which was shown to provide a dose-dependent protective effect against UVB- or *cis*-urocanic acid-induced suppression of CHS (reviewed in Reeve and Tyrrell 2007). Furthermore, immunologically innocuous exposure to UVA in haired mice was found to protect against UVB-induced immune tolerance (Byrne et al. 2002, 2006), and this was associated with the UVA inhibition of the UVB-increased expression of IL-10 mRNA (Stapelberg et al. 2009).

63.5.3 Role of Heme Oxygenase-1

The powerful induction of the stress protein heme oxygenase-1 (HO-1) in UVA-irradiated primary human skin fibroblasts (Tyrrell 1991) suggested that HO-1 might have immunological relevance. It was found that the photoimmune protective doses of UVA radiation also induce HO-1 activity in mouse skin (Reeve and Tyrrell 1999; Allanson and Reeve 2004), and at least one of its enzymatic products, gaseous carbon monoxide, plays a major role in the mouse skin in protecting against photoimmune suppression (Allanson and Reeve 2005). A pathway of UVA-induced cutaneous biochemistry has been revealed showing that the HO-1-produced carbon monoxide acts via the enzyme soluble guanylyl cyclase. Its product, cyclic guanosine monophosphate (cGMP), accumulates in UVA-irradiated skin, and the levels in the skin dose dependently determine the photoimmune protection. Inhibition of the

normal phosphodiesterase (PDE)-catalyzed degradation of cGMP in the skin by topical application of the PDE-5 inhibitor sildenafil was photoimmune protective. Furthermore, mimicking the UVA-induced enzymatic production of carbon monoxide by topical application of a carbon monoxide-releasing molecule to the irradiated skin of mice reduced the severity of photocarcinogenesis (Allanson and Reeve 2007). Since HO-1 induction is a response not only to UVA radiation, but many endogenous and environmental stressors, it is of interest that treating mice with short-term physiological stress (involuntary restraint) during a photocarcinogenesis induction protocol was also recently reported to reduce the severity of the tumor outcome in an immune-protected manner (Dhabar et al. 2010).

The UVA photoimmune protective effect is active in solar-simulated radiation by its UVA component and is UVA dose dependent (Allanson et al. 2006) within a dose window equivalent to the UVA component of approximately 1–6 h of sunlight. Larger UVA doses then become immunosuppressive additively with the UVB (Reeve et al. 2006). The UVA content has been shown to attenuate cutaneous DNA damage and apoptosis in a HO-dependent manner in hairless mice (Ibuki et al. 2007). It remains to be seen whether such waveband interactions also apply to humans, who are prone to prolong their recreational sunlight exposure after using topical sunscreens and thus to absorb disproportionately high amounts of UVA radiation. Waveband interactions will have an important input into future sunscreen design if the UVA waveband is found to have the same advantageous properties that might protect not only mice but humans against sunlight-induced skin cancer development.

63.6 Photoimmune Protection (Non-Sunscreen)

63.6.1 Repair of DNA Damage

It has been demonstrated that treatment of UV-damaged skin with liposomally encapsulated DNA repair enzymes can reverse photoimmune suppression. Both the T4N5 endonuclease and the photolyase photoreactivating enzyme have been used successfully in humans in this way, with considerable advantage particularly for *xeroderma pigmentosum* patients who are genetically deficient in these pathways (Ke et al. 2008; Kuchel et al. 2005; Stege et al. 2000; Wolf et al. 2000).

63.6.2 Bioactive Phytochemicals

Many plant-derived extracts, or purified single phytochemicals, often substances long recognized in traditional medicine, have been reported to have photoimmune protective characteristics, and in numerous reports also to reduce the development of skin cancers. Most frequently, such extracts have powerful antioxidant potential, and their photoimmune protective properties have been demonstrated to be a function of these properties. The active compounds are commonly but not exclusively polyphenolic flavonoids like *Camellia* sp. (green tea), or isoflavones (genistein and daidzein) or proanthocyanidins (grape seed) that possess innate antioxidant activity due to their polyhydroxy molecular structure, but other extracts rich in sulfhydryl groups as in *Allium* sp. (garlic), or in glycosylated polysaccharides (tamarind and goji berry; Strickland 2001) have shown immunoprotective activity. The antioxidant vitamins C and E have also been demonstrated to protect against photoimmune suppression (Nakamura et al. 1997; Yuen and Halliday 1997), and recently, a further vitamin, nicotinamide (vitamin B3), has also shown photoimmune protection from topical or oral administration in mice and humans (Damian 2010). A number of comprehensive reviews have been written (Afaq et al. 2005; Katiyar 2005, 2007; Katiyar et al. 2001; Nichols and Katiyar 2010; Reeve 2001). Traditional Chinese medicine provided historic evidence for multiple health benefits in humans of *Lycium barbarum*, the goji berry, and a new report describes the photoimmune protection of goji berry juice consumption in mice (Reeve et al. 2010). This effect may be related to the report of photoimmune protection in humans supplemented with oral probiotic bacteria (Peguet-Navarro et al. 2008), since glycosylated cell wall polysaccharides appear to be common ingredients to each and have been shown to have relevant health benefits from at least the goji berry.

Complex extracts such as Pycnogenol, a standardized extract from the bark of the French maritime pine *Pinus pinaster*, and Propolis, the waxy honey-bee product, have also been found to afford photoimmune protection in mice from topical application (Cole et al. 2010; Sime and Reeve 2004).

63.6.3 Inducible Antioxidant Pathways

The skin, like other tissues, is well protected against moderate oxidative stress by radical scavenging molecules and enzymes like glutathione, glutathione peroxidase and reductase, catalase, and superoxide dismutase. In addition, two significant inducible responders have been shown to be important photoimmune regulators.

63.6.3.1 Metallothionein

This cysteine-rich protein, best known for its heavy metal chelating properties, also responds robustly to inflammatory cytokines and reactive oxygen and nitrogen species (Hanada et al. 1992). In the skin of mice and humans, it is induced by UVB radiation in the basal and suprabasal epidermal keratinocytes and also in dermal fibroblasts (Ablett et al. 2003; Nishimura et al. 2000). Its photoimmune protective role was shown in metallothionein gene knockout mice, which displayed an exacerbated suppression of CHS by either UV radiation or *cis*-urocanic acid (Reeve et al. 2000). Furthermore, the photoimmune properties of isoflavones or of goji berry juice in mice were reduced in the metallothionein-deficient mice, indicating the significant protective role of this molecule (Reeve et al. 2010; Widyarini et al. 2006a).

63.6.3.2 Heme Oxygenase-1

This stress enzyme, also recognized as heat shock protein-32 in humans, is highly inducible by UVA, but not UVB, in the skin. The gene is activated under many stressful conditions such as hyperoxia, hypoxia, heat, inflammation, heavy metal toxicity, by signaling via transcription factors Nrf2 and AP-1, or by its enzymatic substrate heme. Its inducibility particularly by the UVA waveband has been shown to inhibit photoimmune suppression in mice, as discussed in Section 63.5.3. The immediate products of the enzymatic activity are equimolar amounts of biliverdin, carbon monoxide, and ferrous iron. The fate of the free iron may be important, particularly in conditions of overexpression constitutively, but lack of inducibility, of HO-1 activity, such as have been reported in IL-6-deficient mice, and also in Er- β gene knockout mice (Reeve et al. 2008, 2009).

63.6.4 Estrogen Receptor (Er) Signaling

An interesting series of studies in mice treated topically with an isoflavone, equol, which is related to the primary isoflavone genistein, reported dose-dependent protection from photoimmune suppression of CHS and from photocarcinogenesis (Widyarini et al. 2001, 2005), and supportive evidence for photoimmune protection by equol in humans followed (Friedmann et al. 2004; Widyarini et al. 2006a). It was assumed that this compound, like most flavonoids, was acting as an antioxidant. However, the class of isoflavones is also recognized as phytoestrogenic, and it transpires that equol's photoimmune protective effect could be abrogated by Er blockade in mice (Widyarini et al. 2006b). Thus, a natural photoimmune regulatory role for Er signaling was revealed. Further studies have reported that it is the nonclassical Er- β that plays this role (Cho et al. 2008), and that modulation of the epidermal cytokine pattern is consistent with the protection of the CHS response from UV radiation by Er- β signaling. In Er- β gene knockout mice, there is exacerbated sensitivity to UV-induced erythema, suppression of CHS, and accelerated growth of transplanted skin tumors (Cho et al. 2010). Recent supportive evidence describes significant protection against photocarcinogenesis induction in hairless Skh:hr-1 mice by topical treatment with an Er- β agonist, which also inhibited malignant progression of the tumors, reduced the UV-activation of the mitogen activated protein kinase (MAPK) pathway, and repressed the expression of the proliferation markers proliferating cell nuclear antigen (PCNA), cyclin D1, and vascular endothelial growth factor (VEGF) (Singh et al. 2010).

In a further study, it has been found that the Er- β gene knockout mice have lost the capacity for HO-1 induction in response to UVA irradiation. This indicates that the photoimmune protective Er- β signaling relies on the UVA-inducibility of HO-1, the stress enzyme already established as contributing importantly to photoimmune suppression (Reeve et al. 2009). The mechanisms that underlie these interdependent protective pathways now await definition.

63.6.5 Gender Bias

Consistent with the evidence of photoimmune protection afforded by the Er- β , a gender bias in UV responses has been sought in mice and humans. Male mice have been reported to be more susceptible than females to photoimmune suppression (Hiramoto et al. 2004). Male Skh:hr-1 mice have also been reported to be more susceptible than females to photocarcinogenesis induction (Thomas-Ahner et al. 2007), with apparent estrogen protection against tumor progression from benign papilloma to malignant squamous cell carcinoma that was associated with an increase in the Er- α /Er- β ratio and upregulation of cyclin D1 (Mancuso et al. 2009), consistent with the findings of Singh et al. (2010) noted earlier.

These studies have been conducted in mice; however, whether humans also have a gender bias in immune responses to UV radiation remains uncertain. Photoimmune suppression was observed to be greater in men than women volunteers when elicitation of the Mantoux reaction was the immune test (Damian et al. 2008), although a gender bias was not found in a retrospective study that used dinitrochlorobenzene as a contact sensitizer, thus assessing both sensitization and elicitation reactions, but avoiding testing women within 5 days of their menstrual period (Morrissey et al. 2008). In addition, the level of cutaneous urocanic acid, anticipated to indicate the level of photoimmune susceptibility, when restricted by a polymorphism of the cutaneous histidase gene, appears to be associated with development, rather than inhibition, of squamous cell carcinoma particularly in women, and in women taking oral contraceptives (Welsh et al. 2008). This adds complexity to the human data by suggesting an anticancer function for urocanic acid as proposed for mice by Barresi et al. (in press), but in a manner modulated by estrogenic activity.

Nevertheless, substantial epidemiological data indicate that non-melanoma skin cancers (Armstrong and Kricker 2001; Foote et al. 2001; Graelis 2004; Hayes et al. 2007; Ramachandran et al. 2003; Scrivener et al. 2002; Staples et al. 2006), and possibly melanomas (Molife et al. 2001), are more prevalent in men than in women. It is therefore apparent that the potential gender bias in the role of the immune system response to UV radiation needs to be clarified.

63.7 Temporal UV Irradiation Studies

63.7.1 Neonatal UV Exposure

Migrant studies and epidemiological reports have demonstrated that childhood overexposure to sunlight is a major risk factor for skin cancer development later in life (Cooke and Fraser 1985; Khlát et al. 1992; Kricker et al. 1991; Whiteman et al. 2001). Therefore, it has been of interest to examine the neonatal immune response to UV irradiation, as neonatal immunity is relatively immature and is known to be prone to tolerance induction and to the generation of antigen-specific Treg cells that are long-lived and are detectable in the adult. Furthermore, the neonatal skin is resistant to inflammation, and even in response to large UVB doses, fails to develop an acute inflammatory reaction (Wolnicka-Glubisz et al. 2007). Studies of the LC responses to UV exposure in neonatal mice have identified that these cells differ from adult LC, do not express DEC-205 or langerin, have fewer dendrites, and are less efficient in transporting antigen to the draining lymph node (reviewed in Muller et al. 2008). When the draining lymph node cells were analyzed in adult mice after neonatal UV irradiation, an increase in the percentage of Treg cells and B cells was found compared with controls (McGee et al. 2009), consistent with the photoimmune suppressed state. Thus, neonatal UV irradiation results in a tolerogenic phenotype in the adult, and this immune deficit may account for the increased risk of skin cancers developing in adults.

63.7.2 Chronic UV Exposure

Much of our understanding of photoimmunology has come from acute or short-term UV irradiations in mice and humans. Less is known about immune status in chronically UV-irradiated skin. There is evidence in mice and humans that a form of photoadaptation occurs with repeated UV exposures that might be a reflection of the developed epidermal hyperplasia and thickened *stratum corneum* providing a greater physical barrier against the radiation. This adaptive response can then provide enhanced photoprotection against erythema development from a larger UV exposure. However, whether the immune system can also be primed for resistance in such a way remains improbable. An excellent review has summarized the current available evidence (Norval et al. 2008) and shows that only the induction of epidermal DNA damage and erythema, and possibly the infiltration into the skin of macrophages bringing immunosuppressive cytokines, are reduced by continuing UV exposures. Other markers of the photoimmune response such as urocanic acid levels or isomerization, LC persistence, mast cell numbers, or the CHS and DTH reactions have not shown photoadaptation in chronically irradiated skin.

However, in patients who suffer from the common “sun allergy” or polymorphic light eruption (PLE), a resistant photoimmune suppressive reaction to UV radiation has been identified. PLE patients reveal a combination of a dramatic persistence of the epidermal LC after a UVB exposure (Kolgen et al. 1999), a much reduced infiltration of CD11b+ macrophages/monocytes that are contributing producers of immunosuppressive IL-10 (Kang et al. 1994), and a resistance to photoimmune suppression of CHS (reviewed in De Gruijl 2008; Palmer and Friedmann 2004; Van de Pas et al. 2004). The usual therapy for PLE, “UV hardening,” consists of a series of mild UV exposures over several weeks in Spring that result in resistance against activation of the PLE symptoms by summer sun exposure, and has been shown not only to increase the patients’ resistance against erythema but also to restore the UVB-induced depletion of the LC and the infiltration of the macrophage population (Janssens et al. 2005). Thus, in this disease state, there is evidence that a normalization or photoadaptation of immune function can be induced. It may be significant that females predominate among PLE patients, consistent with their potentially more resistant photoimmune responses.

63.8 Conclusions

As our understanding of photoimmunology has progressed, rather than simplification, increasingly complex pathways and their interactions that regulate this important reaction of the skin to UV radiation have come to light. Multiple cell populations are now known to play a role—LC, T and B cells, mast cells, macrophages, keratinocytes, and more. Multiple modulatory pathways are also now known—DNA lesions, urocanic acid, cytokines, eicosanoids, oxidized lipids, stress proteins, steroid hormone receptors, and enzymes. The challenge now is to clarify whether and how these converge, and which mechanisms predominate for ultimate importance.

Photoimmune suppression is such a well-conserved function of the skin that it has always seemed as if it must have some form of biological advantage. This is now believed to be a protective role against the development of autoimmune responses against self-antigens induced by the UV radiation. However, this comes with the disadvantageous facilitation of the survival and growth of UV-initiated skin tumors. When the balance between these two outcomes is interrupted, either dermatological eruptions occur as in PLE, which can be treated by reinstating the photoimmune suppressive response, or the risk of skin cancer increases. This is well illustrated by the observation that PLE incidence is strongly reduced among skin cancer patients, and that skin cancer is reduced in patients with PLE (Lembo et al. 2008). Thus, the best mode of protection against both skin damage and cancer development might not be by totally inhibiting photoimmune suppression, but by maintaining a healthy balance, were it possible to determine exactly what that might be.

64.1 Introduction and Background

Photodynamic therapy (PDT) is a clinically approved modality that utilizes a photosensitizing compound in conjunction with light and molecular oxygen to produce a localized cytotoxic effect. The photosensitizer is nontoxic in the absence of light. PDT has gained greatest acceptance in the fields of oncology (especially oncological dermatology) and ophthalmology, although other non-oncological and antimicrobial applications have recently begun to be exploited. Specific illumination of the photosensitizer results in the local formation of reactive oxygen species, primarily singlet oxygen, causing a variety of direct and indirect cytotoxic effects on the cellular targets, discussed in more detail in Section 64.2.

Clinical approval has been achieved in the treatment of skin, bladder, lung, head and neck, and esophageal cancers and in certain precancerous conditions (Brown et al., 2004); and the fluorescent properties of photosensitizers can also be used in cancer diagnosis (photodiagnosis). The potential benefits of PDT as an anticancer therapy include its unique targeting mechanisms and the fact that it is relatively noninvasive, induces minimal side effects, is capable of leaving no permanent scarring, and can be administered without lengthy hospital stays. Recent research in the field of oncology has focused on the development of methods by which photosensitizers can be actively targeted to

tumor tissue. PDT is also emerging as an option in the antimicrobial field, for a number of indications, where the potential for a rapid and painless treatment, to which the bacteria are unable to generate resistance, makes it an attractive alternative to antibiotics.

The first reported study of photodynamic action was carried out by Oscar Raab, a German medical student in 1897. He studied the effect of acridine on paramecia and found that light played a role in toxicity. The research group then carried out a number of experiments on photosensitization and discovered that oxygen was also necessary for an effect (described by Moan and Peng, 2003). The first report of human photosensitization was by Friedrich Meyer-Betz in 1913 who tested the effect of hematoporphyrin (on himself) and observed erythema and edema in light-exposed areas. The observation (from fluorescence) that porphyrins exhibit weak selectivity to tumor tissue led to PDT being used as an anticancer treatment, and attention was focused on the identification and purification of suitable photoactive compounds. Hematoporphyrin itself was shown to be a poor PDT agent as it is not effectively retained in tumor tissue. Acetylation and alkaline hydrolysis of hematoporphyrin produces a complicated mixture of mono- and di-acetylated porphyrins and a number of dehydration products. Neutralization of the mixture produces an even more complex mixture of monomers, dimers, and oligomers. This mixture [hematoporphyrin derivative (HpD)] was used in the majority of the early clinical PDT studies including the diagnosis and treatment of bladder cancers. Partial purification and analysis of HpD revealed that the most photoactive component was the oligomeric fraction and an oligomeric-rich HpD preparation was thus produced. This mixture was still complex, consisting of various number of porphyrin molecules linked by ester, ether, and carbon-carbon bonds but it was shown to have improved PDT activity. The mixture was named Photofrin[®] and, in Canada on April 19, 1993, it became the first photosensitizing compound to receive regulatory approval for clinical use.

A wide variety of conditions have now been successfully treated with Photofrin[®] including cancers of the bladder and lung. However, Photofrin[®] has several serious drawbacks as a photosensitizer. The complex mixture is difficult to reproduce exactly. It also shows limited selectivity for tumor tissue and has a low absorption coefficient at tissue-penetrating wavelengths. Patients can also exhibit cutaneous phototoxicity for several weeks after treatment with Photofrin[®] and so have to avoid strong sunlight. These disadvantages of Photofrin[®] as a photosensitizer have led to concentrated research into a number of second- and third-generation photosensitizers, discussed further in Section 64.4. Research is aimed at developing pure compounds that exhibit higher selectivity and have greater extinction coefficients at longer wavelengths (to maximize light penetration through tissue and reduce UV sensitivity).

Despite the intense research undertaken with the aim of optimizing PDT as a cancer therapy, perhaps the greatest clinical success to date is that achieved in the field of age-related macular degeneration (AMD). The success of Visudyne in targeting the abnormal blood vessels in AMD patients is discussed further in Section 64.9.

64.2 Photochemistry of PDT

For successful photodynamic treatment, a photon of visible light emitted from a suitable illumination source must be absorbed by a photosensitizer. The photosensitizer is transformed from its ground state (⁰S) to a short-lived excited singlet state (¹S*) (Figure 64.1). The ¹S* molecule is very short-lived and rapidly loses its additional energy by either fluorescence, loss of heat (internal conversion) or by undergoing intersystem crossing to form the triplet state (³S*). The photosensitizer in the triplet state is a much longer living molecule and can react in two ways:

- The ³S molecule can react via a type 1 reaction with a cellular substrate. Electron or hydrogen transfer forms a photosensitizer radical (S[•]) and a substrate radical (X[•]). The radicals can then react with each other, further substrates or molecular oxygen to propagate the reaction and form reactive oxygen species including the superoxide anion radical (O₂^{•-}).

FIGURE 64.1 Simplified Jablonski diagram. The photosensitizer in the ground state (0S) absorbs light to become excited ($^1S^*$). This energy can be lost via fluorescence, or the molecule can undergo intersystem crossing to form the longer lasting triplet state ($^3S^*$) molecule, which then reacts with oxygen or cellular substrates to form cytotoxic reactive oxygen species.

- A type 2 reaction can occur between the excited triplet photosensitizer and molecular oxygen. This direct energy transfer results in the formation of singlet oxygen (1O_2), which is not a free radical and re-formation of the ground-state photosensitizer.

In the type 2 reaction, the photosensitizer does not itself undergo any chemical change, but simply cycles between different electronic energy states. Thus, once the triplet state photosensitizer has lost its energy and returned to the ground state, further illumination allows further excitation. Type 1 and type 2 reactions can occur simultaneously within a single cell, although it is thought that it is the formation of singlet oxygen via type 2 reactions, which is responsible for the majority of the cytotoxic damage in PDT. Further discussion surrounding the actions of the newly formed reactive oxygen species, and the consequences for the affected cells and tissues, can be found in Section 64.6.

64.3 Requirements for PDT to Become Clinically Successful

The key requirements for any novel therapy to become clinically successful are centered around treatment efficacy and economic viability. Clearly commercial development is essential for the wide use of PDT and, in this regard, the two key components required for a PDT treatment are the photosensitizer and the light source.

Much debate around the properties of an “ideal” photosensitizer can be found in the literature. Clearly a high level of PDT activity is required, usually measured by the quantum yield of singlet oxygen. A high specific absorption coefficient at wavelengths above 600 nm is desirable as light penetration through tissue increases with wavelength. There are many indication-specific requirements for photosensitizers, for example, only cationic photosensitizers can achieve a broad-spectrum antibacterial effect as anionic (and neutral) compounds are unable to efficiently cross the cell wall of Gram-negative organisms. Similarly, photosensitizers can be chosen for their ability to localize to certain areas of tumor cells or tissues.

From a pharmaceutical development point of view, photosensitizers must meet the same criteria as any other drug candidate: the drug should be able to be reproducibly and easily manufactured with a high level of purity. Complete toxicology packages are required: the compound must be nonmutagenic, noncarcinogenic, and minimally toxic in the absence of light. The compound should show optimal absorption, distribution, metabolism, and excretion (ADME) characteristics for the chosen route of administration and should not yield any toxic metabolites. Commercially, the intellectual property position is critical, along with a robust formulation and drug delivery system.

Light sources for PDT need to be simple to use and as inexpensive as possible. Much PDT is laser-based and lasers are essential for illumination of internal lesions. For superficial treatments however (e.g., of skin cancer), lasers are not required, and recent developments in LED technology have led to this option becoming economically favorable. The penetration of light through tissue is key to treating the complete depth of the lesion; therefore, light at a wavelength of greater than 600 nm is desirable. Further consideration of light sources is given in Section 64.7.2.

64.4 Photosensitizers

A vast array of molecules has been found to have photosensitizing abilities, but only a small proportion of those have been used in PDT beyond the laboratory. Several classes of photosensitizer are currently under study including porphyrins, chlorins, bacteriochlorins, phthalocyanines, and phenothiazinium salts.

64.4.1 Porphyrins

The general porphyrin structure is comprised of four pyrrole rings connected by methylene bridges, producing a highly delocalized structure. The side-chain composition gives each porphyrin its unique biological properties. Porphyrins are naturally occurring molecules and have a characteristic absorbance spectrum with maximal absorbance occurring at the Soret band (around 400 nm) and further absorbance peaks (Q bands) at higher wavelengths. For PDT, the Q band at around 630 nm is used to activate the porphyrins, as longer wavelengths of light penetrate the tissue more effectively. HpD and Photofrin are first generation porphyrin photosensitizers and were key to the development of PDT as a treatment modality. Despite being a complex mixture of oligomers, Photofrin is the most widely approved photosensitizer and is currently approved for the treatment of esophageal cancer, lung cancer, gastric and papillary bladder cancer, and cervical cancer/dysplasia. However, the prolonged skin photosensitization and suboptimal tissue penetration have limited its clinical success and have driven research into second- and third-generation photosensitizers.

64.4.2 ALA-PDT

A number of porphyrins play a key role in the heme biosynthetic pathway (Figure 64.2). In this process, 5-aminolevulinic acid (ALA) is synthesized from glycine and succinyl CoA by ALA synthase. This is followed by sequential reactions forming porphobilinogen, hydroxymethylbilane, uroporphyrinogen III, coproporphyrinogen III, protoporphyrinogen IX, and protoporphyrin IX. The addition of Fe^{2+} to protoporphyrin IX by ferrochelatase is the final step in the pathway and produces heme. Protoporphyrin IX is a highly efficient photosensitizer and manipulation of this physiological process gives rise to one of the most successful methods of PDT treatment, ALA-PDT.

ALA is widely used as a prodrug in dermatological PDT. ALA itself has no photosensitizing properties but, when given exogenously to tumor cells, the porphyrin biosynthesis pathway becomes overloaded and ferrochelatase cannot immediately convert all the protoporphyrin formed to heme. An accumulation of protoporphyrin IX can thus be induced and, upon illumination, a strong PDT effect is seen.

Levulan is the commercial name given to formulated ALA, and this was approved by the FDA for the topical treatment of actinic keratoses (AKs) in 1999. It has also been shown to successfully treat other nonmelanoma skin cancer (NMSC; Clark et al., 2003). The methyl ester of ALA (Metvix) has also been approved for topical PDT in NMSC. Metvix has similar photochemical and photophysical properties to Levulan but a higher lipophilicity allows greater penetration through skin. Metvix has been approved for the treatment of AK and basal cell carcinoma (BCC) in Europe. The major limitations of Levulan and Metvix therapy are the depth of penetration through tissue (which limits the treatable lesion depth) and

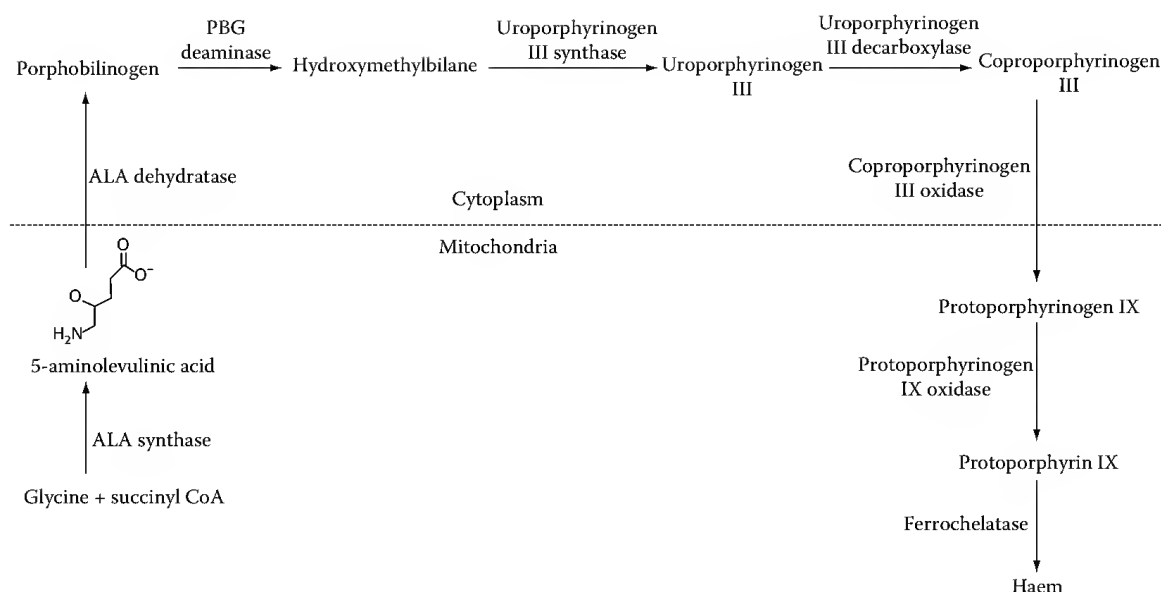

FIGURE 64.2 The heme biosynthetic pathway.

the pain associated with treatment (thought to be due to the accumulation of photosensitizer in nerve tissue). Comparisons between Levulan and Metvix have suggested a similar level of efficacy in AK, with Metvix having an advantage in deeper malignant lesions and also possibly causing less pain (Moloney and Collins, 2007).

64.4.3 Chlorins and Bacteriochlorins

Reduction of the porphyrin chromophore at a pyrrole ring produces a chlorin. This results in a wavelength shift out to the red region and an increase in the molar absorption coefficient, both desirable properties for increasing photosensitizer PDT efficiency. It also may improve the ability of the compounds to effectively penetrate tissue. Benzoporphyrin derivative (BPD) is a complex chlorin preparation but has been further developed to produce BPD monoacid ring A (verteporfin). This compound has shown much promise as a PDT agent and has a high molar extinction coefficient at 686 nm. It is taken up into cells via low density lipoprotein (LDL) receptor-mediated endocytosis and has a significantly damaging effect on tumor vasculature, although the specificity for tumor tissue is not very high. The compound has been used in the treatment of skin cancer, rheumatoid arthritis, endometrial ablation, and especially in AMD (as Visudyne™). Visudyne's use in AMD is the most commercially successful non-oncological use of PDT.

The chlorin, meta-tetra(hydroxyphenyl)chlorin (mTHPC, Foscan) has much greater photoactivity than Photofrin. It was developed for the treatment of cancers of the head, neck, esophagus, and lung and was clinically approved for use in Europe in 2001. Superior photophysical properties and a higher singlet oxygen yield allow much lower drug doses and light intensities to be used to achieve a comparable clinical effect to that seen with Photofrin. However, prolonged skin photosensitization remains an issue, as does the long drug-to-light time interval required.

Further reduction of the chlorin ring produces a bacteriochlorin. This results in a significant red shift in the longest wavelength Q band and an increase in the molar absorption coefficient. Reduction of mTHPC produces the bacteriochlorin, mTHPBC, which has been shown to have potential in the treatment of liver metastases, causing tumor necrosis in all patients taking part in a Phase I clinical trial (van Duijnoven et al., 2005). Bacteriochlorins are the subject of active research in PDT (Huang et al., 2010), and the bacteriochlorin derivative Tookad is in clinical trials for focal ablation of prostate cancer (Huang et al., 2007; Trachtenberg et al., 2008).

64.4.4 Phenothiazinium Salts

Phenothiazinium salts are planar, aromatic blue dyes with a tricyclic ring structure and an overall cationic charge, allowing the molecule to form a complex with an anionic counter ion. Originally used in the dyeing industry, the phenothiazinium salt methylene blue has long been used as a tumor marker and is an effective *in vitro* photosensitizer, although its *in vivo* use has been limited due to low photodynamic activity, relatively high dark toxicity and subcellular localization to the nucleus, causing significant potential mutagenicity. Other drawbacks include the hydrophilic structure, which makes it very inefficient at entering cells.

Analogues of methylene blue have been synthesized with the aim of increasing the hydrophobicity of the compounds to allow easier delivery of the drug to tumor tissue and reducing the dark toxicity and nuclear accumulation. Particular emphasis has been placed on characterizing a series of symmetrical and asymmetrical methylene blue derivatives for use in PDT. These compounds have maximal absorbance peaks at a good tissue-penetrating wavelength, typically around 680 nm (Mellish et al., 2002; Walker et al., 2004) and have demonstrated excellent antibacterial and antiparasitic activity (Akilov et al., 2007; Akilov et al., 2009). Phenothiazinium salts are now in clinical trials for antimicrobial PDT (see Section 64.10)

64.5 Targeted PDT

As with other cancer therapies, much research has recently been put into developing methods, which will allow specific targeted delivery of photosensitizers to tumor tissue and into developing methods to prevent photosensitizer accumulation in non-target tissue. Ideally, the photosensitizer would be able to specifically accumulate within the target tumor tissue without any accumulation in healthy tissue. This absolute localization of the cytotoxic effect would allow greater light doses to be used clinically and may increase treatment efficacy without the side effects associated with systemic phototoxicity. The use of an active targeting mechanism may also increase the usefulness of many compounds, which show good photodynamic properties but are currently of limited use because they do not enter tumor cells effectively.

A complete review of the strategies employed in an attempt to actively target photosensitizers to tumor cells is outside the scope of this chapter. Liposome constructs, antibody conjugates, nanotechnology, specific ligand–receptor interactions, and a variety of other approaches have been tested *in vitro* and some *in vivo*, but none have currently achieved regulatory approval for clinical use. The technologies vary in their approach. Liposome constructs are easily taken up by the cell, once inside they are lysed and their photosensitizer contents released to allow local intracellular photodynamic activation. It has been shown that a liposome:BPD conjugate accumulates within tumor tissue slightly faster and to a higher level than free photosensitizer (Richter et al., 1993). Liposome preparations have also been used to target tumor neovasculature with some success. However, this method of targeting is complicated by difficulties in delivering liposome constructs to tumor cells via irregular and disorganized blood vessels.

The first example of antibody-mediated photosensitizer delivery was reported in 1983. HpD was conjugated to a tumor-specific antibody, and an increased PDT effect was observed, compared to HpD alone (Mew et al., 1983). More recently, a phage-derived L19 antibody has been shown to specifically bind fibronectin on newly formed blood vessels. The accumulation of L19-conjugated photosensitizer in neovasculature allows targeted damage to these vessels. This interaction could be exploited in the treatments of many diseases characterized by new blood vessel formation such as cancers and ocular disorders. A range of photosensitizers has been conjugated to antibodies, including mTHPC, ALPcS₄, and chlorin e₆.

Natural ligand–receptor interactions have also been exploited to enhance specific photosensitizer uptake. Tumor cells have been shown to upregulate LDL and estrogen receptors, effectively internalizing appropriately coupled photosensitizers (Allison et al., 1994; Swamy et al., 2002). Very recent advances in nanotechnology have been applied to PDT, with the conjugation of methylene blue to nanoparticles (Hah et al., 2011).

It is also possible to actively target photosensitizers to the tumor vasculature, with the aim of destroying the blood vessels that feed the tumor to give a more long-term response. This can be achieved via the use of specific peptide sequences that bind molecular targets specifically expressed in the rapidly expanding tumor neovasculature. The upregulation of one such target, integrin $\alpha_v\beta_3$, in tumor neovasculature allows macromolecules to be targeted to these vessels via the conjugation of small arginine-glycine-aspartic acid (RGD) containing peptides such as c(RGDfK) (Conway et al., 2008). It has been recently suggested that targeting the tumor vasculature potentiates the stimulation of the immune system, which would assist with long-term tumor control, but studies in the area are ongoing (Preise et al., in press).

64.6 Mechanism of Action of PDT In Vitro and In Vivo

Upon PDT treatment, several processes occur and combine to damage or destroy the target cells. The formation of reactive oxygen species by the processes discussed in Section 64.2 allows direct damage to both prokaryotic and eukaryotic cellular components. In some therapeutic indications, indirect mechanisms such as tumor vasculature ablation or the activation of the host immune system are also critical for long-term disease control.

64.6.1 Direct Cytotoxicity

A direct cytotoxic response to PDT is observed when the reactive oxygen species generated are able to damage tumor cellular components and induce an apoptotic or necrotic response. This response is dependent upon the subcellular localization of the photosensitizer and the availability of oxygen in the target tissue. Reactive oxygen species, particularly singlet oxygen (1O_2), have a very small diffusion distance (i.e., they react before they can travel very far). The exact measurement of the singlet oxygen lifetime has been a topic of much debate; most recently, the lifetime has been calculated at $3\mu s$ in a metabolically active cell (Hatz et al., 2008), with a resulting diffusion coefficient of $2-4 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ suggesting that the spatial domain of intracellular singlet oxygen will have a spherical radius of about 100 nm. Although these values are significantly greater than reported earlier (Moan and Berg, 1991), the ability of singlet oxygen to diffuse through the cell is still highly limiting and means that the site of primary intracellular damage is always very close to the photosensitizer location.

Many cellular components are susceptible to oxidative attack during PDT including proteins, lipids, and nucleosides. All but the very earliest photosensitizers are designed not to localize to the nucleus, making PDT very unlikely to induce DNA damage or have a carcinogenic effect. Mitochondrial localization of photosensitizers can cause depolarization or permeation of the mitochondrial membranes and induce a rapid apoptotic response via the release of cytochrome *c* and caspase cascade activation. Hydrophobic photosensitizers can localize to the plasma membrane. Here, the oxidation of unsaturated lipids causes a lipid peroxidation cascade and damage to the phospholipid bilayer. Such membrane damage can cause an alteration of membrane permeability and transport or a loss of membrane integrity resulting in rapid cell lysis, a necrotic pattern of death, and often the release of cellular contents inducing an inflammatory response. The induction of necrosis *in vitro* has been shown to be more dependent upon the PDT dose than the individual photosensitizer used; a more intensive PDT regimen gives rise to more necrotic changes and less apoptosis (Vantieghem et al., 1998).

The induction of apoptosis by PDT has been very well studied and recently reviewed (Ortel et al., 2009; Robertson et al., 2009; Reiners et al., 2010). This physiological process for the removal of redundant or potentially damaging cells can be activated by PDT, most often by photosensitizers that localize to the mitochondria of cells and, *in vitro*, under low-dose PDT conditions. The target cells undergo a series of carefully controlled chemical and physiological changes, which result in cell shrinkage and efficient phagocytosis by neighboring cells. As the changes that accompany apoptosis are common to

many different cell types responding to a variety of stimuli, it has been concluded that there is a common underlying program to cause cell death, and that PDT is able to stimulate the initiation of this process in various ways.

Photosensitizers that localize to lysosomes, such as methylene blue and aluminum phthalocyanine disulfonate (AlPcS₂), can cause lysosomal membrane rupture upon illumination and the release of cytotoxic components, such as the proteolytic cathepsin family, into the cytoplasm. However, the induction of apoptosis subsequent to lysosomal bursting is generally slower than after mitochondrial bursting, and it has also been reported that the lysosomal enzymes can be photoinactivated during PDT, which further limits the speed and extent of any cell damage. The observation that PDT with certain photosensitizers can result in lysosome degradation has led to the development of a technique for the intracellular delivery of therapeutic macromolecules known as photochemical internalization (PCI), discussed elsewhere in this book.

During and after PDT *in vivo*, both apoptotic and necrotic events can be seen, and both forms of cell death contribute to treatment success. Much research has illustrated that apoptosis can be initiated by PDT at various points of the signaling cascade and that the point of activation is dependent upon the subcellular localization of the photosensitizer. This most commonly occurs from the mitochondria via cytochrome *c* release or from the plasma membrane via death domain activation. Although apoptosis is an efficient form of cell death, the importance of the necrotic response to PDT should not be underestimated. Phagocytosis of apoptotic cell debris does not cause an immune response but the recruitment of leukocytes into tumor tissue is essential for complete tumor ablation and long-term tumor control. Under tightly controlled *in vitro* conditions, photosensitizers can be shown to cause almost exclusively one form of cell death or the other. However, *in vivo*, the situation is much more complicated, and a balance between apoptosis, necrosis, and other indirect effects of PDT is likely to exist.

Pertinently, only eukaryotic cells are capable of undergoing the complex apoptotic form of cell death. In antibacterial applications of PDT, cell death is generally induced much more quickly by simple lysis of the target bacterial cells. This causes rapid induction of an immune response, which is likely to be essential for long-term infection control.

64.6.2 Indirect Vascular Effects

For anticancer applications, the direct cytotoxic effects of PDT are often not sufficient for complete tumor ablation, and indirect effects on the tumor vasculature and induction of an immune response can be critical. Tumor vasculature can be destroyed via photooxidative damage to endothelial cells: manipulation of the treatment regime such as maximizing photosensitizer accumulation in the vasculature by having a short drug–light interval can potentiate the effect. Endothelial cell rupture is followed by the activation of the coagulation cascade, vessel occlusion, and starvation of the downstream tumor cells. Tumor cell necrosis can also have a stimulatory effect on the coagulation cascade. These indirect effects do not necessarily occur significantly more slowly than the direct effects discussed earlier—vasoconstriction of tumor blood vessels and thrombus formation have been shown to occur within 3 h post-illumination (Dolmans et al., 2002).

64.6.3 Indirect Immune System Effects

Immunological consequences of PDT have been much studied by Korbélik and coworkers and reviewed by Korbélik (2006). Upon PDT treatment, the host immune system becomes activated via the release of cellular constituents and cytokines into the bloodstream. Cytokine signaling causes rapid accumulation of neutrophils and macrophages into the treated tissue, which assist in tumor cell kill and release proteases to destroy the noncellular components of the tumor architecture. Further endothelial cell damage amplifies the inflammatory response. Phagocytosis of tumor cell debris by macrophages allows the maturation of antigen-presenting cells, which can then form part of the “acquired” immune system.

This response plays a critical role in the “mopping up” of any remaining tumor cells. This immunostimulatory action gives PDT a significant advantage over traditional cancer therapies such as chemotherapy and radiotherapy, which require concurrent suppression of the immune system. It is also essential for long-term tumor control and the prevention of disease resurgence as acquired antitumor immunity can slow down (or prevent) the regrowth of tumor at the same site or different sites. There is growing interest in the use of PDT in producing cancer vaccines (Korbelik, 2011).

In antibacterial applications of PDT, the stimulation of the immune system is equally important. Complete sterilization of the target tissue is an unrealistic aim; the objective of most PDT treatments is to significantly reduce the bacterial load, as discussed further in Section 64.10, and simultaneously stimulate the host immune system.

64.7 Clinical PDT: Rationale, Technologies, and Challenges

64.7.1 Rationale for Clinical Use of PDT

PDT is limited to producing a local cytotoxic effect since, although the photosensitizing drug may often be delivered systemically, a therapeutic effect is only possible precisely where the light and drug interact with tissue and there is no current means of whole-body illumination. This has advantages for targeting, and means that PDT is not associated with the kind of systemic toxicity experienced by patients receiving chemotherapy but, conversely, means that PDT cannot produce the same systemic efficacy as chemotherapy or molecular-targeted therapy. PDT is much more analogous to surgery or radiation therapy than to chemotherapy, but a major potential advantage of PDT is that it can potentially achieve selective targeting by two independent, but mutually reinforcing, mechanisms. The primary mechanism uses physical or mechanical targeting via the control of light delivery. The second mechanism is molecular targeting, where the photosensitizer can potentially be delivered selectively to the target lesion, rather than to healthy tissue. In principle, therefore, PDT has the potential to be highly selective for target tissue rather than healthy tissue and therein lies much of its appeal for applications in medicine. It also appears that any PDT damage to healthy tissue which does occur heals very easily without scarring, thought to be due to the preservation of connective tissue following PDT. This normal tissue healing is, in effect, another contributor to the selectivity observed following PDT.

There is ongoing debate as to the extent to which photosensitizing drugs used in clinical PDT are selectively present in target lesion versus normal tissue at the time of light application. This is very dependent on the drug, the tissue, the mode of drug delivery, and the drug-to-light time interval. That there is some selective targeting is certain, because there are many examples where tumors that have been exposed to photosensitizers clearly show much increased fluorescence compared with surrounding healthy tissue. This is especially so for the local administration of ALA or its methyl ester (Metvix), in NMSC or in bladder cancer *in situ* and is the basis of the growing use of photodetection in the clinic. However, there is less evidence for the selective accumulation of systemically administered photosensitizers in tumors.

64.7.2 Light Sources

The targeting of lesions by light has developed substantially in the past 25 years, as has the understanding of the behavior of light in human tissues and organs. By using lasers, optical fibers, and endoscopy, light appropriate for stimulating PDT can be delivered accurately and effectively to most internal organs, and PDT is now rarely rejected because of difficulties in delivering the light. In the early days of PDT development, lasers were extremely large, inconvenient, and expensive, in part because of the need for tunability to different wavelengths as researchers studied different photosensitizers. Developments in laser technology have greatly increased the convenience of PDT application in the clinic, and several watts of power are readily available from fixed wavelength diode lasers,

which are relatively inexpensive and easily transportable in the clinical environment. This is sufficient power to carry out most PDT applications in a clinically convenient timescale (e.g., 10–20 min of illumination).

For superficial PDT, for example, of NMSC or chronic wounds, lasers are not necessary and many non-laser sources have been developed. Among these, light-emitting diodes (LEDs) have now assumed a dominant role. LED-based light sources for PDT are simple to use, very reliable, and long-lasting and can provide sufficient power to allow relatively short treatment times. However, they are relatively inefficient in terms of conversion of electrical energy to light energy (typically around 10%), with the excess energy being released as heat, which means that LED devices for PDT require an integrated cooling system. Using LED technology, it is not yet possible to channel the light into an appropriate optical fiber efficiently, and so lasers are still required where PDT is to be performed internally.

64.7.3 Drugs Approved for PDT

Research on the various families of photosensitizers has been summarized in Section 64.4. Of the hundreds of compounds tested in the laboratory, relatively few have undergone clinical evaluation and only a handful has been approved for routine clinical use. Some of these are listed in Table 64.1, along with the applications for which they are approved.

64.7.4 Challenges in Clinical Development of PDT

One of the significant challenges in the development of clinical PDT is the determination of optimal dosimetry for the application is question. The number of dosing parameters to be optimized is approximately three times that of a drug-only therapy, since there are all of the usual drug-associated parameters (e.g., total dose, frequency of dosing, formulation) coupled with light-associated parameters (e.g., wavelength, total light dose, light dose rate, fractionation, or continuous) and then parameters associated with the combination of light and drug (e.g., drug-to-light time interval). It is practicable to optimize only a very small number of these parameters in clinical trials, and more reliance must be placed on preclinical studies than in clinical development of most therapies. Hence, it is likely that even in approved applications, the recommended protocols may be suboptimal.

In systemic PDT, the induction by the early photosensitizers, Photofrin and Foscan of a lengthy period of cutaneous photosensitivity (up to several weeks following drug administration), has been seen as a major challenge to widespread adoption. In those cases where PDT can be used either curatively or for long-term palliation, this may be acceptable. But for the many short- and medium-term palliative uses of PDT, where life expectancy may be measured in months, induction of lasting photosensitivity may be an unacceptable patient burden. Certainly, the elimination or reduction of cutaneous sensitivity following PDT must be a major aim of future development.

TABLE 64.1 Some Drugs Approved for PDT in the United States and the European Union

Chemical Name	Generic Name	Trade Name	Indications
HpD, polyhematoporphyrin	Porfimer sodium	Photofrin™	Advanced and early lung cancer, esophageal adenocarcinoma, bladder cancer, and Barrett's esophagus
mTHPC	Temoporfin	Foscan™	Head and neck cancer
5-ALA	ALA	Levulan™	AKs
Methyl 5-aminolevulinate	Methyl aminolevulinate	Metvix™	AKs, BCC
BPD	Verteporfin	Visudyne™	AMD

Another significant challenge is securing acceptability of a two-component modality, which may often be seen by practitioners as overly complex. This very much depends on the parameters applying to the photosensitizer being used. In the cases of Photofrin and Foscan, drug-to-light intervals of 3 and 4 days, respectively, have been commonly used, with the need for careful patient management to protect from photosensitivity during the long drug-to-light interval. On the other hand, the most successful PDT approach to date using systemic drug administration (Visudyne in macular degeneration, see Section 64.9) uses a drug-to-light interval of just 15 min. In terms of clinical convenience, this is comparable to MRI using intravenous image enhancement.

64.8 Clinical PDT: Developments in Cancer Treatment

64.8.1 Introduction

There is an extensive literature describing clinical studies of PDT in a large variety of cancers, including the Phase III studies that have led to regulatory approval for some photosensitizing drugs. Detailed considerations are beyond the scope of this chapter, which is restricted to a brief outline of the current clinical scene in PDT. However, reviews are available (e.g., Brown et al., 2004; Fayter et al., 2010). The most recent and extremely thorough systematic review of precancerous skin conditions, Barrett's esophagus, and cancers of the biliary tract, brain, head and neck, lung, esophagus, and skin is especially comprehensive and well-researched (Fayter et al., 2010).

64.8.2 Nonmelanoma Skin Cancer

NMSC includes a group of skin cancers and precancerous lesions, which are generally nonlife threatening if treated. They include BCC that can exist in nodular or superficial forms, and actinic (or solar) keratoses (AKs) and Bowen's disease, which are considered to be precancerous forms of squamous cell carcinoma (SCC). Melanoma is currently not treated by PDT, in part because pigmentation may limit light penetration, but largely because of the high risk of metastasis if removal is incomplete.

NMSC is extremely common in Caucasian populations. For example, the lifetime risk of developing AK is greater than 50% in Australia and the United States (Fayter et al., 2010). If not treated, NMSC may be locally invasive and, in the case of AK, may develop into invasive SCC, which can metastasize. Prompt diagnosis and either surveillance or treatment are therefore indicated.

Treatment of NMSC by PDT using either ALA (Levulan) or methyl aminolevulinate (MAL) (Metvix) is now well-established and widely practiced. While protocols vary, the general approach is to apply the ALA or MAL in a vehicle (solution or cream) to the lesion, allow a drug-to-light interval of between 3 and 10 h and then apply light. Depending on the type of lesion, debridement may be carried out before application of drug. In some applications for nodular BCC, a repeat treatment after 7 days is applied. Broadly, efficacy of PDT in treating NMSC is comparable with other modalities, but cosmetic results are superior with PDT. The safety profile of the treatment is favorable, with no serious adverse events or systemic photosensitivity (Fayter et al., 2010). The most characteristic adverse event is local pain or burning sensation when the light is administered, which usually quickly resolves when the light is switched off.

64.8.3 Barrett's Esophagus and Early, Localized Cancer

Since PDT is able to completely ablate superficial or early lesions, it is potentially curative for a variety of precancerous conditions and for early, localized cancer. In this sphere, it therefore competes with curative surgery, but PDT may have advantages in special niche areas where surgery is difficult or produces more serious sequelae. One such niche area is Barrett's esophagus.

Barrett's esophagus is considered a precursor of adenocarcinoma of the esophagus and is increasing in incidence (Brown et al., 2004). It is caused by acid reflux into the esophagus which damages the

normal esophageal lining, which may be replaced by dysplastic tissue. There are several grades of dysplasia ranging from low to high, with the latter at greatest risk of developing esophageal cancer. Clinical studies have used either Photofrin or Foscan given intravenously or ALA given orally. PDT is currently approved as a first-line treatment for patients with high-grade dysplasia using Photofrin. On the basis of systematic review of several trials, Fayter et al. (2010) concluded that PDT might be beneficial beyond proton pump inhibitors alone. However, there is some concern that after PDT with ALA, there may be submucosal islands of remaining Barrett's epithelium, which might act as foci for the development of future disease (Brown et al., 2004). This is probably due to incomplete uptake of drug and formation of photosensitizer and is less likely with systemic photosensitizers. There were no serious adverse events reported in trials of PDT in Barrett's esophagus suggesting an acceptable safety profile, though further evidence is needed.

There is increasing interest in focal treatment for localized prostate cancer. Currently, patients are offered either surveillance (which carries the risk of undertreatment and anxiety) or radical treatment, which is associated with debilitating side effects. Although still in the early phase of development, PDT is showing promise for focal treatment that involves destroying the cancer focus in order to offer patients the potential of combining cancer control with minimal side effects (Lecornet et al., 2010). Such an approach could avoid both over- and undertreatment. For PDT, such treatment would probably involve interstitial therapy whereby several optical fibers would be inserted into the lesion to ensure adequate light dosimetry.

Other localized cancers which should, in principle, be appropriate for the treatment with PDT include carcinoma *in situ* of the bladder, early non-small cell lung cancer, and intraepithelial neoplasias such as those of cervix and vulva (Brown et al., 2004). In the case of bladder, early treatments caused bladder shrinkage sometimes requiring cystectomy, and currently, PDT is little used in this indication. However, this may change with the introduction of improved photodetection of bladder carcinoma *in situ* using hexyl ALA (Hexvix) (Jocham et al., 2008). There are also recent reports of potential improvement in the treatment of cervical intraepithelial neoplasia by PDT using methyl ALA and hexyl ALA (Soergel et al., 2010).

64.8.4 Advanced Cancers

Photofrin is licensed for reduction of obstruction and palliation of symptoms for patients with completely or partially obstructing endobronchial non-small cell lung cancer, but it is difficult to find evidence on how often it is currently used in this indication. The trials that underpinned this approval were carried out before 2002 and generally did not include any recognized quality of life (QoL) assessment. Indeed, this appears to be a common failing of many PDT trials in the advanced cancer setting. More recently, QoL end points have become much more common and validated in cancer clinical studies in general, though not in PDT trials. This is unfortunate since there is certainly anecdotal evidence that QoL during and following PDT treatments may be better than in alternative treatment modalities.

Photofrin is also licensed for palliation of patients with completely obstructing esophageal cancer or for patients with partial obstruction of the esophagus who cannot be treated satisfactorily with NdYAG laser therapy (Brown et al., 2004). Again it is difficult to assess how frequently this procedure is used. There is a report that PDT is used with curative intent in early esophageal cancer (Gray and Fullarton, 2007). Trials have generally provided evidence of improvement of function (swallowing), with a conclusion that PDT is an effective treatment for palliation of advanced cancer at the gastroesophageal junction (Heier et al., 1995). Interestingly, two studies investigating the addition of hyperbaric oxygen to PDT concluded that patients receiving PDT plus hyperbaric oxygen had significantly longer survival than patients receiving PDT alone, 12 versus 7 months, $p = 0.01$; 13.8 versus 8.7 months, $p = 0.021$ (Maier et al., 2000a,b).

Treatment of head and neck cancer with Foscan has been licensed in Europe since 2001 as a local treatment for patients with advanced head and neck cancer unresponsive to previous therapies and

unsuitable for radiotherapy or chemotherapy. Again, the extent of its use is difficult to establish, but is not likely to be extensive. This is unfortunate as PDT has high potential in this indication (Fayter et al., 2010), especially in palliative treatment, in repeat treatments to control local regrowth (unlike radiotherapy and surgery, PDT can be repeated without safety concerns) and, ultimately, in the treatment of early cancers.

Biliary tract cancer is rare, but difficult to treat. Promising data have been achieved using PDT in cholangiocarcinoma (e.g., see Ortner et al., 2003). Most studies have been palliative in intent, and more extensive, controlled studies are required. Pancreatic cancer is similarly difficult to treat, and there is evidence from small studies that PDT may have a role in the treatment of this indication (Bown et al., 2002). Again, larger more rigorous trials are needed.

Treatment of glioma in the brain by PDT has been considered for many years, and progress has been made in adequate light delivery (Muller and Wilson, 1996). However, only two small trials have been reported (Krishnamurthy et al., 2000; Eljamel et al., 2008) and, yet again, larger more rigorous studies are needed to properly assess the potential of PDT in this indication.

64.9 Clinical PDT: Ophthalmology

AMD is the leading cause of registrable blindness in the Western world (Jager et al., 2008). The macula is the central part of the retina and contains the greatest concentration of photoreceptors, allowing a person to see fine details, to read, and to recognize faces (Jager et al., 2008). The most common form of AMD is the dry form, responsible for about 90% of AMD. However, this can progress into the less common, but much more damaging wet form of AMD, which is characterized by choroidal neovascularization beneath the fovea, with exudation, which leads to vision loss. Until recently, this loss in central vision was considered irreversible and progressive. It may occur in one or both eyes. The successful development of the chlorin verteporfin (under the name Visudyne™) in the late 1990s, represented a major breakthrough, both in the treatment of this disease and in the acceptance of PDT as a mainstream therapy (Mellish and Brown, 2001). The approach has been very successful, being widely applied throughout the world. It involves intravenous administration of Visudyne in a liposomal formulation over a period of 10 min. Five minutes after completion of drug administration, laser light at 690 nm is applied for precisely 83 s, during that time the patient feels no pain. This completes a single treatment, which can be repeated as indicated by fluorescein angiography, which gives an image showing the extent of neovascularization and exudation. On the basis of extensive Phase III studies, Visudyne was widely approved by regulatory authorities and became a commercial success.

Though it has now been largely superseded by targeted therapies, the success of Visudyne points the way for other PDT-based therapies. Not only does it work in the required indication, but it is also extremely convenient clinically, with very short treatment times. Part of the reason for its rapid uptake was due, at least in part, to the familiarity of ophthalmologists with laser technology. This has lessons for the acceptance of other modes of PDT by the clinical community.

64.10 Clinical PDT: Antimicrobial Therapy

There is now a large and expanding literature on the antimicrobial effects of PDT *in vitro*. Almost any photosensitizer and light will inactivate Gram-positive bacteria, including those used in PDT for cancer, but negatively charged and neutral photosensitizers have little effect on Gram-negative bacteria, due to their nonporous cell wall structure, which consists of an inner cytoplasmic membrane and an outer membrane, separated by the peptidoglycan-containing cytoplasm. Neutral and anionic photosensitizers can be made effective against Gram-negative bacteria if used in conjunction with a disrupting agent such as polymyxin. However, in order to obtain true broad spectrum antimicrobial activity, photosensitizers need to be cationic (Merchat et al., 1996; Minnock et al., 1996), and there is a large variation in PDT efficacy depending upon the chemical structure of the cationic molecule. For example, methylene

blue, while being an excellent photosensitizer, has a relatively poor efficacy in bacterial inactivation, while its tetrabutyl analog (3,7-bis[*N,N*-dibutylamino] phenothiazin-5-ium bromide) demonstrates very high antimicrobial activity against both Gram-positive and Gram-negative organisms, as well as fungal species. Using such high activity photosensitizers *in vitro*, it is possible to achieve typically 5–7 logs of cell kill with comparatively very low photosensitizer and light doses.

A number of experimental animal model systems for tissue infection and for acute wounds have now been developed (e.g., Hamblin et al., 2002). Perhaps the most immediate impact of these models is that the high log kills seen by PDT regimes *in vitro* are not easily reproduced *in vivo*, where much higher photosensitizer and light doses are needed and lower log kills are typically achieved. Nevertheless, such models are valuable in establishing the most appropriate parameters to be used in clinical studies.

Antimicrobial PDT works by a completely different mechanism to antibiotics and is multi-targeted, since many types of biomolecule are degraded during antimicrobial PDT, any one of which could prove lethal to the cells. This imparts two key properties to antimicrobial PDT:

- Since it is multi-targeted, development of resistance to PDT is unlikely. Indeed, many attempts to deliberately induce resistance through repeated generations have proved unsuccessful.
- Since bacterial cells have no protection against singlet oxygen, antimicrobial PDT is able to inactivate cells of antibiotic-resistant bacterial strains.

Antimicrobial PDT has potential application across a variety of conditions including dental disease, acute and chronic wounds, parasitic lesions, nasal carriage of MRSA, acne, and superficial skin conditions. Although to date there have been very few reported clinical studies using antimicrobial PDT, this is likely to change as several clinical studies are underway. In a case study, Clayton and Harrison (2006) treated with PDT a 72-year-old woman with chronic recalcitrant venous ulceration of her right lower leg, persisting for more than 12 months and complicated by cellulitis and colonization with methicillin-resistant *Staphylococcus aureus* (MRSA). The PDT was well-tolerated with minimal discomfort to the patient, even without the use of topical local anesthesia (unlike the use of 5-ALA in the treatment of NMSC, where pain is frequently experienced), and significant improvement was subsequently observed in the ulcer.

The use of PDT to treat dental infection has been led by Wilson and coworkers and developed by Ondine. In 33 subjects with moderate to advanced periodontal disease, it was shown that there was a significant advantage (in terms of reduction in probing pocket depths) in combining PDT with scaling and root planing, compared with scaling and root planing alone (Andersen et al., 2007).

Following extensive preclinical safety and toxicology testing, Photopharmica Ltd is developing the photosensitizer PPA 904 (3,7-bis[*N,N*-dibutylamino] phenothiazin-5-ium bromide) for the treatment of chronic leg ulcers. This photosensitizer has several key advantages for antimicrobial PDT as follows:

- Very high, broad-spectrum antimicrobial activity compared with many other photosensitizers (e.g., methylene blue)
- Strong light absorption at 680 nm
- Easily manufactured and purified as good manufacturing practice (GMP) material (no isomers)
- Small molecular size compared with porphyrins and phthalocyanines
- Excellent preclinical safety profile

In a small antimicrobial PDT pilot study using broad-spectrum light, eight patients with bacterially colonized chronic ulcers, four with diabetic foot ulcers, and four with venous leg ulcers, a single PDT treatment with PPA 904 was well tolerated, and in each of the patients, there was a decrease in total bacterial load immediately after the treatment compared to pretreatment (median 2.5 log₁₀ reduction) and this was statistically significant ($p = 0.0078$) as determined by the Wilcoxon rank nonparametric test. This was the first demonstration of a clinically significant reduction in bacterial load by a PDT treatment in this indication, and both Gram-positive and Gram-negative microorganisms were susceptible to the treatment. This was followed up by a Phase IIa, randomized, placebo-controlled trial in 32 patients, 16 each with chronic diabetic foot ulcers and venous leg ulcers. All patients received standard wound

therapy (compression bandaging for venous leg ulcers and standard dressing for diabetic foot ulcers) as well as a single treatment of either PPA 904 plus light or placebo plus light. The data showed a strongly significant reduction in bacterial load following PDT and a trend toward accelerated healing in the PPA 904 group compared with the placebo group. The study showed the therapy to be safe and without treatment-induced pain. A repeat dose study is now in progress, powered to detect significance in reduction of microbiological load, but also assessing healing.

64.11 Future of PDT

It is more than 30 years since PDT was first used in oncology and many thousands of patients have been treated. It cannot be described as a new therapy and yet its rightful place in the cancer armamentarium remains unclear. Why has PDT not achieved a more sustained place in cancer management and what is its future? This question was asked and tentative answers put forward in 2004 (Brown et al., 2004). Those responses bear repetition now and include the difficulty in establishing optimum treatment parameters, clinician and hospital resistance to a two-component approach, and the capital cost of setting up a PDT center. However, the chief reason is likely to be that the drugs in current use (with their inherent challenges of long drug-to-light intervals, coupled with prolonged skin photosensitivity) have not shown sufficient advantage over alternative treatments in large, randomized, controlled trials. Such trials are expensive and have been difficult to perform because of the lack of strong commercial support from the large oncology companies and from national agencies. New improved drugs are, however, entering clinical trials, such as Tookad for prostate cancer. As stated in the recent systematic review of PDT in oncology, while further research is needed to develop the field of PDT for cancer, appraisal of all the available trial evidence leads to the conclusion that PDT appears to be a promising treatment in the majority of conditions reviewed (Fayter et al., 2010), but the potential place of PDT among the range of other treatments available for each condition is not yet clearly defined.

Those who have been closely associated with clinical PDT programs in oncology have been impressed by patient feedback. Where alternatives are available, PDT is widely preferred by patients. Until now, QoL and patient preference studies have been largely anecdotal, but more sophisticated instruments are now available and such qualitative research must be part of future PDT trials.

We have much to learn from the success of Visudyne PDT, where treatment is very simple (at least to patients), there is no sustained photosensitivity and treatment times are extremely short. These advantages also apply to antimicrobial PDT, where there is a building momentum in the product pipeline moving from discovery through the clinical trial pathway and into products.

65.1 Introduction

Photodynamic therapy (PDT) is considered to be a site-specific cancer therapy because the therapeutic effects only take place in the area exposed to light. With the rapid expansion of PDT, many new drugs either chemically or endogenously synthesized have been developed and exploited in various ways. Among them, there is a group of photosensitizers with a unique intracellular distribution pattern observed under fluorescence microscopy.

These photosensitizers enter cells through endocytosis and localize at the membrane of endocytic vesicles instead of being diffusely localized in the cytosol. Upon irradiation, the generated cytotoxic agents destroy the endocytic membranes and release the content inside these organelles (e.g., lysosomal enzymes) [1,2]. Moreover, the redistribution of these sensitizers (i.e., an increase of fluorescence intensity and the change of distribution phenomenon to become diffuse) was also observed. This particular lysosomal photosensitization and the membrane disruption accompanying the release of content led to the concept of photochemical internalization (PCI)—a novel photochemical technology for inducing the release of macromolecules from endocytic vesicles [3].

Macromolecules generally refer to oligo- and polynucleotides, peptides, proteins, and polymers whose sizes are normally larger than 1 kDa. They can serve as alternatives to traditional drugs (e.g., low-molecular-weight chemotherapeutics) but their bioavailabilities are usually limited [4]. First of all, the cell membrane is normally impermeable to the aforementioned large molecular complexes, whereas

small molecules such as glucose, ions, or amino acids can quickly diffuse into cells. Secondly, even though macromolecules still can enter cells through various active internalization mechanisms called endocytosis, escaping from endocytic vesicles to reach the intracellular targets is another problem [5]. Thirdly, degradation of these macromolecules within acidic lysosomes, which contain proteolytic enzymes, is a further factor that limits efficient delivery. There is therefore growing awareness of the need to develop drug delivery systems, which can efficiently release therapeutics accumulated in endosomes and lysosomes.

The fact that macromolecules retain in intracellular vesicles and remain inactive is not ultimately a hindrance. If their biological effects can be manipulated by a delivery system, these macromolecular drugs will be superior to traditional chemotherapeutics in terms of specificity. In this regard, PCI that causes the rupture of endo/lysosomal membranes during photosensitization can provide a site-specifically light-induced delivery of macromolecules.

The aim of PCI is to relocalize the therapeutics—escape from the barrier of endo/lysosomal membrane and ability to reach their targets. In other words, the principal considerations are the drug delivery effects and the cytotoxicity from macromolecules after PCI. The light and sensitizer doses required for PCI are much lower than the ones for PDT treatment whose ultimate goal is to kill the whole cell. Moreover, because the therapeutics used for PCI are normally potent drugs but not bioavailable without efficient delivery system, the drug dose can be reduced to extremely small (compared to its LD₅₀ dose) using PCI technology. For these reasons, synergistic effects are expected for PCI strategy where individual treatment (i.e., PDT and drug alone) exhibits minor effect but an enhanced killing effect can be achieved when these macromolecules are activated after photosensitization.

This is different from most of the combination therapies, which combines PDT with another treatment modality (e.g., hyperthermia, radiation therapy, antibody therapy, or chemotherapy). Although a synergistic response can be obtained if one mechanism influences the other, additive effects are often the results of these combined strategies where treatments are working independently.

PCI has been established to enhance the intracellular delivery of a large variety of macromolecules including peptides, protein toxins, and genes [6]. It has been shown to be effective for release of these therapeutics both *in vitro* and *in vivo* [7]. However, some details of PCI remain to be investigated such as the exact mechanism of membrane rupture at molecular scale and the optimization of PCI in terms of the balance of photochemical treatment and drug toxicity.

65.2 Mechanisms of Action

65.2.1 Photosensitizers and Their Subcellular Localization

To date, meso-tetraphenylporphine (TPPS_{2a}) and aluminum phthalocyanine disulfonate (AlPcS_{2a}) are the most efficient photosensitizers for PCI with two sulfonate groups on adjacent phthalate/phenyl rings (Figure 65.1). After being taken up by cells through endocytosis, these sensitizers localize specifically at the membrane of endo/lysosomes, with a hydrophobic part inserted into the membranes and a hydrophilic part free inside the vesicle matrix. This amphiphilic feature ensures their membrane localization and inhibits further penetration.

It is not expected that all endo/lysosome-localized photosensitizers are suitable to be used for PCI. The selection of PCI sensitizers is based on the property of “membrane” localization at these endocytic vesicles. The reason for this requisition is simply to limit the photochemical destruction to the membrane and therefore minimize the possible photo-damage to the delivered macromolecules in the lumen compartment. As the reactive oxygen species, particularly singlet oxygen, generated from photochemical reactions have a short diffusion distance [8,9], amphiphilic sensitizers are desirable to fulfill this certain criteria.

Evidence has also been shown that the exact lysosomal membrane localization is crucial to an efficient PCI effect [10]. To study the impact of intracellular localization of photosensitizers for PCI, several photosensitizers were examined for their ability to induce polylysine-mediated gene transfection.

FIGURE 65.1 The structures and molecular weights of three PCI photosensitizers—(from the left) TPPS_{2a}, AlPcS_{2a}, and TPCS_{2a}.

This study showed that photosensitizers that are localized at the endo/lysosomal membrane (e.g., AlPcS_{2a} and TPPS_{2a}) have the greatest effects on the transfection of plasmid encoding enhanced green fluorescent protein (EGFP). In contrast, transfection was not significantly stimulated after photoactivation of non-lysosomally localized photosensitizers (e.g., meso-tetrahydroxyphenyl porphyrin (3THPP) and 5-aminolevulinic acid (5-ALA)). Moreover, other hydrophilic sensitizers, such as TPPS₄ and Nile blue A, which localize within endocytic vesicles displayed only weak or negligible EGFP expression after exposure to light. As a result, the physical property of photosensitizers determines their intracellular localizations and amphiphilic sensitizers are the best photosensitizing compounds for PCI applications.

Amphiphilic sensitizers also exhibit some advantageous photodynamic properties [11]. The cell uptake of amphiphilic photosensitizers was detected as good as hydrophobic ones but the tendency to aggregate was lower. This is an important feature as dimerized photosensitizers are less effective in inducing photochemical reactions.

The absorbance spectrum should also be considered, especially in clinical practice, since near-infrared is preferable for deeper tissue penetration of light. Phthalocyanines have a porphyrin-based macrocycle with four benzo rings on the pyrrole units, which results in a strong absorption in the far-red region of spectrum (>670 nm) [12]. In this regard, AlPcS_{2a} may be preferable to TPPS_{2a} for *in vivo* or in clinic utilization.

Tetraphenylchlorin disulfonate adjacent (TPCS_{2a}, Amphinex[®]) is a new chlorin-based amphiphilic photosensitizer (PCI Biotech, Norway), which is designed for PCI (Figure 65.1). The chemical synthesis of Amphinex is rather simpler than AlPcS_{2a}, and it is proposed to be as efficient as the well-known chlorin sensitizer, m-THPC, regarding the photodynamic ability.

65.2.2 Light-Induced Macromolecule Delivery

Figure 65.2 depicts the principle mechanism of PCI. It contains three processes: the uptake of photosensitizer and macromolecules, the illumination and induced membrane rupture, and finally the release of macromolecules. After diffusing into the cytosol, macromolecules can thereby perform their pharmacological action when reaching their targets. The key step is the photochemically induced membrane rupture. As PCI also utilizes the same photochemical reactions as PDT, the fundamental requirements, such as the presence of oxygen and sufficient photosensitizers, are also essential to PCI.

It should be noted that the whole PCI process is dynamic, and therefore, the efficacy is highly dependent on the timing of drug (both sensitizers and macromolecules) administration and light exposure. Ideally, illumination should be carried out when sensitizers are sufficiently localized at the biomembranes, and the macromolecules have been internalized in endocytic vesicles but before being degraded

FIGURE 65.2 The principle of PCI. S: photosensitizer; G: molecules to be delivered. (From Hogset, A. et al., *Drug Deliv. Rev.*, 56, 95, 2004.)

FIGURE 65.3 Possible mechanism for “light before” PCI. S: photosensitizer; G: molecules to be delivered. (Modified from Hogset, A. et al., *Drug Deliv. Rev.*, 56, 95, 2004.)

by the lysosomal enzymes. As a result, understanding the kinetics of the endocytosis of both sensitizers and macromolecules is very important.

In contrast to the conventional concept of PCI as described earlier, another strategy called “light before” PCI has been found to be as effective as or even better than “light after PCI” in some cases *in vitro* [13]. The possible mechanism is shown in Figure 65.3. Irradiation is performed after photosensitizers have been localized at the membrane of endocytic vesicles but before the administration of the macromolecules. It is suggested that the molecules will be taken up through endocytosis as well but can leak out immediately once the vesicles fuse with the ones damaged by light treatment. The foremost advantage is that the possible photochemical effects on the therapeutics should therefore be diminished since those drugs are delivered after illumination.

65.3 *In Vitro* Applications in Macromolecule Delivery

65.3.1 Peptides and Proteins

PCI has been employed to release some peptides or small proteins efficiently. It was reported that more than 60% of endocytosed horseradish peroxidase (HRP) can be released into cytosol using TPPS_{2a} PCI. Similar findings were also obtained when it was shown that fluorescein-labeled ras peptide (p21^{ras}), a cancer-specific peptide, was colocalized granularly with ALPcS_{2a} in cells but became diffuse in cytosol after light exposure [3].

The studies of PCI-induced delivery of protein have mainly focused on ribosome-inactivating proteins (RIPs), a group of protein toxins that inhibit protein synthesis by damaging ribosomes

catalytically. RIPs from plants are usually divided into two groups: Type II RIPs consist of an enzymatically active A chain (approximately 30 kDa) linked to a B chain (approximately 35 kDa), which contains a binding domain. Type I RIPs, however, which only consist of the A chain, are hardly taken up by cells.

The absence of a B chain with a binding domain indeed limits the entry of type I RIPs into cells and justifies their very low toxicity to cells and to animals compared to type II RIPs, with LD₅₀ for mice of 40–75 mg/kg [14]. However, if they are delivered into cells, they can induce efficient inhibition of protein synthesis. Several strategies have been employed to improve the cellular delivery of type I RIPs including enclosing them in drug carriers [15], subjecting cells to shock waves [16], and conjugating to antibodies [17]. These protein toxins are ideal model proteins to evaluate and demonstrate PCI effects.

Gelonin and saporin are two type I RIP toxins, which are mostly used in PCI strategy. The effect of PCI-induced delivery of gelonin has been investigated using several photosensitizers in a large number of cell lines of various origins [18]. The best results were found using TPPS_{2a} PCI of gelonin in NHIK 3025 cells where protein synthesis was significantly reduced by more than a factor of 300 compared to each treatment alone [3].

Saporin is another type I RIP, which exerts a higher toxicity than gelonin [19]. Lai et al. investigated the PCI effect using AlPcS_{2a} in combination of saporin *in vitro* [20]. In addition, the introduction of polyamidoamine (PAMAM) dendrimer to saporin showed an increased cellular uptake and cytotoxicity using PCI.

Bleomycins are a family of water-soluble glycopeptidic antibiotics with at least four functional domains mediating DNA breakage, ion binding, and O₂ activation [21]. Since first isolated by Umezawa in 1966, bleomycins have been used in combination with several anticancer agents for a number of cancer chemotherapies, notably squamous cell carcinomas and malignant lymphomas [22].

With a very high cytotoxicity, as few as 500 bleomycin molecules translocated to cytosol are sufficient to kill a cell in combination with electroporation *in vitro* [23,24]. However, due to its hydrophilic property, bleomycin penetrates membrane structures poorly and therefore accumulates in endocytic vesicles. The sensitivity of tumor cells to this drug is accordingly variable. Although many fundamental properties of bleomycin are still unknown, its therapeutic potential could be activated if delivered and exported sufficiently into cytosol.

PCI has demonstrated enhanced cell growth inhibition in combination with bleomycin *in vitro* using different cell lines [25]. Further *in vivo* studies of PCI of bleomycin will be described later.

65.3.2 Targeted Macromolecules: Immunotoxins

The targeting strategy was developed due to the demand of specific and efficient drug delivery system, especially in the *in vivo* studies. Immunotoxins are one of the designs that link antibodies with specific binding function to therapeutics which are mainly bacteria or plant protein toxins. The aims of combining targeting ligands are to achieve tumor specificity and a favorable biodistribution between normal and tumor tissues. The conjugates should meet several criteria to be used in clinical practice for cancer treatment: Because the number of receptors presenting on the cell surface is usually less than 10⁵ molecules per cell, it is important to have very high toxicity to kill targeted cells efficiently. Moreover, most toxins enter the cell through the endocytic pathway; therefore, the toxin must be able to survive from the acidic compartments of endo/lysosomes and the proteolytic process [26].

Since cooperation of PCI and RIPs has inactivated protein synthesis efficiently, the use of immunotoxins—monoclonal antibody conjugated type I RIP—is believed to be able to increase the drug uptake and specificity. The first studies of PCI in combination with immuno-RIP conjugates were introduced by Selbo et al. coupling of monoclonal antibody MOC31 with gelonin [27,28]. This conjugation enables gelonin to directly bind to epithelial glycoprotein-2 (EGP-2), which is expressed on most carcinoma cells, resulting in increased uptake of the conjugates. The cell viability was significantly reduced using

TPPS_{2a}, ALPcS_{2a}, and ALA PCI compared to immunotoxins alone. Moreover, the results also show that there was no difference between immunotoxin and toxin alone in the case of using PCI in a EGP-2 negative cell line. The specificity might be very useful for *in vivo* application.

Epidermal growth factor receptor (EGFR) involves in regulating cell proliferation, metastasis, angiogenesis and is overexpressed in a variety of tumor cell lines [29], and targeting EGFR is one of the most common strategies to achieve specific cancer therapies. The EGFR inhibitor, C225, has been used as an anticancer drug in Phase-I to Phase-III trials for several malignant diseases and is approved for treatment of head and neck squamous cell carcinoma and colorectal cancer. It may therefore be a good combination employing EGFR-targeting system to PCI. Weyergang et al. established an EGF-saporin affinity toxin (biotin-streptavidin linkage) to investigate the PCI effects [30]. PCI of EGF-saporin enhanced the cytotoxicity about 1000-fold in EGFR overexpressing cells. Researchers from the same group later demonstrated increased cytotoxicity using PCI in combination with saporin-C225 complex (via the same linking method) in EGFR-positive cells [31]. The efficacy and selectivity of this combination of PCI and EGFR-targeting system indicate it can be of benefit for cancer therapies in clinic.

65.3.3 Multiple Drug Resistance (MDR)

Since PCI has been employed for enhancing the cellular uptake of drugs, which have difficulties in entering the cell, it is predicted that PCI might have the potential to deal with multiple drug resistance, which is a serious problem affecting many chemotherapy drugs. Two main mechanisms for MDR: The overexpression of p-glycoprotein (p-gp) efflux pumps leads to the extrusion of drugs from cytosol. The entrapment of anticancer drugs in endosome/lysosomes induces the degradation of drugs by lysosomal enzymes [32]. It was firstly established by Lou et al. that successful reversal of drug resistance can be induced by PCI [33]. Doxorubicin, a weak base chemotherapeutics, is often trapped in endocytic vesicles due to the increased acidification of these intracellular compartments. After TPPS_{2a} PCI treatment, doxorubicin (administered after irradiation) was observed in the nuclei of MCF-7/ADR cells (a breast cancer cell line which is resistant to doxorubicin), and the drug dose required for 50% inhibition of cell survival was reduced to 10 times lower.

Another study using similar concepts also indicated the PCI effects on the improvement of drug resistance. The cytotoxicity of mitoxantrone (a chemotherapy agent) against its drug-resistant cancer cells sensitized with hypericin (a photosensitizer) was enhanced after illumination [34]. The mobilization of mitoxantrone to cell nuclei was also found after light exposure.

As pointed out earlier, there are many different phenotypes of drug resistance and some mechanisms may not be affected by PCI treatment. Selbo et al. reported that TPPS_{2a} PCI has no influence in reducing the level of resistance to doxorubicin for MES-SA/Dx5 cells, a MDR cell line [35]. However, PCI of gelonin successfully reduced the cell survival. The results suggest that PCI may not be able to adjust the drug sensitivity for some MDR cells, but it still can be useful as a cancer treatment when in combination with other macromolecules.

65.3.4 Oligonucleotides

Oligonucleotides are a group of macromolecules with recognized therapeutic potential. Some of these molecules exhibit antisense effects, resulting in site-specific gene silencing in the host cell through steric blocking of gene expression or degradation of mRNA. Peptide nucleic acids (PNAs) are examples of the former action, which are DNA mimics with a pseudopeptide backbone [36]. Small interfering RNA (siRNA) molecules are the example for the latter mechanism, which are able to control gene expression through the process of RNA interference [37]. The inefficient cellular uptake is the major obstacle for both therapeutic agents [38] and, as a result, several strategies, including PCI, have been explored to enhance the drug delivery.

Recent studies have clearly shown that PCI represents an efficient delivery system for naked PNA conjugated with the catalytic component of human telomerase reverse transcriptase (hTERT-PNA) [39] and various cell-penetrating peptides (CPPs-PNA) [40]. As for siRNA molecules, substantial gene silencing was induced by PCI-mediated gene transfection of siRNA molecules against S100A4, a protein associated with the invasive and metastatic phenotype of cancer cells [41]. These promising *in vitro* results open the future applications using PCI technology for activating the biological antisense effects of oligonucleotides on animals or humans.

65.3.5 Gene Therapy

The basic principle of gene therapy is that insertion of corrective genetic material into cells alleviates the symptoms of disease. However, there are some obstacles, and consequently few successes in gene therapy. One of the main problems of gene therapy is the lack of efficient delivery systems [42] and PCI, as a novel technology for releasing macromolecules from endosomes to cytosol could provide efficient delivery for gene therapy.

Recent studies have shown encouraging results in gene transfection via either viral or nonviral vectors. AlPcS_{2a}-based PCI-induced EGFP/polylysine complex delivery was tested and the transfection efficiency reached above 50% of surviving cells [43]. PCI using different photosensitizers has also been examined to induce EGFP transfection, and a light-dependent transfect efficacy was found [10].

In addition, various delivery agents have been evaluated in PCI-mediated gene transfection where transfection can be enhanced using polycationic vectors [e.g., polylysine or polyethylenimine (PEI)], but was inhibited by cationic lipid vector-mediated transfection [e.g., dioleoyltrimethylammoniumpropane (DOTAP)] [44]. One possible explanation suggested was that the photochemical treatment might perturb the dissociation of DNA/DOTAP complex and cause DNA inactivation.

PCI-mediated delivery requires administration of both photosensitizers and candidate drugs or genes. There is a new design devised a complex composed of a core DNA packaged with cationic peptides and enveloped in the anionic dendrimer phthalocyanine (DPc) [45]. The concept was to reduce the administration of photosensitizers and drugs into one and was thought to be more suitable for *in vivo* application due to the integration of photosensitizers and DNA/polymer complex. After irradiation, an enhancement in transfection but with lowered photocytotoxicity was established *in vitro* compared to the results using unconjugated AlPcS_{2a}. This study is also the first success in PCI-mediated gene delivery *in vivo* with transgene expression in conjunctival tissues of rats.

Gene delivery through viral vectors is usually regarded as a very efficient process because of the natural occurrence of virus infections [46]. However, after being taken up into cells through endocytosis (mostly) [47], virus-DNA complex may still be trapped inside the endocytic system in cases of some virus vectors or in certain cell lines [48].

PCI-mediated gene transfection by adenoviral vectors was firstly introduced by Hogset et al. using β -galactosidase-encoding adenovirus [49]. Pronounced transduction efficiency was obtained, and the amount of virus dose was significantly lowered to achieve the same results using PCI compared with conventional adenovirus transfection (no illumination). A later study investigated the transfection efficacy of PCI-induced transduction of polycation-complexed adenovirus using several cell lines [50]. The efficacy was found to be cell type dependent but positive transgene expression was observed in all cell lines including cells with low or without the receptors to adenovirus on the cell surface.

65.4 *In Vivo* PCI Studies

Most of the *in vivo* PCI studies have been carried out using AlPcS_{2a} in transplanted xenograft tumor models in nude mice. AlPcS_{2a} PCI of gelonin delayed the tumor growth significantly compared to animals treated with PDT alone [51,52].

Bleomycin has been employed for *in vivo* PCI with AlPcS_{2a} in four different xenograft tumors in mice [25,53]. A synergistic delay in the tumor growth was found in all models. The histological examination on the samples 7 days after surgery showed that the tumor regrowth in the peripheral zone was inhibited by PCI treatment. A further study also indicated that PCI treatment could act as an adjunct to surgery, resulting in the delay of tumor growth [54]. It is thus suggested that PCI may be suitable for treating residual tumor cells after incomplete surgical resection from the clinical point of view.

Another combination strategy was investigated using AlPcS_{2a} PCI of bleomycin and radiotherapy. The time to tumor progression was increased when ionizing radiation was carried out after PCI compared to PDT or bleomycin combined with radiotherapy [55].

None of these studies quantified the effects of PCI compared with PDT other than by tumor growth delay. However, this has now been done in a normal tissue, liver. The therapeutic efficacies between AlS_2Pc PDT and PCI of gelonin were compared by measuring the necrosis induced in healthy rat liver in three dimensions [56]. The influence of drug doses and drug administration intervals to light delivery was investigated: the greatest enhancement in tissue damage was observed when gelonin was injected 1 h before irradiation and the effect was independent of the gelonin dose under a range of 5–50 $\mu\text{g}/\text{kg}$. In other words, significant treatment response can be induced with a very low dose of gelonin (5 $\mu\text{g}/\text{kg}$, 10,000 times lower than the LD_{50}). This study demonstrated the dependence of the drug–light intervals on the treatment effects and emphasized the importance of optimization of the treatment conditions. In addition, the PCI-induced relocalization of gelonin *in vivo* was established for the first time using immunohistochemistry (Figure 65.4).

Another study further compared the PCI effects of different drugs on different tissues. Experiments were undertaken using TPCS_{2a} PCI in combination with saporin and bleomycin in normal rat liver/colon and a transplanted syngeneic rat fibrosarcoma model (Wang et al., unpublished). Significantly enhanced necrosis was induced in combination with saporin in liver and tumor but not colon, and with bleomycin in each case. The lack of enhanced tissue damage in colon after PCI with saporin is due to the fact that saporin does not accumulate significantly in colon, in contrast to liver and tumor. This study demonstrates that the uptake of the individual drugs in different organs can strongly affect the treatment response to PCI.

Altogether, the consistency between *in vitro* and *in vivo* experiments indicates the benefits of the PCI approach, which enhances PDT treatments and displays synergistic effects in combination with other therapeutic agents.

FIGURE 65.4 (See color insert.) PCI-induced relocalization of gelonin in rat liver. Tissues were stained with the primary antibody against gelonin and counterstained with hematoxylin. Animals were treated with 25 J light delivered 48 h after 1 mg/kg AlS_2Pc and 1 h after 500 $\mu\text{g}/\text{kg}$ gelonin, examined 30 min after irradiation. (a) Area of liver not exposed to light (inset white arrows: distribution of gelonin in liver). (b) Areas exposed to light (inset black arrows: redistribution of gelonin).

65.5 Concluding Remarks and Clinical Applications

PCI is attracting interest as a novel technology for improving macromolecule delivery to cells. The key advantage of PCI is the site specificity due to the light-dependent activation of a photosensitizer, which is coadministered with the macromolecule. Additionally, PCI has the potential to approach different cancer treatments when in combination with different therapeutic agents since various macromolecules have been shown to be released by PCI and their size can range from small peptides to genetic materials. The combination with drugs coupled with specific targeting ligands may also improve the specificity of PCI treatment *in vivo* by directing drugs to the tumor cells. A recently published study demonstrated the use of a fusion toxin for PCI, which was recombinant fusion protein composed of gelonin and a single-chain Fv antibody fragment against a marker protein associated with a large number of cancer cells [57]. This construct was able to inhibit tumor growth significantly.

The uptake of photosensitizers and macromolecules varies between cell lines and so does the light sensitivity [6]. In fact, these are all factors, which relate to the optimization of PCI treatment conditions. The killing effect originating from the photochemical reaction is beneficial to cancer therapy where the final goal is to kill the malignant cells, whereas it might be a disadvantage for gene therapy of other diseases. Toward this point, optimizing the treatment conditions should therefore be emphasized again.

Collectively, PCI is a promising technology to improve a cytosolic delivery of macromolecules *in vitro* and *in vivo*. Despite the unclear mechanism, the significant release of large particles such as viral vectors indicates that PCI provides a remarkable drug delivery platform. A successful PCI should be well planned, and the photochemical reaction has to be efficient, precise, and well timed, in respect to the incorporated therapeutics.

It is important to point out that PCI is in the stage of its first clinical trial using TPCS_{2a} PCI in combination with bleomycin for head and neck cancers in University College London Hospital. As a cancer treatment, the challenges will be the same as what PDT faces: the benefit of its therapeutic effects against the conventional well-established therapies, such as chemotherapy, radiation therapy, and surgery. The fact that PCI seems flexible for delivering a variety of anticancer drugs certainly broadens the future applications of PCI in clinic to deal with different cancers.

66.1 Introduction

Photosensitizing effects of xenobiotics are of increasing concern in dermatology since modern lifestyle often associates sunlight exposure with the presence of chemical substances in the skin. Photosensitization is defined by the development of abnormal cutaneous reactions triggered by sunlight doses regarded as harmless, most often in the UVA range (320–400 nm). The photosensitizing compound, generally not toxic by itself, becomes reactive under irradiation. An important number of chemicals like perfumes, sunscreen components, or therapeutic agents have been reported as photosensitizers [1–5].

In this context, a number of efforts have been made to design a model system for photosafety assessment. Indeed, screening for phototoxicity is necessary at the early phase of drug discovery process, even before introducing drugs and chemicals into clinical therapy, to prevent undesired photoreactions in humans. In the case of new pharmaceutical or cosmetic compounds, their phototoxic potential has to be tested when they absorb in the regions corresponding to the solar spectrum, that is, for wavelengths >290 nm. So, there is an obvious need for a screening strategy based on *in vitro* experiments. Until now, the 3T3 neutral red uptake (NRU) test is the only validated *in vitro* method for phototoxicity assessment [6]. In spite of its advantages, it also shows some limitations. Thus, it addresses on phototoxicity and does not provide any information on photogenotoxicity, photocarcinogenicity, photoallergy, etc. Moreover, the large number of “false positives” might rule out some useful highly active therapeutic substances.

In this chapter, the attention will be focused on photosensitization by drugs and especially on two well-established photoactive families: the arylpropionic acid derivatives acting as nonsteroidal anti-inflammatory drugs (NSAIDs) and the fluoroquinolone (FQ) antibiotics [7–26]. First, a summary of clinical reports and *in vitro* assessment of phototoxicity by the 3T3 NRU test over the 10 last years is provided. Then, a mechanistically based strategy is presented in order to get insights into the molecular mechanism of drug photosensitization.

66.2 Clinical and Experimental Data on Humans

A systematic approach including pertinent patient history, physical examination, phototesting, and laboratory investigation is essential for evaluating a photosensitive patient. Photosensitivity induced by exogenous agents can be divided into two phenomena: phototoxicity and photoallergy.

Phototoxicity can be elicited by a wide range of pharmaceutical agents (but also by their metabolites or photoproducts). The reaction is essentially immediate and resembles an exaggerated sunburn. It is dependent on the photosensitizer concentration in the skin and on the light dose received. Phototoxic reactions are much more prevalent than photoallergic ones; they exhibit a maximum intensity early after ultraviolet (UV) exposure, followed by a decrescendo evolution within 24–72 h. Eruptions occur on exposed skin areas, giving a clear delineation of shading caused by clothing. The lesions are characterized by erythema, infiltration, edema, or blisters, followed by desquamation and hyperpigmentation. It has also been suggested that repeated phototoxic reactions have the potential to increase the already high risk of skin cancer from sunburn [4].

By contrast, photoallergy is uncommon and immunologically mediated requiring previous exposure to the photosensitizing agent and an induction period. In some cases, sensitization may be provoked by a structurally related chemical, a phenomenon that is called cross-reactivity. Clinically, it is very similar to plain contact allergic reactions, with a delayed onset and a crescendo reaction pattern. Photoallergic contact dermatitis may generally affect well-defined areas exposed to sunlight. However, it may extend to other parts of the body, sometimes distant from the initially affected area. The corresponding skin lesions are erythema, infiltration, papulovesicles, erosions, or bullae. The molecular mechanism completely differs from that of phototoxicity; the irradiated drug (metabolite or photoproduct) plays the role of a photohapten, which may covalently bind to a carrier protein (photobinding), giving rise to a photoantigen able to trigger the immunological process.

Diagnosis of drug-induced photosensitization can be clinically made by photopatch testing. Nevertheless, the methodology is not fully standardized; this could result in variations of the results from studies performed in different laboratories. Photopatch testing consists of topical application of the suspected agent (epicutaneous administration) on the upper back of the patient in duplicate; one area is then exposed to UV lamps (at suberythemal dose), whereas the other one is kept covered. Both, the UV shielded and non-shielded areas, are evaluated immediately, after 24 h, and up to 72 h after testing. The photosensitizing character of a chemical is positively established when its presence results in reduction of the minimal erythema dose (MED, leading to the first faint reddening of the skin). Reactions are generally graded to a 4-point scale: 0, no reaction; 1, erythema; 2, erythema and dermal infiltrate; 3, erythema and blisters or erosions.

Arylpropionic acid derivatives are NSAIDs widely used for their analgesic and antirheumatic properties. Their photosensitive potential has largely been reported over the years, with the first photoallergic contact dermatitis to ketoprofen (KP) published in 1985 [27]. As shown in Table 66.1, KP, tiaprofenic acid, suprofen, naproxen, piktoprofen, and carprofen induce skin photosensitivity (Figure 66.1) [1,2,7–20]. Among these drugs, KP is by far the most frequently reported causing photoallergic contact dermatitis [2,16,17,28,29]. KP is administered in more than 70 countries in various forms of systemic or topical application: poultice, gel, tape, cream, oral medicine, suppository, and injection. However, the largest number of photosensitive disorders reported for this drug might be associated with its topical use, a formulation that is available in many countries without medical prescription (over the counter). An overview of photosensitivity disorders induced by topical drugs has shown that KP represents the majority of cases (i.e., 82%) although it is less used than diclofenac [17]. Severe skin dermatitis was reported as pruritic and papulovesicular, bullous, and edematous lesions, often leading to residual pigmentation (Table 66.1). Treatment of these skin symptoms required systemic corticotherapy [7,9,14] and eventually hospitalization [7,9]; KP was also found to induce prolonged photosensitivity in some cases [8,9,28].

In addition, cross-reactivity to KP has frequently been evidenced. It is now recognized that the benzophenone moiety, rather than the arylpropionic acid side chain, is responsible for the photoallergy triggered by this drug, which explains the cross-reactions elicited by suprofen, tiaprofenic acid, fenofibrate,

or piktetoprofen [7,10,11,14,17]. Qualitative structure-activity relationships are clear for this series of compounds, bearing a diaryl ketone moiety. Nevertheless, some positive reactions to the photopatch test have been interpreted as resulting from potential cosensitization (i.e., fentichlor) [8,12,17].

It is noteworthy that notification of a large number of photosensitivity reactions to topical KP has modified its conditions of use in some countries. In France, topical preparations containing KP have been recently withdrawn from the market, waiting for a reevaluation of the risk/benefit ratio by the European Medicine Agency (EMA) [30].

FQs are antibacterial agents with activity against a variety of Gram-positive and Gram-negative organisms. Cutaneous photosensitivity is relatively uncommon, but characteristic side effects of FQs are recognized to be caused by either a phototoxic or a photoallergic mechanism [16,17,21–26]. A related drug, nalidixic acid, has been registered as a photosensitizer since 1964 in Europe [24]. Phototoxicity cases have been described for most FQs (Figure 66.2). Interesting data from the French drug monitoring system reveal that the rate of treated patients suffering phototoxicity were 0.4% for sparfloxacin, 0.12% for lomefloxacin, 0.005% for pefloxacin, 0.0003% for ofloxacin, and 0.0001% for ciprofloxacin and norfloxacin (NFX) [26,31]. Thus, it is evident that FQs with two halogen substituents at positions 6 and 8 have a greater photosensitizing potential (i.e., lomefloxacin, sparfloxacin, fleroxacin) [21,25,26].

Interestingly, it has been shown that 8-halogenated FQs induce severe skin reaction in comparison with the low phototoxicity exhibited by 8-methoxy derivatives [32]. This can be correlated with the higher photostability of the latter, as compared with the efficient dehalogenation of the former, which gives rise to highly reactive carbene intermediates.

Phototosensitivity induced by FQs shows a spectrum from moderate reactions, that is, erythema, edema, desquamation, and hyperpigmentation, to more severe cases of blistering and scarring that might require hospitalization (Table 66.1). Systemic administration of ciprofloxacin provoked a case of photoinduced acute exanthematous pustulosis characterized by the rapid onset of photodistributed cutaneous pustules, fever, and leukocytosis [23].

FIGURE 66.2 Structure of the phototoxic FQs.

It is remarkable that FQ photosensitization, in addition to induce skin photoreactions, is also suspected to be responsible for cutaneous photocarcinogenicity, as revealed by *in vivo* studies on mice [33–35].

66.3 *In Vitro* Phototoxicity Testing

The current protocol for phototoxicity testing is based on the *in vitro* 3T3 NRU assay. This is now recommended by the European Union Commission and member states for all compounds showing significant absorption of UVA and visible light. It is based on a protocol validated in 1998 by the European Centre for the Validation of Alternative Methods (ECVAM) and the European Cosmetic, Toiletry and Perfumery Association (COLIPA) and later in 2004 at a worldwide level by the Organization for Economic Cooperation and Development (OECD) [6,36,37].

The principle of this assay is to compare the cytotoxic potential of the considered chemicals to Balb/c 3T3 mouse fibroblasts when tested with and without UV irradiation (dose of $5 \text{ J} \times \text{m}^{-2}$). Viability is assessed 24 h after treatment by spectroscopic measurements of the vital dye neutral red (NR) uptake by the cell, as dead and damaged cells are unable to take up and retain NR. Cytotoxicity is expressed as a dose-dependent reduction of the growth rate of cells in the presence and in the absence of UV irradiation. The EC_{50} values are obtained from the concentrations of the test compounds causing a 50% reduction in NR dye. Then, the photoirritation factor (PIF) is calculated as the ratio between EC_{50} with and without UV light. A cutoff value of $\text{PIF} = 5$ for predicting the phototoxic potential of a chemical has been established, thus any chemical with a higher value is defined as having a potential phototoxic hazard.

In spite of its proved usefulness, it is now well established that a high number of compounds reported as positive in the 3T3 NRU assay are negative when tested *in vivo* using animal models. The important occurrence of these “false positives” (over predicting the human hazard) has encouraged the development of new strategies to assess and understand the phototoxic potential of drugs. Nevertheless, it should be underlined that this assay predicts negatives with excellent fidelity.

Another limitation of the 3T3 NRU test is that it has been designed to assess the photoirritant potency of compounds, and thus, it does not allow prediction of other important adverse photobiological effects, such as photogenotoxicity, photocarcinogenicity, or photoallergenic potential.

Table 66.2 summarizes the 3T3 NRU test results obtained with arylpropionic acids active as NSAIDs and with the antimicrobial FQ [38–40]. The high PIF values reported for KP and tiaprofenic acid are in agreement with the clinical data discussed earlier.

TABLE 66.2 PIF Values of Arylpropionic Acids (NSAIDs) and FQ Antibiotics Obtained during 3T3 Assays

Family	Drug	3T3 NRU Test	Reference
NSAIDs	Ketoprofen	PIF > 488	[38]
	Tiaprofenic acid	PIF 714.5	[38]
FQs	Ciprofloxacin	PIF 1.7	[39]
		PIF 5.35	[40]
	Sparfloxacin	PIF 10	[39]
		PIF 8.44	[40]
	Lomefloxacin	PIF 4	[39]
		PIF 6.88	[40]
	Ofloxacin	PIF > 6.5	[38]
	Norfloxacin	PIF > 25.5	[38]
		PIF 5.17	[40]
	Moxifloxacin	PIF 1	[39]
	Nadixilic acid	PIF 13.6	[40]

Literature data recovered from the last 10 years.

In the case of FQs, moxifloxacin and ciprofloxacin appear to be nonphotoirritant drugs with PIF values <2, whereas the other tested FQs exhibited a higher phototoxic potential.

66.4 Mechanistically Based Studies

66.4.1 General Reaction Scheme

A mechanistically based strategy taking into account the sensitizer's photophysical and photochemical properties has to be considered for a deeper understanding of the molecular processes involved in the photosensitivity side effects. In this way, study of well-established phototoxic drugs provides helpful information on the mechanisms. This knowledge can then be applied in the drug development process to design new pharmaceuticals with a higher photosafety.

Such a strategy should include not only the study of photophysical and photochemical properties of the drug alone but also in the presence of biomolecules like lipids, proteins, DNA, and their simple building blocks.

The primary characteristic for a compound to be considered a potential photosensitizing agent is absorption in the UVA–UVB and visible range (i.e., at $\lambda > 290$ nm). After photon absorption, the molecule reaches a singlet excited state (Scheme 66.1). This generally short-lived state (in the nanosecond timescale) decays by different processes: (1) fluorescence, (2) intramolecular reactions generating reactive intermediates and/or photoproducts formation, (3) nonradiative processes like internal conversion, and (4) intersystem crossing leading to the population of the triplet excited state. It has been recognized that triplet states (with lifetimes of 10^{-6} to 10^{-3} s) are the key intermediates responsible for intermolecular reactions. Indeed, these states are considered as the biologically active species, due to their central role in the photosensitization of biomolecules. Generally, photosensitized reactions are classified into two processes. Type I mechanisms including H-abstraction or electron transfer processes result in the production of radical species that can further lead to oxidation of biomolecules. On the other hand, in type II mechanisms, energy transfer to molecular oxygen gives rise to the formation of reactive singlet oxygen, which in turn reacts with biological substrates.

To illustrate this concept, the results available for two relevant photosensitizing drugs, namely KP and NFX, will be considered for type I and type II processes, respectively.

66.4.2 Ketoprofen

66.4.2.1 Photophysical and Photochemical Properties

KP shows a maximum of absorption at 260 nm with an extended spectrum reaching the UVA region up to 350 nm. Its photochemistry in neutral aqueous media is dominated by an efficient photodecarboxylation ($\phi = 0.75$) triggered by intramolecular electron transfer from the carboxylate group to the

SCHEME 66.1 Mechanistic pathways involved in photosensitization by drugs.

SCHEME 66.2 Mechanism of KP photodecomposition resulting in formation of the major product, 3-ethylbenzophenone.

excited carbonyl [41]. Steady-state irradiation gives rise to a variety of photoproducts, the major one being 3-ethylbenzophenone (Scheme 66.2).

From a photophysical point of view, KP exhibits an intersystem crossing quantum yield of unity, which results in quantitative population of its triplet state. Phosphorescence experiments show the typical characteristics of benzophenone-derived emission with an $n\pi^*$ nature and a triplet excited state energy of $69.3 \text{ kcal} \times \text{mol}^{-1}$. Picosecond laser flash photolysis studies reveal formation of several transients, including a very short-lived triplet state ($\lambda = 526 \text{ nm}$ and lifetime of ca. 250 ps) and a biradical anion ($\lambda = 570 \text{ nm}$ and lifetime ca. 120 ns) [42,43].

Moreover, it has been shown that such photodecarboxylation process is retarded by a simple modification based on keeping away the carboxylate from the ketone carbonyl group and maintaining intact the arylpropionic part of KP. In this context, derivatization of KP with glycine results in a remarkable decrease of the photodecarboxylation quantum yield ($\phi < 0.06$); thus, it allows its photophysical study and determination of excited triplet state quenching rate constants by amino acids and nucleosides in phosphate buffer saline solution (PBS) [44].

Reactive oxygen species (ROS), that is, singlet oxygen, superoxide anion, and hydroxyl radical are formed during KP photolysis [41,45]. However, the high photolability of the drug renders it a poor candidate for ROS generation. A potentially superior photosensitizer is its main photoproduct, 3-ethylbenzophenone, which exhibits a singlet oxygen quantum yield of 0.29.

It is important to underline that photophysical and photochemical characteristics are dependent on the medium, in such a way that results obtained in PBS can only provide an approximation of drug behavior in a biological environment. As an example, laser flash photolysis studies of NSAIDs showed a remarkable increase of triplet excited state lifetimes when the drug is complexed with human or bovine serum albumin (HSA or BSA) [46,47]. In the case of KP, such increase represents more than three orders of magnitude (from 250 ps in PBS to 500 ns in HSA) [48,49]. It has been hypothesized that interaction of the negatively charged carboxylate group with positively charged amino acids disfavors intramolecular reactivity, thus enhancing the relatively slower intermolecular processes.

66.4.2.2 Interactions with Biomolecules

The strong photosensitizing properties of KP have been assigned to its benzophenone chromophore with a lowest lying $n\pi^*$ triplet excited state. Accordingly, it should exhibit an important reactivity as H-acceptor compound, and in fact a major contribution of type I processes has been observed in KP photosensitization.

66.4.2.2.1 Lipid Peroxidation

Hydrogen abstraction from target biomolecules appears to be the main process responsible for KP-induced phototoxicity, playing a key role in photodynamic lipid peroxidation, which is in the

origin of cell membrane lysis. Indeed, radical-mediated photohemolysis of red blood cells by KP has been described [41,50]. For a better understanding of the chemical mechanisms, studies were performed with linoleic acid and cholesterol, two structural components of cell membrane that may be oxidized by type I and/or type II mechanisms.

After irradiation in the presence of KP, lipid-derived dienic hyperoxides are produced. A type I mechanism initiated by abstraction of the double allylic hydrogen by the excited benzophenone moiety has been shown to occur, as the key step in radical chain oxygenation [41]. The KP ability to induce lipid peroxidation can be correlated with its potential to produce cell membrane lysis.

Further mechanistic studies have been performed on model diastereoisomeric bichromophoric model compounds containing KP tethered to cholesterol, but also to tetrahydrofuran, 1,4-cyclohexadiene, or isopropylbenzene derivatives as hydrogen donors. For the KP-cholesterol model, intramolecular hydrogen abstraction from the 7-allyl cholesterol position by the benzophenone moiety was established by laser flash and steady-state photolysis. This was based on detection of a transient species assigned as a ketyl-allyl biradical and, on the isolation and characterization of macrocyclic photoproducts arising from C-C coupling [51,52]. Similar results were obtained for KP tethered to the other H-donors [53–56]. Interestingly, chiral discrimination was demonstrated not only in the photoreactivity of the dyads but also in their very short triplet excited state lifetimes.

66.4.2.2.2 DNA Damage

DNA damage is not directly linked with phototoxicity; nevertheless, it is now well established that lethal, mutagenic, and/or carcinogenic effects might be the result of photochemical modification of DNA.

KP photosensitization of supercoiled ϕ X174 DNA induces single-strand breaks (ssb) formation. A type I mechanism has been assessed by the use of radical scavengers [41]. On the basis of gel sequencing experiments, an electron transfer mechanism between the guanine nucleobase and the excited drug has been proposed. Indeed, after alkali-labile treatment of ^{32}P -labeled oligonucleotide, selective DNA strand break at the 5'-G of a -GG- site is observed as a hallmark of electron transfer process. Accordingly, negative values of free energy changes have been determined by the Rehm Weller equation [45]. These results are in agreement with the bimolecular rate constant of $1 \times 10^9 \text{ M}^{-1} \times \text{s}^{-1}$ obtained by laser flash photolysis for the interaction between triplet excited state of KP and 2'-deoxyguanosine [57]. A recent mechanistic study of KP-purine dyads also supports an intramolecular electron transfer from the nucleobase to KP. This initial step is followed by subsequent deprotonation of the C1' purine radical cation leading to the generation of 2-deoxyribonolactone [58].

Moreover, formation of cyclobutane thymine dimers has been evidenced by the use of T4 endonuclease V, a DNA repair enzyme that specifically recognizes this lesion [41,45]. Thymine dimers are mutagenic damages formed by a triplet-triplet energy transfer mechanism from the excited state of the photosensitizer to the thymine triplet state. Indeed, this process is thermodynamically favored for KP, as its triplet state energy is $5 \text{ kcal} \times \text{mol}^{-1}$ higher than that of thymine in DNA, a value recently established at $64 \text{ kcal} \times \text{mol}^{-1}$ [59].

The ability of KP to induce DNA damage in the more complex environment of the whole cell has been assessed by the alkaline comet assay [60]. However, the major role of the 3-ethylbenzophenone photoproduct has been hypothesized from the observation of a delayed mechanism.

66.4.3 Norfloxacin

FQs have been reported to produce phototoxic, photoallergic, photomutagenic, and phototumorigenic effects, both *in vitro* and *in vivo* [34,61,62]. The photoreactivity of the 6,8-dihalogenated drugs has been associated with an efficient dehalogenation that results in the generation of highly reactive intermediates, able to attack biological components. By contrast, the phototoxic potential of some monohalogenated FQs has been related to type II processes.

66.4.3.1 Photophysical and Photochemical Studies

It is now well established that the excited state properties of FQs are strongly dependent on the pH as expected from the presence of both a carboxylic group and 7-amino substituent in their structures ($\text{pK}_{\text{a}1}$ 5.5–6.5 and $\text{pK}_{\text{a}2}$ ca. 8.5). For biological studies, the experiments are generally performed in neutral aqueous solutions, where the prevailing FQ species is the zwitterionic form.

In phosphate buffer, NFX absorption spectrum is characterized by an intense absorption band that peaks at 275 nm, a weaker band centered at 340 and a long tail extending until 380 nm [63]. Under the same conditions, a fluorescence emission at $\lambda_{\text{max}} = 410$ nm, with a quantum yield of ca. 0.1 and a lifetime of 1.5 ns has been reported [63–66]. The singlet excited state is not significantly reactive, and an important deactivation channel is intersystem crossing to the triplet manifold. This excited state is detected by laser flash photolysis as a triplet-triplet transition centered at 620 nm and characterized by a lifetime of 3.5 μs , a molar absorption coefficient of $\epsilon = 7900 \text{ M}^{-1} \times \text{cm}^{-1}$, and an intersystem crossing quantum yield of 0.52 [59]. Moreover, NFX triplet excited state energy has been determined at room temperature by applying Sandros' equation to the rate constants of energy transfer to a series of acceptors. The obtained value, estimated at $64.3 \text{ kcal} \times \text{mol}^{-1}$, is close to that observed by low temperature phosphorescence measurements [64]. A particular property of FQs is their dynamic triplet state quenching by phosphate; a rate constant of $k_{\text{q}} = 8 \times 10^7 \text{ M}^{-1} \times \text{s}^{-1}$ has been determined for NFX [64].

The main photoreaction observed is heterolytic defluorination from the triplet state manifold [66,67]. However, important changes are induced by phosphate both in the decomposition quantum yields and in photoproduct distribution. Photolysis of NFX in neat water has a quantum yield of 0.5 and leads essentially to a single compound, the corresponding 6-hydroxyquinolone (Scheme 66.3). By contrast, in neutral sulfite or phosphate buffer, the decomposition quantum yield is two orders of magnitude lower ($\phi = 0.004$) and reductive defluorination is the main reaction pathway [63,68].

Production of ROS has also been reported. NFX generates both singlet oxygen (quantum yield < 0.1 in PBS) and superoxide anion [69].

66.4.3.2 Membrane Damage

A microspectrofluorometric study of skin fibroblasts has shown that NFX is localized in various cytoplasmic structures, especially in lysosome and mitochondria. Irradiation of the cells in the presence of NFX induces damage to these subcellular components, which results in membrane destabilization [69,70].

Photohemolysis of red blood cells has been reported, together with lipid peroxidation, estimated as the amount of species reactive to the thiobarbituric acid reactive substances (TBARS) assay [71,72].

66.4.3.3 DNA Damage

Formation of DNA strand breaks upon irradiation in the presence of NFX has been observed in plasmid and in cellular DNA [33]. In order to obtain more information on the nature of DNA

SCHEME 66.3 Photolysis of NFX in water and in phosphate or sulfite buffer.

photoproducts, formation of oxidized purines and pyrimidines has been studied by using the specific DNA repair enzymes *E. coli* formamidopyrimidine DNA glycosylase and endonuclease III, respectively. Only lesions on purine bases are observed. Accordingly, formation of 8-oxo-7,8-dihydro-2'-deoxyguanosine (8-oxodGuo) has been evidenced both in cellular and naked DNA. Nevertheless, this lesion does not give any information on the mechanism of the photodynamic process involved, as it can be obtained both by type I and type II guanine oxidation. To address this issue, a quantitative determination of the photoproducts of free dGuo nucleoside is necessary. This DNA component is the only one that can suffer both type I and type II processes, leading to mechanistically relevant photoproducts. On the one hand, the oxazolone derivative (2,2-diamino-4-[(2-deoxy- β -D-erythro-pentofuranosyl)amino]-2,5-dihydrooxazol-5-one) is considered as a hallmark of type I processes; it is obtained from the guanine radical cation initially generated by electron abstraction from dGuo. On the other hand, the diastereoisomeric spiroiminodihydantoin (dSp) are diagnostic of a singlet oxygen mechanism. The relatively high ratio between the yields of dSp and oxazolone formation found for NFX reveals its ability to act mainly as type II photosensitizer [33].

Other studies have shown that NFX is one of the few photosensitizers able to induce formation of T<>T cyclobutane dimers in cellular and isolated DNA. This result, attributed to energy transfer from NFX triplet excited state to the thymine bases, is in agreement with the triplet state energies of both compounds [59,73].

66.5 Conclusions

Photosensitization by drugs is an important issue as demonstrated by the large number of compounds involved in phototoxic and photoallergic reactions. Indeed, evaluation of drug photosensitizing potential relies on a series of *in vivo* and *in vitro* investigations. The photosensitizing history of a drug encompasses clinical observation in patients, photopatch tests but also 3T3 NRU assay and, fundamental studies taking into account its photophysical and photochemical properties. In this chapter, such an overview has been presented for KP and NFX; it demonstrates that a complete photophysical, photochemical, and photobiological study is fundamental to understand the key molecular mechanisms involved in the photosensitization process.

67.1 Introduction

The question of water supply and distribution is becoming of utmost importance worldwide from both a social and a scientific point of view. Actually, a growing number of countries around the world, especially developing countries but also several Mediterranean countries, face increasingly difficult situations concerning the availability of irrigation, industrial, and drinking water from both surface and groundwater stocks. Many water sources are heavily polluted by hazardous chemicals, which are known to be harmful to humans and a variety of animal and vegetal ecosystems, as well as by several kinds of pathogenic microorganisms, such as bacteria, fungi, molds, viruses, and parasitic protozoa. Potential contaminants include agricultural runoff, landfill leachates, and industrial activities [1,2]. Therefore, there is an urgent need for the definition of efficacious and environmentally safe techniques yielding an efficient water purification and disinfection. Currently, the most commonly adopted approaches are based on physical methods (e.g., filtration, heating, or irradiation with ultraviolet [UV] light or x-rays), even though reliance is mainly placed on chemical treatments with oxidizing species, such as chlorine, chlorine dioxide, or ozone [3]. However, such methods often exhibit a number of negative aspects, in particular the formation of endoperoxides or trihalomethanes as by-products of the reaction between the chemical disinfectant and organic matter, or the selection of multidrug resistant microbial strains upon repeated treatment of waters characterized by a large microbial flora [4,5]. Moreover, chlorine is often phytotoxic [6], while the use of ozone proved to be moderately expensive and involve a high consumption of energy, thereby making its implementation on a large scale a not very attractive endeavor. The evolvement of resistance by microbial cells represents a particularly challenging problem as a consequence of the truly large variety of mechanisms, which have been found to be developed by pathogenic agents in order to increase their defensive strategies against external insults: these include a thickening of their outer wall, encoding of new proteins that prevent the penetration of drugs, onset of mutants deficient in those porin channels allowing the influx of externally added chemicals, etc. [7]. The transfer of such resistance to human pathogens represents a potentially serious threat to public health [8]. Therefore, it is by now apparent how difficult it is to identify a comprehensive strategy.

The use of photochemical techniques for the treatment of chemically or microbiologically contaminated waters has been operative for many years with so far contrasting results. Thus, the effectiveness of UV light is often limited by the reduced penetration power (<1 cm) of wavelengths shorter than 350 nm into natural water [9]; moreover, the direct absorption of UV-C and UV-B wavelengths by nucleic acids is a main cause of the onset of mutagenic processes leading to the selection of possibly dangerous new kinds of microbial strains [10]. To address these problems, novel photochemical pathways for water purification have been devised, including (a) the direct irradiation with full sunlight spectrum using specifically designed apparatuses in order to take advantage of the significantly deeper penetration of visible light wavelengths even into water samples characterized by relatively high levels of turbidity [11] and (b) the introduction of photoassisted reactions via semiconductors (e.g., TiO_2 or ZnO), which can be electronically excited by light wavelengths in the UV-A spectral range giving raise to the formation of strongly oxidizing and highly cytotoxic species, *in primis* the OH radical and hydrogen peroxide [6,12].

In actual fact, the disinfection of drinking water affected by an unusually high population of the Gram-negative bacterium *Escherichia coli* by means of solar reactors equipped with parabolic collectors has been obtained, even though the efficiency of the overall process was markedly enhanced by the presence of TiO_2 as a photocatalyst [13]. The addition of the semiconductor also yields an extensive destruction of a variety of organic micropollutants [14]. However, in spite of the intrinsic and experimentally demonstrated high efficiency of such approaches, their usefulness is presently confined to small-scale water treatment, mainly owing to the reduced water volumes that can be illuminated in a homogeneous way by using light wavelengths in the UV-A spectral range, as well as to the relatively high costs associated with the operation of this technology. Furthermore, the oxidizing intermediates normally involved in such photoprocesses display an appreciable reactivity against most nucleotides, hence there is again a high probability of promoting mutagenic effects [15].

Recently, a novel approach has been proposed, which appears to be of low cost and minimal impact on environment, namely, the use of photodynamic sensitizers, which can be activated by irradiation with selected intervals of visible light wavelengths. This methodology appears to be particularly useful for the decontamination of waters, which are characterized by a large level of microbial pathogens [16].

67.2 Photodynamic Sensitization of Biological Systems

67.2.1 Photodynamic Processes: Basic Mechanisms

The term “photodynamic effect” refers to a process that involves the combined action of three factors, namely, light of an appropriate wavelength, oxygen, and a photosensitizer to induce a biological damage [17]. A simplified mechanistic scheme of photosensitized processes is shown in Figure 67.1. The electronic excitation of the photosensitizer is generally achieved via a one-photon transition from the ground state Sens^0 to a more energetic singlet state Sens^* .

Relaxation of Sens^* through vibrational decay modes yields the lowest excited singlet state Sens^1 . Several deactivation pathways are open to the Sens^1 species; the critical step from the point of view of the photodynamic process is represented by the intersystem crossing from Sens^1 to the first excited triplet state Sens^3 , whose lifetime is in the order of the micro- to millisecond range, so that this intermediate can play a major role in diffusion-controlled processes. Actually, Sens^3 can promote two reaction mechanisms (Figure 67.1). The type I pathway involves hydrogen or electron transfer between Sens^3 and a nearby substrate with generation of radical species; the direction of the transfer is controlled by the relative redox potentials of the triplet photosensitizer and the electron acceptor or donor. In particular, electron transfer to oxygen yields the superoxide radical anion $\text{O}_2^{\cdot-}$, which under suitable experimental conditions can be converted to the hydroxyl radical OH^\cdot via the Haber–Weiss reaction. In the type II mechanism, the Sens^3 can give raise to the electronically excited oxygen species known as singlet oxygen ($^1\text{O}_2$) through electronic energy transfer to ground state molecular oxygen (which is a triplet). All the activated oxygen derivatives thus produced are highly electrophilic

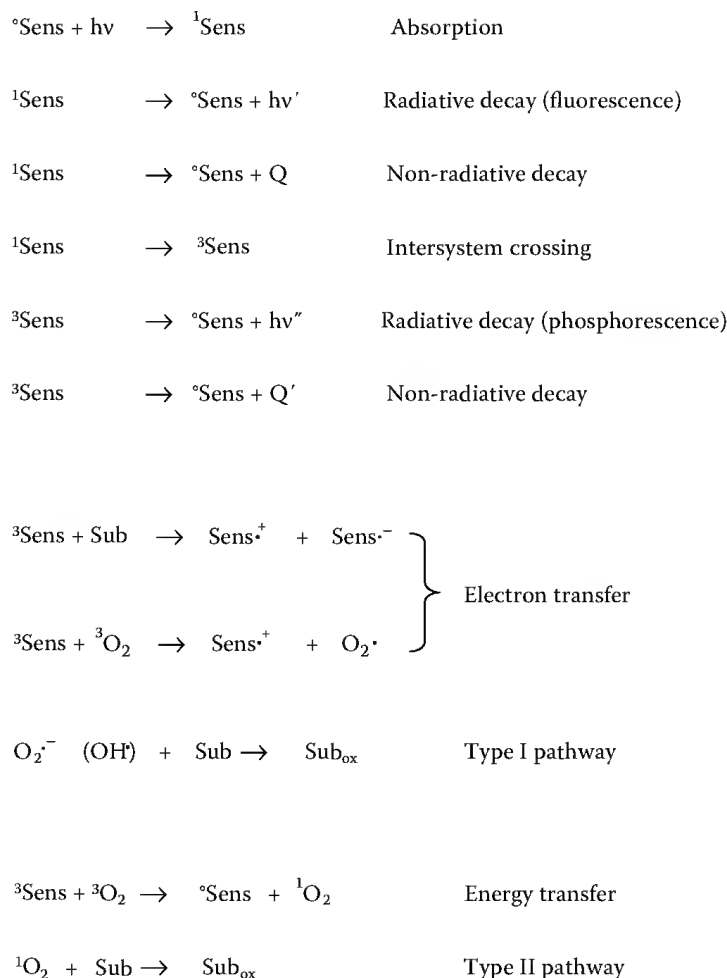

FIGURE 67.1 Schematic representation of the photophysical and photobiological steps involved in photodynamic sensitization processes.

moieties, hence they can rapidly react with electron-rich sites of a cell or tissue causing the formation of photooxidized products. A detailed description of the mechanisms controlling the fate and efficiency of photodynamic sensitization can be found in Ref. [18].

The biomolecules that are most sensitive to the photodynamic processes are listed in Table 67.1. Clearly, the side chains of aromatic- or sulfur-containing amino acids, guanosine nucleotides, and unsaturated lipids and steroids represent potential targets for attack by OH^{\bullet} or ${}^1\text{O}_2$. In general, such compounds are almost ubiquitously present in various subcellular compartments. Therefore, if such activated oxygen species are generated by a cell-bound photosensitizer, the overall process has a very high probability to be confined within a sphere with a diameter no greater than 1–2 nm around the Sens-binding site [19]. For example, the intracellular diffusion distance of ${}^1\text{O}_2$ has been estimated to be $2\text{--}4 \times 10^{-6} \text{ cm}^2 \text{ s}^{-1}$ [20]. In some cases, one can distinguish between the two competing type I and type II mechanisms on the basis of the final photooxidation products, as outlined in Table 67.1.

As a general minor alternative to the type I and type II mechanisms, electronically excited sensitizers often undergo a chemical reaction, which results in the irreversible modification of their chemical structure [21]. The process is defined as “*photobleaching*” since it involves the loss of absorption and fluorescence intensity, so that with very few exceptions the photodegradation products do no longer contribute to the photosensitized process. In general, the quantum yields for the photobleaching of most photodynamic sensitizers are in the 10^{-4} to 10^{-5} range, namely, only a tiny fraction of the absorbed visible light photons eventually induce photobleaching of the sensitizer molecule. While some degree of

TABLE 67.1 Main Biological Targets of Photosensitized Processes

Cell Constituent	Target	Modified Functional Group	Main Biological Effects
Proteins	Tryptophan	Indole	Loss of enzymic activities; formation of protein–protein cross-links; inhibition of K ⁺ pump; impairment of DNA synthesis
	Tyrosine	Phenol

	Methionine	Thioether	
	Cysteine	Thiol	
Unsaturated lipids steroids	Oleic, linoleic, linolenic acid	Carbon–carbon double bond	Blockade of metabolic processes; alteration of membrane potential and fluidity
	Cholesterol		
Nucleic acids	Guanosine	Purine	Alteration of chromatin; disturbed synthesis of membrane and cell wall

reduced efficacy of the photodynamic agent as the irradiation progresses can have some positive consequences in clinical antineoplastic applications [22], it is usually highly preferable to have active principle concentrations that remain at the maximal possible level throughout the exposure of the target system to light [23].

The biological consequences of the photoinduced chemical damage described are multiform and include protein denaturation, impairment of DNA replication, inhibition of transport processes across the cytoplasmic membrane, and loss of integrity of several subcellular organelles. If the alterations caused to cell metabolism and homeostasis are sufficiently extensive, then the cells can enter a death process via necrosis, apoptosis, or autophagia [24,25].

67.2.2 Photodynamic Inactivation of Microbial Cells

The possibility to kill microorganisms by the combined action of visible light and a photosensitizing dye was discovered at the very beginning of the twentieth century [26]. However, the use of this methodology to treat infectious diseases of microbial origin was not developed for several decades owing to two main reasons [27]: (a) the discovery of antibiotics raised the feeling that such diseases could be efficaciously controlled and counteracted even though this expectation was rapidly disappointed by the worldwide outbreak of antibiotic resistance and (b) microbial pathogens typically exhibit a very broad variety of cellular organization and defense strategies, so that it appeared quite problematic to devise a therapeutic approach, which could simultaneously achieve the death of bacterial, fungal, and parasitic cells. Thus, some porphyrin derivatives, such as hematoporphyrin, Photofrin, or tetrasulfonated porphyrins, which are known to be very active as antitumor photosensitizing agents [28], are ineffective against Gram-negative bacteria, whereas they still promote an extensive killing of Gram-positive bacteria [29,30]. The differences in the photoantimicrobial activity displayed by these porphyrin derivatives were ascribed to the anionic nature of the porphyrins used in photodynamic therapy (PDT) of neoplastic lesions; this feature precludes their close or stable interaction with the array of negatively charged moieties (largely, teichoic and teichuronic acids), which are present at the surface of the outer wall surrounding the cells of Gram-negative bacteria and several yeasts or fungi [30,31].

A significant change in the overall scenario of antimicrobial PDT occurred as a consequence of the discoveries independently made by three research groups showing that visible light-activated cationic photosensitizers belonging to the family of phenothiazines [32], porphyrins [33], and phthalocyanines [34] induce a fast and extensive killing of typical Gram-negative bacteria, such as *E. coli* and *Pseudomonas aeruginosa*, in addition to the inactivation of fungi and Gram-positive bacteria. Mechanistic investigations demonstrated that such positively charged photosensitizing agents are taken up by microbial cells via the so-called “self-promoted uptake pathway” [31,35], whose essential steps are schematically illustrated in Figure 67.2. A similar pathway has been observed for some cationic peptides, which can

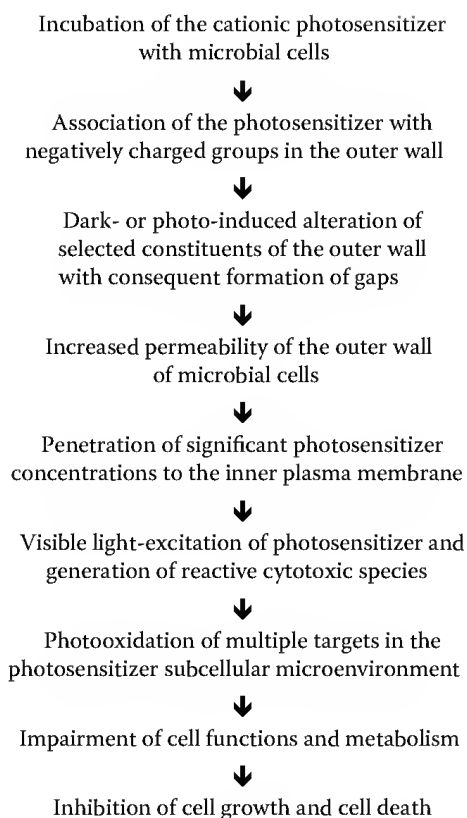

FIGURE 67.2 Schematic mechanism involved in the photosensitized inactivation of microbial cells.

displace divalent cations, such as Mg^{2+} or Ca^{2+} , from their binding sites on the cell surface owing to their 2–4 orders of magnitude larger affinity. The consequent reorganization of the outer membrane structure has been found to facilitate the penetration of various antibiotics and hydrophobic molecules to inner cellular compartments. Moreover, the close proximity of the photosensitizer to potentially sensitive targets in the outer wall (e.g., lipoproteins) can induce their preferential photooxidative modification, thus further enhancing the alteration of the compact native structure.

The initial binding of the photosensitizing agent is driven by an electrostatic interaction between the positively charged groups in its molecule and the negative charges at the cell surface, hence the process occurs at a very fast rate and is completed within 5–10 min. incubation. As a consequence, the visible light irradiation of the photosensitizer-loaded bacterial cells can start after very short incubation times and in the presence of photosensitizer dosages in the micromolar range: under these experimental conditions, very little, if any, amounts of photosensitizer are accumulated by mammalian cells, which guarantees a high selectivity of microbial cell damage as compared with the host tissue. In particular, the significant hydrophobic contribution of the large aromatic macrocycle typical of phenothiazine and porphyrinoid compounds favors the localization of the photosensitizer in the plasma membrane, which is the main site of the photoprocess. The genetic material becomes involved only in the later stages of the photosensitized process, which minimizes the risk for the onset of mutagenic processes [30,31].

A very similar scenario obtains for the photosensitized inactivation of fungi and yeasts, whose photosensitivity is less strictly dependent on structural factors as compared with Gram-negative bacteria [35]. In general, the stepwise scheme previously detailed for the photosensitized inactivation of bacteria (Figure 67.2) can be accepted also for this class of microbial cells. Thus, negatively charged photosensitizers, such as protoporphyrin [35,36], and mono- or tetra-sulfonated Al(III)-phthalocyanines [3] are accumulated by *Candida* spp. and photosensitize an extensive killing of this microorganism. On the other hand, also in the case of yeasts, cationic phthalocyanines are taken up

TABLE 67.2 Effect of the Porphyrin Photosensitization on the Survival of Selected Gram-Positive (*Enterococcus seriolicida*), Gram-Negative (*E. coli*) Bacteria, and Fungi (*Candida albicans*)

Photosensitizer	Irradiation Time (min)		
	1	5	10
<i>E. seriolicida</i>	2.3	4.9	5.8
<i>E. coli</i>	1.9	3.1	4.5
<i>C. albicans</i>	3.1	5.7	>6.5

Bacterial cells were irradiated with 600–700 nm light at a fluence rate of 40 mW cm⁻² after 5 min incubation with 5 μM porphyrin (TMPyP). The photosensitivity is expressed as log decrease in cell survival.

in larger concentrations and display a more pronounced photosensitizing activity than their neutral or anionic analogues [37]. Interestingly, yeasts are also sensitive to the photodynamic action of cationic dyes even at the stage of biofilms [37]. Typical examples of the time-dependent photosensitized killing of selected bacterial and fungal cells in the presence of tetra-meso(*N*-methyl-pyridyl)porphine (TMPyP) are reported in Table 67.2.

Lastly, photodynamic sensitization can play a useful role for the efficient inactivation of parasitic protozoa. Thus, a cationic porphyrin bearing four positively charged meso-*N*-methyl-pyridyl peripheral substituents at 1–10 μM concentrations, upon visible light irradiation, induces an extensive damage of cystic cultures of *Colpoda inflata*, a soil and freshwater-dwelling ciliate, as well as of the free-living opportunistic *Acanthamoeba palestinensis*; in addition, the porphyrin photosensitizes the inhibition of excystment to produce vegetative cells [38]. The phototoxic activity is markedly enhanced by the replacement of at least one methyl group with a longer hydrocarbon chain. Analogously, a tetracationic Zn(II)-phthalocyanine can efficiently inactivate cultures of *A. palestinensis* in both the cystic and vegetative stages upon illumination with 600–700 nm light [39,40]: the two forms exhibit a comparable dependency on the photosensitizer concentration; however, cysts require a significantly longer irradiation time to give a similar degree of inactivation. A phthalocyanine concentration as low as 0.5 μM, followed by 20 min irradiation, induces 50% inhibition of excystment in vegetative cells after the addition of fresh culture medium.

Similarly, a variety of parasites such as the blood-borne pathogens *Plasmodium falciparum* and *Babesia divergens*, the protozoan responsible for Chagas disease *Trypanosoma cruzi*, or the agent causing visceral leishmaniasis *Leishmania donovani infantum* undergo an extensive inactivation upon irradiation with visible light wavelengths in the presence of selected photosensitizers (see for a recent review Ref. [41]).

67.3 Use of Photodynamic Processes for Decontamination of Water

67.3.1 General Features of the Approach

Water resources are suffering from a progressive and sometimes dramatic reduction in quantity and quality worldwide, as specified in the introductory paragraph. The situation is largely determined by the steady increase in environmental pollution and the lack of safe and efficient technologies for wastewater treatment. Therefore, there is an urgent need for the development of novel, convenient, and low cost methods for combating water contamination, especially that caused by biological agents that can originate dangerous epidemic diseases. In this connection, the results so far obtained on the

antimicrobial properties of photodynamic sensitizers clearly suggest that the combination of cationic porphyrins and visible light (or even sunlight under specific climatically favorable situations) could represent a viable and environmentally friendly alternative for the control of the population of potential pathogens in waters of different origin. The main favorable features of this technique can be summarized as follows:

1. The photosensitizing and cytotoxic activity of positively charged porphyrins appears to be characterized by a broad spectrum, since an extensive drop in the population of a variety of microorganisms can be achieved, such as Gram-positive and Gram-negative bacteria, typically including aggressive and antibiotic-resistant bacteria, for example, methicillin-resistant *Staphylococcus aureus* (MRSA), a variety of fungal pathogens, viruses, and parasitic protozoa in both the cystic and vegetative stage. Such a behavior is typical of several photosensitizing agents bearing cationic functional groups; however, as regards the antimicrobial activity, porphyrins appear to be superior to other families of polycyclic compounds [42]. In particular, the presence of peripheral substituents with a relatively long hydrocarbon chain ($C > 10$) appreciably enhances the cytotoxic effect: this chain acts as a hydrophobic arm, which penetrates into lipid and protein domains of the cytoplasmic membrane, thereby altering its permeability [43]. This allows the use of lower dosages of photosensitizer to achieve a satisfactory extent of pathogen cell killing.
2. The multitarget nature of the mode of action typical of porphyrins (see Table 67.1) makes it very unlikely that photoresistant strains of bacterial and fungal cells are selected. Thus, up to 10 consecutive generations of bacteria have been exposed to the photosensitizing action of cationic porphyrins with no detectable modification of their degree of photosensitivity [44].
3. At the same time, the presence of the flat aromatic macrocycle favors the partitioning of porphyrin derivatives in the cell membranes or their stable association with a variety of proteins [21,41]; as a consequence, exogenously administered porphyrins have a high probability to be “intercepted” before significant concentrations reach the genetic material. All the evidences available so far indicate that photoprocesses promoted by porphyrins have a very low mutagenic potential. This feature is important for the safety of the procedure in the case of repetitive treatments.
4. Most porphyrins display no significant toxicity toward the normal constituents of animal or vegetal ecosystems at doses which are photochemically active and induce a marked mortality of microbial pathogens. This finding is in agreement with previous observations dealing with the effect of porphyrins on a variety of higher organisms, which justifies their increasing utilization as food additives or phototherapeutic agents [28,45]. Several porphyrins and their chlorine analogues are widespread in numerous ecosystems and their toxicity to cells and tissues becomes important only at millimolar concentrations [21], namely, for dosages that are 2–3 orders of magnitude larger than those yielding a satisfactory antimicrobial effect.
5. The intense absorption band of porphyrins in the 420–430 nm spectral region allows a very efficient interaction with blue light wavelengths, which are endowed with maximum penetration power into natural waters out of the wavelengths that are present in the solar spectrum [46]. On the basis of the Beer–Lambert law, one can estimate that for a porphyrin concentration of $0.5 \mu\text{M}$, which exhibits a high photoantimicrobial activity (Table 67.2) and a molar extinction coefficient ϵ value of $194,000 \text{ M}^{-1} \text{ cm}^{-1}$ in the blue spectral region, the absorption A of the incident light will be around 0.085 cm^{-1} ; since total light absorption by a system corresponds with $A = 2.0\text{--}2.2$, the illumination can be assumed to be sufficiently uniform to a water depth of about 25 cm. Less efficiently absorbed wavelengths (e.g., those in the green and red spectral regions, where porphyrins possess weaker absorption bands) will allow the illumination of even larger water volumes, even though the smaller probability of porphyrin photoexcitation by such wavelengths may require longer light exposure times.

6. The overall treatment time is further reduced by the short incubation, which is required in order to achieve a significantly large association of the porphyrin photosensitizer with the microbial cells. Such a fast kinetics is determined by the fact that the binding is of electrostatic nature, namely, it is promoted by the real time interaction between the positively charged peripheral substituents in the tetrapyrrolic macrocycle of the porphyrin molecule and the large number of negatively charged functional groups (e.g., lipopolysaccharides, lipoteichoic, and teichuronic acids), which are present in the outer wall of many microbial cells. Thus, previous investigations showed that prolonging the incubation of porphyrin-type derivatives with microbial cells from a few minutes to 1–2 h brings about no measurable increase in the amount of cell-bound antimicrobial agent [30,33]. The close proximity between the porphyrin and the potential targets of the photosensitized process represents an important factor for enhancing the efficacy of the treatment, since several photosensitive sites will be within the normal endocellular diffusion range ($<0.1\ \mu$) of the photogenerated reactive oxygen species, such as singlet oxygen [47].
7. The water disinfection can be successfully obtained by using a simple and inexpensive technology. In actual fact, an extensive decrease in microbial population is achieved by using low light intensities, of the order of $50\ \text{mW cm}^{-2}$, which can be easily reached by irradiation with halogen or incandescent filament lamps, that is, light sources of low cost, which have a long life span (a few thousand hours) and require no protective measures for the operators, the ecosystems and humans. Moreover, the low fluence rate causes no detectable thermal effect, thus avoiding any problems related with the possible increase in water temperature.
8. Lastly, the proposed methodology appears to be environmentally friendly, since it is based on the use of sunlight or sunlight simulators in combination with antimicrobial agents of natural origin. In any case, the accumulation of porphyrins in the various ecosystems is unlikely owing to their gradual photobleaching under the action of ambient light, as shown by studies from our laboratory and as repeatedly reported in the literature [21,48]. Moreover, the ready water solubility of cationic porphyrins should guarantee their fast dilution in the ground to levels that are below any risk threshold. In any case, the photobleaching products of these porphyrins also show no major toxic effects [41].

67.3.2 Photodynamic Treatment of Water from Fish-Farming Plants

Photodynamic sensitization appears to be endowed with a particularly great potential for the disinfection of waters from aquaculture systems. Such waters are often characterized by the presence of a large population of microbial pathogens owing to the often large density of fish in the farming structures, as well as to the high concentration of food residues, organic debris, and defecation products. In actual fact, several bacterial and fungal species, which are known to infect fish-farming waters, have been shown to be rapidly and efficiently inactivated upon visible light irradiation in the presence of porphyrin-type photosensitizers: these include *Vibrio anguillarum* [33,49], *Vibrio vulnificus* [50], *Bacillus* endospores [51], *Saprolegnia parasitica* [52], and several fecal coliforms and fecal enterococci isolated from wastewater samples [53]. The latter authors also propose a simple and expeditious method to evaluate the rate and extent of bacteria photoinactivation in wastewater; the method is based on the analysis of β -galactosidase activity and leucine incorporation as a function of the irradiation time. Moreover, preliminary studies performed in our laboratory using aquaria as model systems mimicking a variety of fish microenvironments clearly pointed out that the combined action of a tetracationic porphyrin, that is TMPyP, and visible light emitted by the aquaria-incorporated fluorescent lamps induces the regression or cure of several bacterial or fungal infections of different fish without any parallel (photo)toxic effect on the fish, as well as on other constituents of the aquaria ecosystem, such as invertebrates, algae, or green plants (see Table 67.3).

TABLE 67.3 Effect of Porphyrin and Visible Light Treatment on Aquaria Fish Affected by Bacterial or Parasitic Infections

Species	Pathology	Protocol	Results
<i>Grammaloretus</i>	White spots on a darkened skin	0.6 mg L ⁻¹ for 3 days	Disappearance of white spots
<i>Lysmata</i>	Black spots throughout the body	0.3 mg L ⁻¹ for 3 days	Disappearance of black spots
<i>Megalamphodus</i>	White spots on the skin	0.6 mg L ⁻¹ for 3 days	Fast spot disappearance
<i>Symphysodon discus</i>	Opaque and worn fins	0.6 mg L ⁻¹ for 3 days	Clear and reactive fins
<i>Cheirodon axelrodi</i>	Bleaching of skin color	0.6 mg L ⁻¹ for 6 days	Regression of infection
<i>Colisa golden</i>	Extensive lethality	0.6 mg L ⁻¹ for 6 days	Blockage of lethality
<i>Discus</i>	Mucous secretion and cotton-type outgrowth	0.6 mg L ⁻¹ for 2 days	Disappearance of pathologies

In all cases, the irradiations (400–800 nm light) were performed by using the light sources, which are naturally incorporated into the aquaria.

On the basis of such findings, the feasibility of this procedure for the disinfection of microbiologically polluted waters from fish-farming ponds was tested in pilot aquaculture plants involving either spontaneously or artificially *Saprolegnia*-infected rainbow trouts (*Oncorhynchus mykiss*) [52]. Actually, mycotic infections caused by members of *Saprolegnia* species, as well as by their close water mold relatives, represent a major challenge to a number of freshwater fishes and their eggs. Prevention and control of saprolegniasis are especially difficult, even under precisely established fish-farming conditions, owing to the ubiquitous nature and the rapid spreading of such fungi. The problem is further aggravated by various concomitant factors, such as (a) different stages of the fish life cycle are susceptible to saprolegniasis and in particular a marked increase in infection risk is observed during sexual maturation; (b) several forms of environmental stress, leading to a decreased water quality (e.g., increased average temperatures, high organic loads), act as predisposing agents for the outbreak of the disease, often by weakening the innate defense systems of the fish; (c) many fungicides that are effective against higher fungi exhibit a low activity against oomycetes; (d) spores of the pathogen can successfully locate in the fish epidermis and, while the majority are removed or inactivated during quarantine in clear water, a significant number of viable fungal units persist on the body surface [54]. *Saprolegnia*-induced mycotic infections have been traditionally treated by the application of malachite green, a triarylmethane dye. However, recent concerns about the safety of this aromatic derivative led to the banning of its use as a fisheries chemotherapeutant in many parts of the world. Even formalin, a 24% aqueous solution of formaldehyde, which has been introduced to replace malachite green, does not eliminate the risk for acute impact on ecosystems and potential harmful effects on human health [55].

On the other hand, the use of TMPyP and visible light proved to represent an efficacious technique for an environmentally friendly treatment of *Saprolegnia* infections. Two protocols were developed: a *preventive treatment* based on the irradiation of artificially infected trout (about 4×10^{11} zoospores deposited on a 2 cm² area of scraped skin) for 1 h day⁻¹ and for 10 consecutive days after addition of 0.3 mg L⁻¹ TMPyP; and a *curative treatment* where trout that had already developed a marked infection by *Saprolegnia*, as shown by the presence of cottony-like patches of the mycelium, were exposed to visible light (1 h day⁻¹ for 6 consecutive days) in the presence of 0.6 mg L⁻¹ TMPyP. The results unequivocally showed that the outlined procedures were very successful in both inhibiting the formation of the fungal infection and causing a complete disappearance of the preexisting infection with no detectable damage in correspondence of the perilesional tissue districts. Quite interestingly, such important effects were obtained by using fluence rates of the order of 50 mW cm⁻², which suggests that even sunlight in cloudy days can be used to disinfect waters in open-air fish-farming systems, thus further reducing the overall cost of the procedure and meeting the recommendations to increase the use of natural resources for energy-saving reasons. In actual fact, the killing of *Deinococcus radiodurans* by the use of sunlight-activated cationic Zn(II)-porphyrin derivatives [56], as well as of *E. coli* by sunlight-activated tetracationic meso-substituted porphyrins [57] has been demonstrated.

Recent investigations from our laboratory also showed that tetracationic porphyrins at doses as low as $0.3\text{--}0.6\text{ mg L}^{-1}$ efficiently protect trout eggs against infections by *Saprolegnia*. In this case, the irradiation by visible light needs to be carried out on the potentially polluted water before it flows through the container of trout eggs. The direct irradiation of eggs by full-spectrum 400–800 nm light provokes irreversible toxic effects on the trout eggs, since a broad number of visible wavelengths are directly absorbed by carotenoid pigments, which are present in the eggs, and these once photoexcited in turn promote photochemical damage in their surrounding leading to egg death (Magaraggia and Jori, unpublished results). The preventive efficiency of specific cationic porphyrins against saprolegniasis of trout eggs is comparable with that found for some commercially used chemical disinfectants, such as formalin or bronopol, which represent a serious threaten for fish and environment.

These findings can be correlated with experimental observations by other authors pointing out that cationic porphyrins can efficiently and extensively photosensitize the destruction of fecal bacteria [42,53], helminth eggs [58], and sewage bacteriophage [59]. Therefore, the photodynamic methodology appears to represent a very flexible and reliable tool for the decontamination of microbiologically polluted waters of different origins.

67.3.3 Future Perspectives

In spite of the favorable features that appear to presently characterize the use of porphyrin photosensitization for the control of microbial population in water, several approaches can be explored in order to enhance the efficiency, the economic convenience, and the safety of the technique.

So far, tetracationic porphyrins have been most frequently utilized as antimicrobial photosensitizing agents with a broad spectrum of activity. However, there are at least preliminary evidences suggesting that the number of positively charged functional groups and the distribution of the charges at the periphery of the tetrapyrrolic macrocycle can appreciably modulate both the interaction of the porphyrin with the microbial cells and the efficacy of the photosensitized killing of such cells [60,61]. Therefore, more studies are needed in order to gather a detailed understanding of the relationship between the chemical structure and the photoantimicrobial activity of porphyrins. In this connection, it is worthwhile taking into consideration the information provided by scattered reports that suggest that the overall photophysical properties and photosensitizing efficiency of porphyrins are enhanced by the introduction of fluorine atoms [62,63] or conjugation with saccharides [64] and poly-peptides, especially those of cationic nature, such as poly-lysine or poly-ornithine [30,65]. In particular, the positively charged poly-peptide acts as a destabilizing agent for the compact 3D organization of the outer wall, which surrounds several types of microbial cells, thereby enhancing their degree of photosensitivity [66,67]. Last, some photosensitizing agents that are structurally unrelated with porphyrins, such as phenothiazinium salts [68] and fullerenes derivatized to give them a cationic character [69], also display important antimicrobial properties. In all cases, the photoantimicrobial activity is by far superior for the positively charged compounds as compared with their neutral or anionic counterparts; one essential requirement is a high water solubility for the photosensitizer, since previous studies demonstrated [49] that the incorporation of a hydrophobic compound into various types of delivery vehicles (e.g., liposomes [49] or cyclodextrins [70]) results in a significant drop of the photocidal efficacy, especially toward Gram-negative bacteria.

From the economic point of view, a major progress for the future of environmental application of photodynamic antimicrobial methodologies is represented by the possibility to utilize photosensitizing agents, which are immobilized in inert matrices. This possibility was explored by a number of authors [71] at least for those photosensitizers that act via the production of singlet oxygen as the main cytotoxic agent: this hyperreactive oxygen species has a relatively long natural lifetime, especially in nonpolar media, hence it can diffuse to distances of up to almost 1 mm before undergoing deactivation to the ground state. As a consequence, the killing of bacteria physically separated from the immobilized photosensitizers has been observed [72,73]. The use of photosensitizers bound to solid particles of approximately micrometer size would allow their recovery from the water system at the end of the treatment

and even the irradiation of water prior to its introduction into (for example) the fish-farming ponds, thus avoiding any direct contact between the photoreactive species and the fish or other nontarget organisms. In addition, such complexes between the photosensitizing agent and the supporting matrix have been often found to be endowed with a significantly long shelf life, which facilitates their storage and reuse [56]. In this connection, porphyrins [74,75], phthalocyanines [76], and Ru(II) coordination complexes [77] immobilized on a variety of supports have been successfully tested for killing of microbial cells and proposed for the disinfection of water specimens, which are characterized by the presence of a significant flora of microbial pathogens.

In conclusion, photoactivated porphyrins and their analogues appear to possess a large scope and potential for addressing problems of high social interest, such as the disinfection of waters, with particular emphasis on aquaculture. The widespread application of this technique could provide a viable alternative to the currently adopted pharmaceutical or biological agents, whose continuous accumulation in the environment will inevitably result in an unbearable burden for a variety of ecosystems and human health [78].

FIGURE 10.3 Compound parabolic collector.

FIGURE 18.3 (a) Three-dimensional representation of transient absorption spectra of **51c** in methanol recorded after excitation at 260 nm.

SCHEME 38.2 Family of fluorescent PET switches with one receptor (IDENTITY gate, 1), two receptors (two-input AND gate, 2), and three receptors (three-input AND gate, 3).

FIGURE 50.3 Action spectrum of intrinsically photosensitive retinal ganglion cells (ipRGCs) compared with action spectra of other photoreceptors of the rat retina. The curve shapes indicate that each photopigment uses a vitamin A-based chromophore. Relative trends of the curves on the wavelength axis reflect differences in the opsin component of the photopigment. Wavelengths: ipRGCs (red), 484 nm; green cones (green), 510 nm; UV cones (purple), 359 nm; rods (blue), 500 nm. (Adapted from Berson, D.M., *Trends Neurosci.*, 26, 314, 2003.)

FIGURE 50.5 Action spectrum of human melanopsin showing an optimal sensitivity to short-wavelength “blue” light at 480 nm. The spectral sensitivity profile indicates an opsin-based photopigment utilizing a vitamin A-based chromophore. The spectral sensitivity of scotopic (rod-based) and photopic (cone-based) vision is presented for comparison. Although melanopsin sensitivity peaks around 480 nm, it shows in addition a good responsiveness into the green/yellow portion of the spectrum. (Adapted from Bailes, H.J. and Lucas, R.J., *Cell. Mol. Life Sci.*, 67, 99, 2010.)

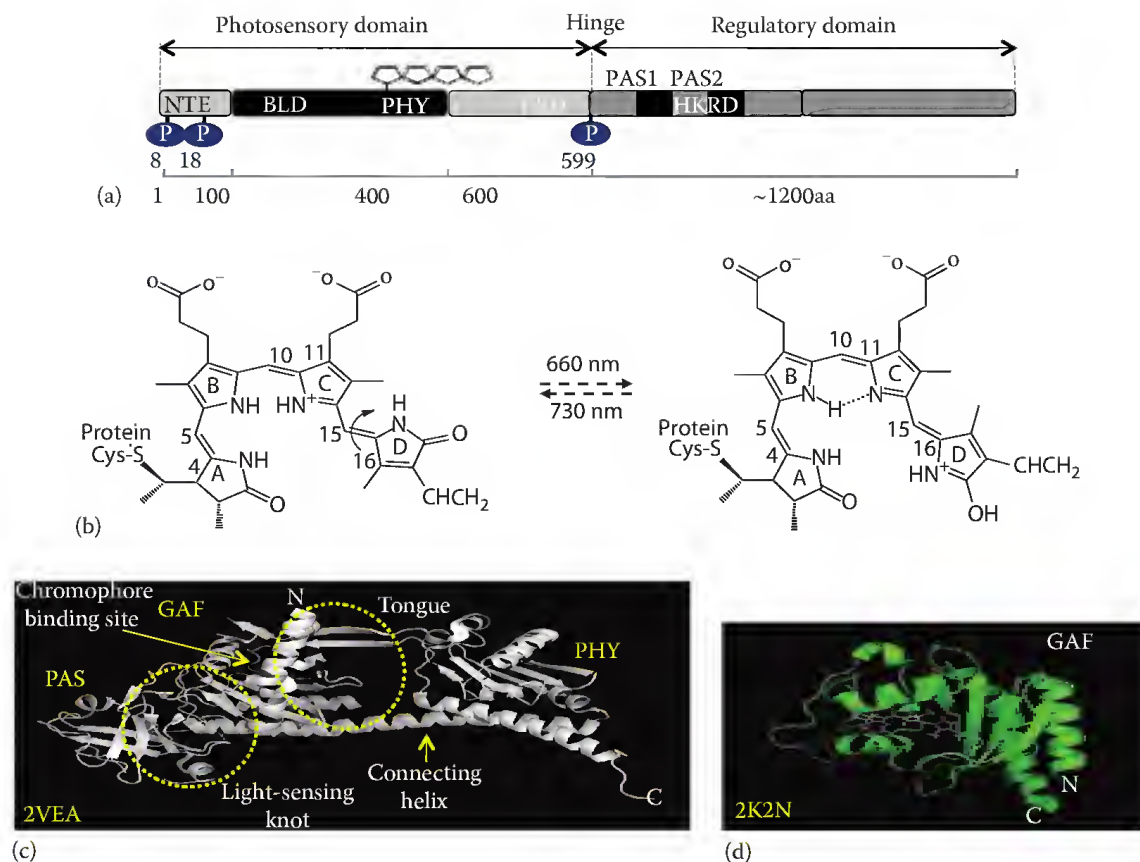

FIGURE 52.1 Domain and protein structures of phytochrome. (a) Domain structure of phytochrome. Phytochrome has a two-domain structure, N-terminal photosensory domain and C-terminal regulatory domain. The photosensory domain contains both light sensor chromophore (phytochromobilin) and signaling motifs for phosphorylation and interactions with phytochrome-interacting factors (PIFs) (see text). NTE, N-terminal extension; BLD, bilin lyase domain consisting of PAS and GAF; PHY, phytochrome-specific GAF-related domain; PRD, PAS-related domain; PAS1 and PAS2, two PAS repeats; HKRD, histidine kinase-related domain. As examples, *Arabidopsis* phyA and phyB are composed of 1122 and 1172 amino acids, respectively. The four-connected pentagon in the BLD is the chromophore (i.e., phytochromobilin) that binds to the cysteine residue at 322. Three phosphorylation sites on oat phyA are also shown. (b) Photoisomerization of phytochromobilin during the Pr-to-Pfr phototransformation. (c) The N-terminal photosensory module structure (residues 1–514) of cyanobacterial phytochrome (Cph1).²¹ The complete sensory module (PDB ID: 2VEA) consists of PAS, GAF, and PHY domains. Chromophore-binding site and connecting helix are indicated. The regions for light-sensing knot and the tongue are shown as circles. (d) The structure of the Cph1 GAF domain (PDB ID: 2K2N) assembled with phytocyanobilin.³⁴ N-terminus (N) and C-terminus (C) are labeled, and the chromophore is shown in white.

FIGURE 53.2 Top: topology of (a) light oxygen voltage (LOV) and (b) blue light sensing using FAD (BLUF) domains. Secondary structure elements have been named after [57] and [58]. Arrows: strands, cylinders: helices. The caps at the N- or C-termini of the domain core are given without color. The caps may adopt different conformations/geometries in different proteins or/and in a different state (dark or lit). Relative size of loops, strands, and helices are not respected. In (a) the N-cap has been labeled $\alpha 0$. Bottom: structure of a (c) LOV (PDB 1V1A [59]) and of a (d) BLUF (PDB 3GFX [56]) domain, highlighting residues involved in signal propagation, in different LOV and BLUF proteins. Numbering is from *Asphot1*-LOV2 and *KpBlrP1*, respectively (*As* = *Avena sativa*, *Kp* = *Klebsiella pneumoniae*), see Tables 53.1 and 53.2 for details. We also show residues that are not known to be involved in signal transduction, but participate in the modification of the HB network around the flavin after photoexcitation (N482, N492, and R451 in (c); K30 and N31 in (d)). Some secondary structure elements, or part of them, have been cut to better show the chromophore cavity. Note that, from available data, signal transmission from the α/β light-sensing domain favors, in both cases, the β -sheet/helical cap mechanism (Section 53.3.1). (From Wu, Q. and Gardner, K.H., *Biochemistry*, 48, 2620, 2009. With permission.)

FIGURE 54.4 Some marine bioluminescent organisms: (a) *Vibrio fischerii* bioluminescent bacteria, (b) sea firefly *Vargula hilgendorffii* (ostracod), and (c) firefly squid *Watasenia scintillans*.

FIGURE 54.5 Some bioluminescent beetles (a) *Cratomorphus concolor* firefly, (b) *Pyrophorus divergens* click beetle, and (c) *Phrixothrix* railroad worm.

FIGURE 54.8 3D structures of luciferases and photoproteins: (a) bacterial luciferase according to Tu (2007), (b) firefly luciferase (*Photinus pyralis*), and (c) Obelin (coelenterate photoprotein) according to Vysotski and Lee (2004). (From Vysotski, E. and Lee, J., *Acc. Chem. Res.*, 37, 405, 2004. With permission.)

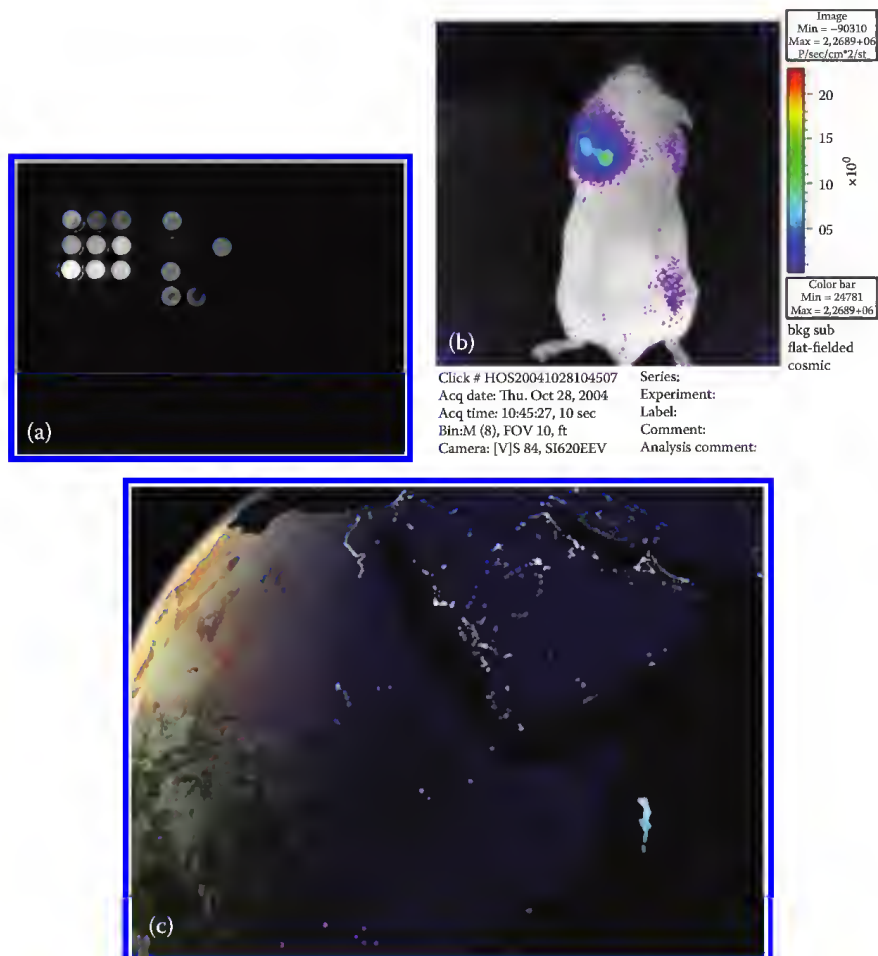

FIGURE 54.11 Biotechnological and environmental applications of bioluminescence: (a) a whole cell biosensor in a 96-well plate format for toxicity based on bioluminescent *Escherichia coli* engineered with *Macrolampis* firefly luciferase gene; (b) real-time *in vivo* bioimaging of metastasis using cell line transformed with firefly luciferase gene (kindly donated by Y. Ohmiya); and (c) bioluminescent bacteria populational boom, a perspective for global level environmental biosensing. (From Haddock, S. et al., *Annu Rev. Mar. Sci.*, 2, 443, 2010.)

FIGURE 57.9 Main steps in global genome repair (GGR) in eukaryotic cells.

FIGURE 62.1 Vitiligo of the face treated with NB-UVB: (a) before treatment and (b) after treatment.

FIGURE 62.2 Psoriasis of the trunk treated with PUVA: (a) before treatment and (b) after treatment.

FIGURE 65.4 PCI-induced relocation of gelonin in rat liver. Tissues were stained with the primary antibody against gelonin and counterstained with hematoxylin. Animals were treated with 25 J light delivered 48 h after 1 mg/kg AlS_2Pc and 1 h after 500 $\mu g/kg$ gelonin, examined 30 min after irradiation. (a) Area of liver not exposed to light (inset white arrows: distribution of gelonin in liver). (b) Areas exposed to light (inset black arrows: redistribution of gelonin).

3D structures of antenna and RC complexes in bacteria (B, left side) and plants (P, right side).

Bacteria

FIGURE 55.B1 Top view of the pigments and ions of the RC-LH1 complex from *Rhodospseudomonas palustris*. Note the highly symmetric arrangement of LH1 pigments around the RC [142]. The bacteriochlorophylls and the bacteriopheophytins of the RC are orange, the nonheme iron is red, and the bacteriochlorophylls of the LH1 complex are green. The average distance between the central magnesium ions of two consecutive pigments in the outer green circle is 9.13 Å with a minimum of 6.71 Å and a maximum of 11.31 Å.

Plants

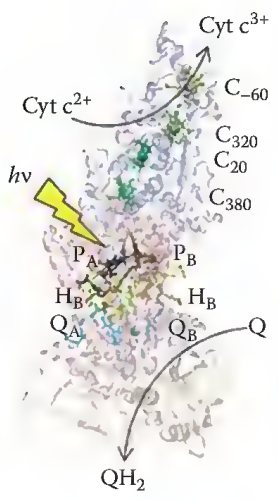

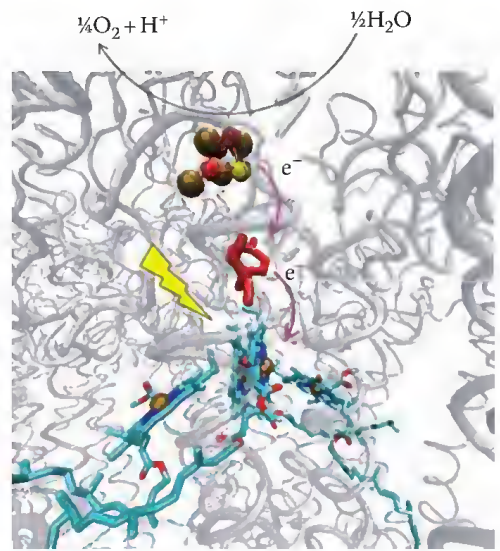

FIGURE 55.P1 Top view of the pigments and the ions in the PSII core complex at 3.50 Å resolution [141]. Protein Data Bank code 1s5l.pdb. The chlorophylls, the pheophytins, and the PQs of the D1 and D2 subunits are shown in orange. The central red sphere represents the nonheme iron of the RC. The chlorophylls of the core antenna subunits CP43 and CP47 are shown in green. The carotenoids are shown in violet. The white and the blue spheres represent the manganese and calcium ions of the OEC. In this representation, the OEC sticks out of the plane toward the reader in the cytoplasm.

FIGURE 55.B2 3D structure of the RC-LH1 core complex from *R. palustris* at 4.8 Å resolution [142]. Protein Data Bank code 1PYH.pdb. The transmembrane domain is formed by the almost parallel set of alpha helices. The hydrophobic part is formed by the sole H subunit of the RC that protrudes toward the cytoplasm. The three subunits forming the RC (L, M, and H) are shown in orange while the 15 couples of alpha and beta subunits of the light-harvesting 1 (LH1) complex are shown in green. The structure is much simpler than the PSII core complex shown in (P2). In contrast to PSII, the antenna ring and the central RC are not connected in the bacterial RC-LH1 core complex, as seen on the top view (B1).

FIGURE 55.P2 3D structure of photosystem II core complex from *T. elongatus* at 2.9 Å resolution [144]. Protein Data Bank codes 3BZ1.pdb and 3BZ2.pdb. The transmembrane domain is formed by the almost parallel set of alpha helices, while the hydrophilic part is formed by a number of randomly distributed short alpha helices and by an organized structure of beta sheets protruding toward the periplasm. The two central polypeptides (D1 and D2) form the RC (orange), CP47 and CP43 are the two peripheral core antenna polypeptides (green), and the other 16 polypeptides (gray) are also shown (for more details see [145]).

3D structures of antenna and RC complexes in bacteria (B, left side) and plants (P, right side).	
Bacteria	Plants
 <p>FIGURE 55.B3 Catalytic sites of the RC with internal cytochrome subunit of <i>Blastochloris viridis</i> at 2.45 Å resolution [143]. Protein Data Bank code 2prc.pdb. Color codes of the polypeptides: light red (L subunit), light orange (H subunit), light gray (M subunit), and light blue (C subunit). The iron is shown as a green sphere; the four hemes of the C subunit are green. Cofactors, catalytic reactions of quinone reduction and cytochrome oxidation initiated by light, are indicated in figure by arrows.</p>	 <p>FIGURE 55.P3 Catalytic donor site of photosystem II at 3.50 Å resolution [141]. Protein Data Bank code 1s5l.pdb. The ET started by light absorption is directed from water troughs the OEC (oxygen, red; manganese, brown; calcium, yellow) and the tyrosine Y_Z (red) to the chlorophyll dimer (cyan). The final by-products (oxygen and protons) are released.</p>
